This method is best illustrated by an example. Consider the state machine which is represented by the state transition graph shown in Fig. 68.29. This simple example is a state machine with two inputs, X_1 and X_2, and two outputs, Y_1 and Y_2. This machine cannot be reduced, i.e., it is a minimal state machine. Assume that this machine is the control unit of an FSMD block and that the control output Y_1 is the output which indicates the completion of the "data processing" when its value is 1. Thus, output Y_2 is an "insignificant output" in terms of delay in accordance with Step 1. Therefore, a don't-care value is assigned to Y_2 as per Step 2. The modified STG is shown in Fig. 68.30. As per Step 3, the modified STG is then reduced. In this example, states A, C, and E are equivalent (can be replaced by a single state, K) and the minimal machine consists of three states, K, B, and D. This minimal machine is described by the State Table shown in Table 68.2.

TABLE 68.2 Next-State and Output Y_1 of the Minimal Machine

P.S.\X_1X_2	00	01	10	11
K = (ACE)	K, 0	K, 0	B, 0	B, 0
B	K, 0	K, 0	D, 0	D, 0
D	K, 1	K, 1	D, 0	D, 0

All possible input combinations appear explicitly in Table 68.2. However, it can be seen that the first two columns of the table are identical (i.e., the same next state and output value for all possible present states). Similarly, the last two columns of the table are identical. Therefore, in accordance with Step 4, these columns can be combined yielding the reduced State Table shown in Table 68.3.

TABLE 68.3 The Minimal Machine with Implicit Input Enumeration

P.S. \ X1X2	0-	1-
K = (ACE)	K, 0	B, 0
B	K, 0	D, 0
D	K, 1	D, 0

The reduced state table reveals that the minimal machine does not depend on the value of input X_2. Therefore, the conclusion is that input X_2 is not a DAI. This result implies that by knowing only the value of input X_1, the number of clock cycles (transitions in the original STG) required to reach the condition that output $Y_1 = 1$ can be determined regardless of the values of X_2. This is the case for any given initial state. It is important to emphasize that the paths in the original STG and their lengths are those which must be considered

© 2003 by CRC Press LLC

during the traversal process and that the modified state machine is used only for the purpose of detecting non-DAIs. The machine which is actually being traversed during the mixed-level simulation is the original state machine with all its functionality.

To demonstrate the meaning of an input which is not a DAI, consider the original state machine represented by the graph in Fig. 68.29 and assume that the initial state is A. Consider, for example, one possible sequence of values on input X_1 to be 0, 1, 0, 0, 1, 1, 0. By applying this input sequence, the sequence of values on output Y_1 is 0, 0, 0, 0, 0, 0, 1, regardless of the values applied to input X_2. Therefore, two input sequences which differ only in the values of the non-DAI input X_2 will produce the same sequence of values on the "significant" output Y_1. For example, the sequence X_1X_2 = 00, 10, 00, 01, 10, 10, 01 will drive the machine from state A to E, B, C, E, B, D, and back to A, and the sequence of values on output Y_1 will be as above. Another input sequence, X_1X_2 = 01, 11, 01, 00, 11, 11, 00, in which the values of X_1 are identical to the pervious sequence, will drive the machine from state A to C, B, E, C, B, D, and back to A, while the sequence of values on output Y_1 is identical to the previous case. Therefore, the two input sequences will drive the machine via different states but will produce an identical sequence of values on the "significant" output (which also implies that the two paths in the STG have an equal length).

Traversing the STG for Best and Worst Delay

After extracting all possibilities for minimizing the number of unknown inputs, a method for determining values for those unknown inputs which are DAIs is required. The method developed for mixed-level modeling is based on the traversal of the original STG of the sequential interpreted element. As explained earlier, some combination of output values may signify the completion of processing the data. The search algorithm will look for a minimum or maximum number of state transitions (clock cycles) between the starting state of the machine and the state (Moore machine) or transition (state and input combination — Mealy machine), which generates the output values which signify the completion of data processing. Once this path is found, the input values for the unknown DAIs that will cause the SDE to follow this state transition path will be read from the STG and applied to the interpreted component in the simulation to generate the required best- or worst-case delay. Since the state machine is represented by the STG, this search is equivalent to finding the longest or shortest path between two nodes in a directed graph (digraph).

The search for the shortest-path utilizes a well-known algorithm. Search algorithms exist for both single-source shortest-path and all-pairs shortest-path. One of the first and most commonly used algorithm is Dijkstra's algorithm,[42] which finds the shortest-path from a specified node to any other node in the graph. The search for all-pairs shortest-path is also a well-investigated problem. One such algorithm by Floyd[43] is based on work by Warshall.[44] Its computation complexity is $O(n^3)$ when n is the number of nodes in the graph, which makes it quite practical for moderate-sized graphs. The implementation of this algorithm is based on Boolean matrix multiplication, and the actual realization of all-pairs shortest-paths can be stored in an $n \times n$ matrix. Utilizing this algorithm required some enhancements in order to make it applicable to mixed-level modeling. For example, if some of the inputs to the interpreted element are known (from the performance model), then the path should include transitions that include these known input values.

On the other hand, the search for the longest path is a more complex task. It is an NP-complete problem that has not attracted significant attention. Since most digraphs contain cycles, the cycles need to be handled during the search in order to prevent a path from containing an infinite number of cycles. One possible restriction that makes sense for many state machines that might be used in mixed-level modeling is to construct a path that will not include a node more than once. Given a digraph $G(V,E)$ which consists of a set of vertices (or nodes) $V = (v_1, v_2, \ldots\}$ and a set of edges (or arcs) $E = \{e_1, e_2, \ldots)$, a simple-path between two vertices v_{init} and v_{fin} is a sequence of alternating vertices and edges $P = v_{init}$, e_n, v_m, e_{n+1}, v_{m+1}, e_{n+2}, …, v_{fin} in which each vertex does not appear more than once. Although an arbitrary choice was made to implement the search allowing each vertex to appear in the path only once, the same algorithm could be easily modified to allow the appearance of each vertex a maximum of N times.

© 2003 by CRC Press LLC

Given an initial node and a final node, the search algorithm developed for this application starts from the initial node and adds nodes to the path in a depth-first-search (DFS) fashion until the final node is reached. At this point, the algorithm backtracks and continues looking for a longer path. However, since the digraph may be cyclic, the algorithm must avoid the possibility of increasing the path due to a repeated cycle, which may produce an infinite path.

The underlying approach for avoiding repeated cycles in the algorithm dynamically eliminates the cycles while searching for the longest-simple-path. Let u be the node that the algorithm just added to the path. All the in-arcs to node u can be eliminated from the digraph at this stage of the path construction. The justification for this dynamic modification of the graph is that, while continuing in this path, the simple-path cannot include u again. While searching forward, more nodes are being added to the path and more arcs can be removed temporarily from the graph. At this stage, two things may happen: (1) either the last node being added to the path is the final node, or (2) the last node has no out-arcs in the dynamically modified graph. These two cases are treated in the same way except that in the first case the new path is checked to see if it is longer than the longest one found so far. If it is, the longest path is updated. However, in both cases the algorithm needs to backtrack.

Backtracking is performed by removing the last node from the path, hence decreasing the path length by one. During the process of backtracking, the in-arcs to a node being removed from the path must be returned to the current set of arcs. This process will enable the algorithm to add this node when constructing a new path. At the same time, whenever a node is removed from the path, the arc that was used in order to reach that node is marked in the dynamic graph. This process will eliminate the possibility that the algorithm repeats a path that was already traversed. Therefore, by dynamically eliminating and returning arcs from/to the graph, a cyclic digraph can be treated as if it does not contain cycles. The process of reconnecting nodes, i.e., arcs being returned to the dynamic graph, requires that the original graph be maintained. A more detailed description of this search algorithm can be found in Reference 45.

In some mixed-level modeling cases, more realistic restriction on the longest-path than that it must not include any node more than once is that it not include any transition (arc) more than once. A longest-path with no repeated arcs may include a node multiple times as long as it is reached via different arcs. In the case of more than one transition that meets the condition on the output combination, a search for the longest-path should check all paths between the initial state and all of these transitions. However, such a path should include any of these transitions only once, and it should be the last one in the path.

Performing a search with the restriction that no arc is contained in the path more than once requires maintaining information on arcs being added or removed from the path. Maintaining this information during the search makes the algorithm and its implementation much more complicated relative to the search for the longest path with no repeated nodes. Therefore, a novel approach to this problem was developed. The approach used is to map the problem to the problem of searching for the longest path with no repeated nodes. This mapping can be accomplished by transforming the digraph to a new digraph, to be referred to as the transformed-digraph (or Tdigraph). Given a digraph, $G(V, E)$, which consists of a set of nodes $V = (v_1, v_2, \ldots, v_k)$ and a set of arcs $E = (e_1, e_2, \ldots, e_l)$ the transformation τ maps $G(V, E)$ into a Tdigraph $TG(N, A)$, where N is its set of nodes and A is its set of arcs. The transformation is defined as $\tau(G(V, E)) = TG(N, A)$ and contains the following steps:

Step 1: $\forall\ (e_i \in E)$ generate a node $n_i \in N$
Step 2: $\forall\ (v \in V)$ and $\forall\ (e_p \in d_{in}{}^{v}, e_q \in d_{out}{}^{v})$ generate an arc $a \in A$ such that A: $n_p \rightarrow n_q$.

The first step is used to create a node in the Tdigraph for each arc in the original digraph. This one-to-one mapping defines the set of nodes in the Tdigraph to be $N = \{n_1, n_2, \ldots, n_l\}$ which has the same number of elements found in the set E.

The second step creates the set of arcs, $A = \{a_1, a_2, \ldots, a_u\}$, in the Tdigraph. For each node in the original digraph and for each combination of in-arcs and out-arcs to/from this node, an arc in the Tdigraph is created. For example, given a node v with one in-arc e_i and one out-arc e_j, e_i is mapped to a node n_i, e_j is mapped to a node n_j, and an arc from n_i to n_j is created. In Step 2 of the transformation

© 2003 by CRC Press LLC

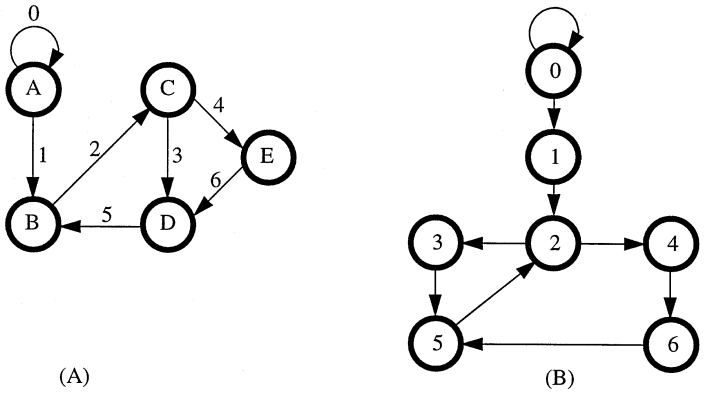

FIGURE 68.31 Transformation of a digraph.

process, it is guaranteed that all possible connections in the original digraph are preserved as transitions between nodes in the Tdigraph. As a result of this transformation, the restriction on not visiting an arc more than once in the original digraph is equivalent to not visiting a node more than once in the Tdigraph. Therefore, by using this transformation, the problem of searching for the longest path with no repeated arcs in the original digraph is mapped to a search for the longest path with no repeated nodes in the Tdigraph. The algorithm described above can then be used to search the Tdigraph.

This transformation is best illustrated by a simple example. Consider the digraph shown in Fig. 68.31(A). The arcs in this digraph are labeled by numbers 0 to 6. The first step of the transformation is to create a node for each arc in the original digraph. Therefore, there will be seven nodes, labeled 0 to 6, in the Tdigraph as shown in Fig. 68.31(B). The next step is to create the arcs in the Tdigraph. As an illustration of this step, consider node C in the original digraph. Arc "2" is an in-arc to node C, while arcs "3" and "4" are out-arcs from node C. Applying Step 2 results in an arc from node "2" to node "3" and a second arc from node "2" to node "4" in the Tdigraph. Considering node B in the original digraph, the Tdigraph will include an arc from node "1" to node "2" and an arc from node "5" to node "2". This process is repeated for all the nodes in the original digraph until the Tdigraph, as shown in Fig. 68.31(B), is formed. A search algorithm can now be executed to find the longest path with no repeated nodes.

A mixed-level modeling methodology, which is composed of all the methods described previously, has been integrated into the ADEPT environment. The steps for minimizing the unknown inputs can be performed prior to simulating the mixed-level model. On the other hand, the search for longest/shortest possible delay must be performed during the simulation itself. This requirement arises because each token may carry different information, which may alter the known input values and, therefore, alter the search of the STG. The STG traversal process has been integrated into the ADEPT modeling environment using the following steps: (1) when a token arrives to the mixed-level interface, the simulation is halted and the search for minimum/maximum number of transitions is performed; and (2) on completion of the search, the simulation continues while applying the sequence of inputs found in the search operation. The transfer of information between the VHDL simulator and the search program, which is implemented in C, is done by using the simulator's VHDL/C interface. A component called the Stream_Generator has been created that implements the STG search process via this interface.

Since mixed-level models are part of the design process and are constructed by refining a performance model, it is likely that many tokens will carry identical relevant information. This information may be used for selective application of the STG search algorithm, hence increasing the efficiency of the mixed-level model simulation. For example, if several tokens carry exactly the same information (and assuming the same initial state of the FSM), the search is performed only once, and the results can be used for the following identical tokens.

An Example of Mixed-Level Modeling with an FSMD Component

This section presents an example of the construction of a mixed-level model with an FSMD interpreted component. The example is based on the performance model of an execution unit of a particular processor. This execution unit is composed of an Integer Unit (IU), a Floating-Point Unit (FPU), and a Load-Store Unit (LSU). These units operate independently, although they receive instructions from the same queue (buffer of instructions). If the FPU is busy processing one instruction and the following instruction requires the FPU, it is buffered, waiting for the FPU to be free again. Meanwhile, instructions which require the IU can be consumed and processed by IU at an independent rate. Both the FPU and the IU have the capability of buffering only one instruction. Therefore, if two or more consecutive instructions are waiting for the same unit, the other units cannot receive new instructions (since the second instruction is held in the main queue). One practical performance metric that can be obtained from this model is the time required for the execution unit to process a given sequence of instructions.

Because the Floating-Point Unit was identified as the most complex and time critical portion of the design, a behavioral description of a potential implementation of it was developed. At this point, a mixed-level model, in which the behavioral description of the FPU is introduced into the performance model, was constructed using the interface described above. The mixed-level model is shown in Fig. 68.32. The mixed-level interface is constructed around the interpreted block which is the behavioral description of the FPU. This FPU is an FSMD type of element, and the interpreted model consists of a clock cycle accurate VHDL behavioral description of this component. The inputs to the FPU include the operation to be performed (Add, Sub, Comp, Mul, MulAdd, and Div), the precision of the operation (single or double) and some additional control information. The number of clock cycles required to complete any instruction depends on these inputs.

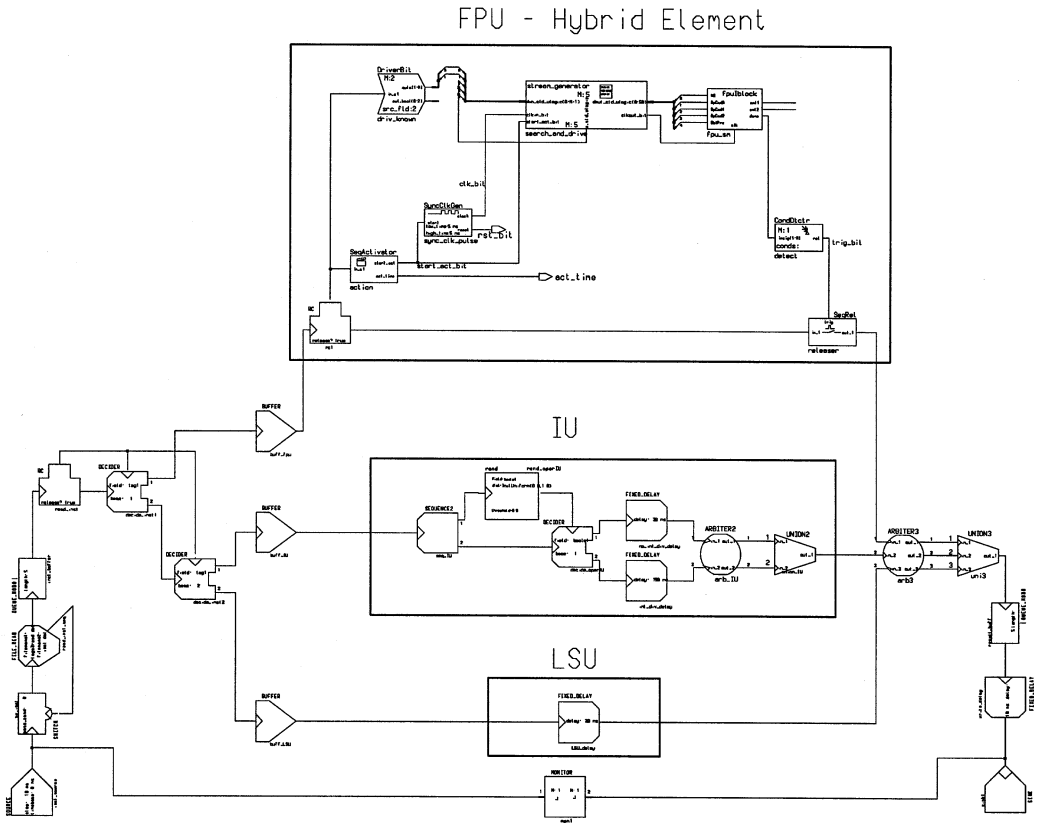

FIGURE 68.32 Mixed-level model with the FPU behavioral description.

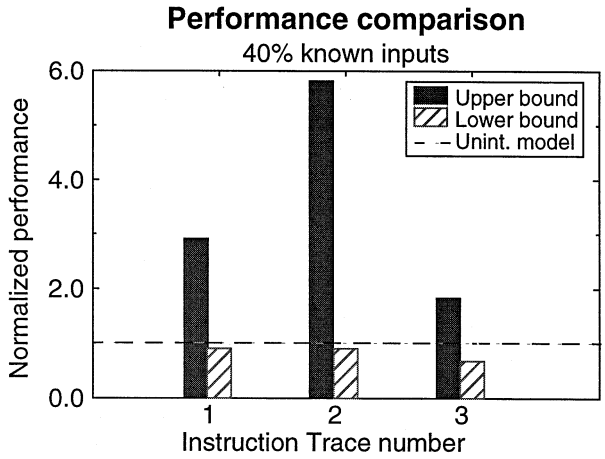

FIGURE 68.33 Performance comparison of the execution unit for three instruction traces.

Figure 68.33 shows the execution unit performance derived from the mixed-level model for three different instruction traces. In this case, only 40% of the inputs have values that are supplied by the abstract performance model; the remainder of the values for the inputs are derived using the techniques described in the section "Finding Values for the 'Unknown Inputs' in an FSMD Based Mixed-Level Model." The performance value is normalized by defining unity to be the amount of time required to process a trace according to the initial uninterpreted performance model. In this example, the benefit of the simulation results of the mixed-level model is clear. It provides performance bounds in terms of best- and worst-case delays for the given implementation of the FPU.

An Interface for Mixed-Level Modeling with Complex Sequential Components

A methodology and components for constructing a mixed-level interface involving general sequential interpreted components that can be described as FSMDs was detailed in the previous section. However, many useful mixed-level models can be constructed that include sequential interpreted components that are too complex to be represented as FSMDs, such as microprocessors, complex coprocessors, network interfaces, etc. In these cases, a more "programmable" mixed-level interface that is able to deal with the additional complexity in the timing abstraction problem was needed. This section describes the "watch-and-react" interface that was created to be a generalized, flexible interface between these complex sequential interpreted components and performance models.

The two main elements in the watch-and-react interface are the trigger and the driver. Figure 68.34 illustrates how the trigger and driver are used in a mixed-level interface. Both elements have ports that can connect to signals in the interpreted components of a model. Collectively, these ports are referred to as the probe. The primary job of the trigger is to detect events on the signals attached to its probe, while the primary job of the driver is to force values onto the signals attached to its probe. The driver decodes information carried in tokens to determine what values to force onto signals in the interpreted model (the U/I interface), and the trigger encodes information about events in the interpreted model onto tokens in the performance model (the I/U interface).

The trigger and driver were designed to be as generic as possible. A command language was designed that specifies how the trigger and driver should behave to allow users to easily customize the behavior of the trigger and driver elements without having to modify their VHDL implementation. This command language is interpreted by the trigger and driver during simulation. Because the language is interpreted, changes can be made to the trigger and driver programs without having to recompile the model, thus minimizing the time required to make changes to the mixed-level model.

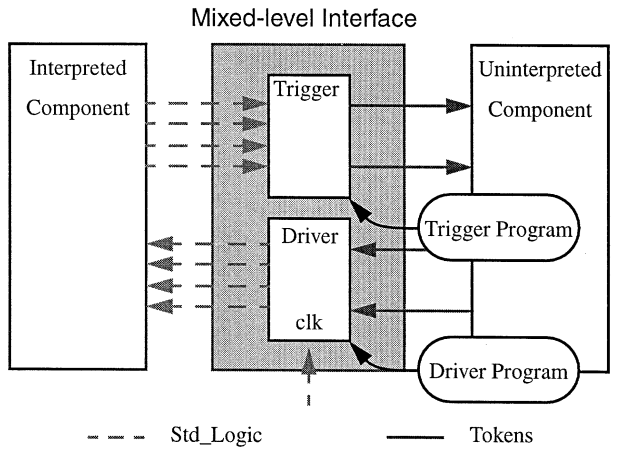

FIGURE 68.34 The watch-and-react mixed-level interface.

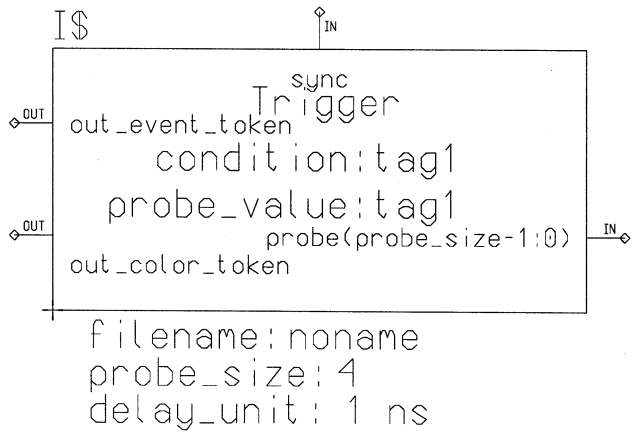

FIGURE 68.35 Schematic symbol for the trigger.

The schematic symbol for the trigger is shown in Fig. 68.35. The primary job of the trigger is to detect events in the interpreted model. The probe on the trigger is a bus of std_logic signals `probe_size` bits wide, where `probe_size` is a generic on the symbol. There is one token output called `out_event_token` and one token output called `out_color_token`. Tokens generated by the trigger when events are detected are placed on the `out_event_token` port. The condition number (an integer) of the event that caused the token to be generated is placed on the `condition` tag field, which is specified as a generic on the symbol. Also, each time a signal changes on the probe, the color of the token on the `out_color_token` port changes appropriately regardless of whether an event was detected or not. The probe value is placed on the `probe_value` tag field of the `out_color_token` port. The `sync` port is used to synchronize the actions of the trigger element with the driver element as explained below.

The name of the file containing the trigger's program is specified by the `filename` generic on the symbol. The `delay_unit` generic on the symbol is a multiple that is used to resolve the actual length of an arbitrary number of delay units specified by some of the interface language statements.

The schematic symbol for the driver element is shown in Fig. 68.36. The primary job of the driver is to create events in the interpreted model by driving values on its probe. These values come from either the command program, or from the values of tag fields on the input tokens to the driver. The probe on the driver is a bus of std_logic signals `probe_size` bits wide, where the `probe_size` is a generic on the

© 2003 by CRC Press LLC

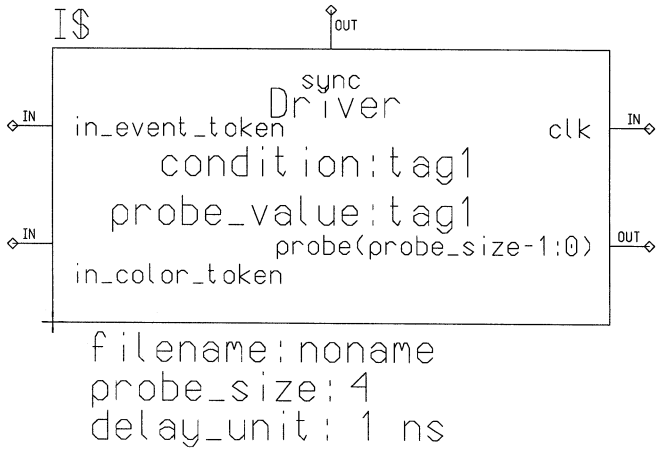

FIGURE 68.36 Schematic symbol for the driver.

symbol. There is one token input called `in_event_token`, one token input called `in_color_token`, and a special input for a std_logic type clock signal called `clk`. The `clk` input allows driver to synchronize its actions with an external interpreted clock source. The `sync` port is used to synchronize the actions of the driver element with the trigger element. The `filename` and `delay_unit` generic on the symbol function the same as for the trigger.

As discussed previously, a command language was developed to allow the user to program the actions of the trigger and driver. This command language is read by the trigger and driver at the beginning of the simulation. Constructs are available within the command language to allow waiting on events of various signals and driving values or series of values on various signals, either asynchronously or synchronously, with a specified clock signal. In addition, several looping and go-to constructs are available to implement complex behaviors more easily. A summary of the syntax of the command language constructs is shown in Table 68.4.

Example of Mixed-Level Modeling with a Complex Sequential Element

This section presents an example which demonstrates how the trigger and driver elements can be used to interface an interpreted model of a complex sequential component with an uninterpreted model. In this example, the interpreted model is a microprocessor-based controller and the uninterpreted model is that of a motor control system that includes a motor controller and a motor. The motor controller periodically asserts the microcontroller's interrupt line. The microcontroller reacts by reading the motor's current speed from a sensor register on the motor controller, calculating the new control information, and writing the control information to the motor controller.

The microcontroller system consists of interpreted models of eight-bit, RISC-like microprocessors; RAM; memory controller; I/O controller; and clock. The memory controller handles read and write requests issued by the processor to the RAM, while the I/O controller handles read and write request issued by the processor to an I/O device. In the system model, the I/O device is the uninterpreted model of a motor controller. A schematic of the model is shown in Fig. 68.37.

Three triggers and two drivers are used to construct the mixed-level interface for the control system model. One of the triggers is used to detect when the I/O controller is doing a read or write. The other two triggers are used to collect auxiliary information about the operation, such as the address on the address bus and data on the data bus. One of the drivers is used to create a microcontroller interrupt, and the other driver is used to force data onto the data bus when the processor reads from the speed sensor register on the motor controller.

The interrupt driver's program is listed in Fig. 68.38. The program begins by forcing the interrupt line to 'Z' and then waiting for a token from the uninterpreted model of the motor controller to arrive. Once

TABLE 68.4 Trigger and Driver Command Programming Language Constructs

Command	Element	Meaning
--<comment>	both	comment — no action
alert_user	both	print message in simulation window
delay_for <T>	both	delay for <T> time units where the time unit is specified as a generic on the module's symbol
end	both	end the command program
for <N> <loop body>	both	iterate N times over the sequence of statement in the loop body
next		
goto <L>	both	go to line <L> in the command program
output_sync	both	generate a token on the sync output of the module
wait_on_sync	both	wait for an occurrence of a token on the sync port of the module
case_probe_is **when** <STD_LOGIC_VAL> <sequence of statements> **when**…	trigger	conditionally execute some sequence of statements depending on the STD_LOGIC value of the probe signal
end_case		
output <INTEGER_VAL> **after** <T>	trigger	generate a token on the trigger's output with the value of <INTEGER_VAL> on the tag field specified by the generic on the symbol after <T> time units
trigger	trigger	must appear as the first statement in the trigger's command program
wait_on <STD_LOGIC_VAL>	trigger	wait until the probe signal takes on the specified STD_LOGIC value
wait_on_probe	trigger	wait until there is ANY event on the probe signal
case_token_is **when** <INTEGER_VAL> <sequence of statements> **when**…	driver	conditionally execute some sequence of statements depending on the integer value of the input token's tag field specified by the generic on the symbol
end_case		
driver	driver	must appear as the first statement in the driver's command program
dynamic_output_after <T>	driver	force the value from the specified tag field of the input token onto the probe after <T> time units
output <STD_LOGIC_VAL> **after** <T>	driver	force the specified STD_LOGIC value onto the probe signal after <T> time units
wait_on <INTEGER_VAL>	driver	wait until a token with the given integer value on the tag field specified by the generic on the symbol arrives on the in_event_token signal
wait_on_fclk	driver	wait until the falling edge of the clock occurs
wait_on_rclk	driver	wait until the rising edge of the clock occurs
wait_on_token	driver	wait until a token arrives on the in_event_token signal

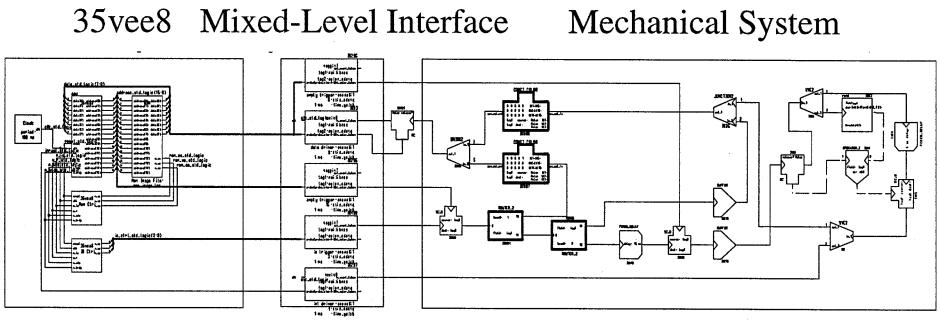

FIGURE 68.37 Schematic of control system model.

a token arrives, the program forces the interrupt line high for ten clock cycles. This condition is accomplished by using a `for-next` statement with a `wait_on_rclk` as the loop body. After ten clock cycles, the program jumps to line 10 where the cycle begins again.

© 2003 by CRC Press LLC

The data driver's program is listed in Fig. 68.39. The program begins by also waiting for a token from the uninterpreted model of the motor controller to arrive. If the value on the condition tag field of the token is 1, then "ZZZZZZZZ" is forced onto the data bus. If the condition tag field value is 3, then the value on the probe_value tag field of the in_color_token input is forced on the data bus. This process is repeated for every token that arrives.

The I/O trigger's program is listed in Fig. 68.40. This trigger waits until there is a change on the probe. Once there is a change, the program checks to see if the I/O device is being unselected, written to, or read from. If one of the when statements matches the probe value, then its corresponding output statement is executed. An output of 1 corresponds to the I/O device not being selected. An output of 2 corresponds to the processor writing control information to the motor controller. An output of 3 corresponds to the processor reading the motor's speed from the sensor register on the motor controller.

```
driver
10 output Z after 0

30 output 1 after 0
40 for 10
50    wait_on_rclk
60 next
70 goto 10
80 end
```

FIGURE 68.38 The interrupt driver's program for the control system.

Figure 68.41 shows the results from the mixed-level model as a plot of the sensor output and the processor's control response. Some random error was introduced to the sensor's output to reflect variations in the motor's load as well as sensor noise. The target speed for the system was 63 ticks per sample time (a measure of the motor's RPM). The system oscillates slightly around the target value because of the randomness introduced into the system.

68.5 Conclusions

Integration of performance modeling into the design process such that it can actually drive the refinement of the design into an implementation has clear advantages in terms of design time and quality. The ability to cosimulate detailed behavioral models and abstract system-level models is vital to the development of a design environment that fully integrates performance modeling into the design process. One methodology and implementation for cosimulating behavioral models of individual components with an abstract performance model of the entire system was presented. This environment results in models that can provide estimates of the performance bounds of a system that converge as the refinement of the overall model increases.

This chapter has only scratched the surface on the possible improvements that performance or system-level modeling can have on the rapid design of complex VLSI systems. As more and more functionality can be incorporated into the embedded VLSI systems and these systems find their way into safety-critical applications, measures of dependability such as reliability and safety at the system-level are becoming of great interest. Tools and techniques are being developed that can use the performance model from which to derive the desired dependability measures. In addition, behavioral fault simulation and testability analysis are finding their way into the early phases of the design process. In summary, the more attributes of the final implementation that can be determine from the early and often incomplete model, the better the resulting design and the shorter the design cycle.

69.1 Introduction

An electrical filter is a system that can be used to modify, reshape, or manipulate the frequency spectrum of an electrical signal according to some prescribed requirements. For example, a filter may be used to amplify or attenuate a range of frequency components, reject or isolate one specific frequency component, and so on. The applications of electrical filters are numerous, for example,

- to eliminate signal contamination such as noise in communication systems
- to separate relevant from irrelevant frequency components
- to detect signals in radios and TV's
- to demodulate signals
- to bandlimit signals before sampling
- to convert sampled signals into continuous-time signals
- to improve the quality of audio equipment, e.g., loudspeakers
- in time-division to frequency-division multiplex systems

© 2003 by CRC Press LLC

- in speech synthesis
- in the equalization of transmission lines and cables
- in the design of artificial cochleas.

Typically, an electrical filter receives an input signal or *excitation* and produces an output signal or *response.* The frequency spectrum of the output signal is related to that of the input by some rule of correspondence. Depending on the type of input, output, and internal operating signals, three general types of filters can be identified, namely, continuous-time, sampled-data, and discrete-time filters.

A **continuous-time** signal is one that is defined at each and every instant of time. It can be represented by a function $x(t)$ whose domain is a range of numbers (t_1, t_2), where $-\infty \le t_1$ and $t_2 \le \infty$. A **sampled-data** or **impulse-modulated** signal is one that is defined in terms of an infinite summation of continuous-time impulses (see [1, ch. 6]). It can be represented by a function

$$\hat{x}(t) = \sum_{n=-\infty}^{\infty} x(nT)\delta(t - nT)$$

where $\delta(t)$ is the impulse function. The value of the signal at any instant in the range $nT < t < (n + 1)T$ is zero. The frequency spectrum of a continuous-time or sampled-data signal is given by the Fourier transform.[1]

A **discrete-time** signal is one that is defined at discrete instants of time. It can be represented by a function $x(nT)$, where T is a constant and n is an integer in the range (n_1, n_2) such that $-\infty \le n_1$ and $n_2 \le \infty$. The value of the signal at any instant in the range $nT < t < (n+1)T$ can be zero, constant, or undefined depending on the application. The frequency spectrum in this case is obtained by evaluating the z transform on the unit circle $|z| = 1$ of the z plane.

Depending on the format of the input, output, and internal operating signals, filters can be classified either as **analog** or **digital** filters. In analog filters the operating signals are varying voltages and currents, whereas in digital filters they are encoded in some binary format. Continuous-time and sampled-data filters are always analog filters. However, discrete-time filters can be analog or digital.

Analog filters can be classified on the basis of their constituent components as:

- passive *RLC* filters
- crystal filters
- mechanical filters
- microwave filters
- active *RC* filters
- switched-capacitor filters

Passive *RLC* filters comprise resistors, inductors, and capacitors. **Crystal** filters are made of piezoelectric resonators that can be modeled by resonant circuits. **Mechanical** filters are made of mechanical resonators. **Microwave** filters consist of microwave resonators and cavities that can be represented by resonant circuits. **Active** *RC* filters comprise resistors, capacitors, and amplifiers; in these filters, the performance of resonant circuits is simulated through the use of feedback or by supplying energy to a passive circuit. **Switched-capacitor** filters comprise resistors, capacitors, amplifiers, and switches. These are discrete-time filters that operate like active filters but through the use of switches the capacitance values can be kept very small. As a result, switched-capacitor filters are amenable to VLSI implementation.

This section provides an introduction to the characteristics of analog filters. Their basic characterization in terms of a differential equation is reviewed in Section 69.2 and by applying the Laplace transform, an algebraic equation is deduced that leads to the *s*-domain representation of a filter. The representation of analog filters in terms of the transfer function is then developed. Using the transfer function, one can

[1]See Chapter 4 by W. K. Jenkins.

© 2003 by CRC Press LLC

obtain the time-domain response of a filter to an arbitrary excitation, as shown in Section 69.3. Some important time-domain responses, i.e., the impulse and step responses, are examined. Certain filter parameters related to the step response, namely, the overshoot, delay time, and rise time, are then considered. The response of a filter to a sinusoidal excitation is examined in Section 69.4 and is then used to deduce the basic frequency-domain representations of a filter, namely, its frequency response and loss characteristic. Some idealized filter characteristics are then identified and the differences between idealized and practical filters are delineated in Section 69.5. Practical filters tend to introduce signal degradation through amplitude and/or delay distortion. The causes of these types of distortion are examined in Section 69.6. In Section 69.7, certain special classes of filters, e.g., minimum-phase and allpass filters, are identified and their applications mentioned. This chapter concludes with a review of the design process and the tasks that need to be undertaken to translate a set of filter specifications into a working prototype.

69.2 Characterization

A linear causal analog filter with input $x(t)$ and output $y(t)$ can be characterized by a differential equation of the form

$$b_n \frac{d^n y(t)}{dt^n} + b_{n-1} \frac{d^{n-1} y(t)}{dt^{n-1}} + \cdots + b_0 y(t) = a_n \frac{d^n x(t)}{dt^n} + a_{n-1} \frac{d^{n-1} x(t)}{dt^{n-1}} + \cdots + a_0 x(t)$$

The coefficients a_0, a_1, …, a_n and b_0, b_1, …, b_n are functions of the element values and are real if the parameters of the filter (e.g., resistances, inductances, etc.) are real. If they are independent of time, the filter is time invariant. The input $x(t)$ and output $y(t)$ can be either voltages or currents. The order of the differential equation is said to be the *order* of the filter.

An analog filter must of necessity incorporate reactive elements that can store energy. Consequently, the filter can produce an output even in the absence of an input. The output on such an occasion is caused by the initial conditions of the filter, namely,

$$\left.\frac{d^{n-1} y(t)}{dt^{n-1}}\right|_{t=0}, \left.\frac{d^{n-2} y(t)}{dt^{n-2}}\right|_{t=0}, \ldots, y(0)$$

The response in such a case is said to be the *zero-input response*. The response obtained if the initial conditions are zero is sometimes called the *zero-state response*.

The Laplace Transform

The most important mathematical tool in the analysis and design of analog filters is the Laplace transform. It owes its widespread application to the fact that it transforms differential into algebraic equations that are a lot easier to manipulate. The Laplace transform of $x(t)$ is defined as[2]

$$X(s) = \int_{-\infty}^{\infty} x(t) e^{-st} dt$$

where s is a complex variable of the form $s = \sigma + j\omega$. Signal $x(t)$ can be recovered from $X(s)$ by applying the inverse Laplace transform, which is given by

$$x(t) = \frac{1}{2\pi j} \int_{C-j\infty}^{C+j\infty} X(s) e^{st} ds$$

[2]See Chapter 3 by J. R. Deller, Jr. for a detailed exposition of the Laplace transform.

© 2003 by CRC Press LLC

where C is a positive constant. A shorthand notation of the Laplace transform and its inverse are

$$X(s) = \mathcal{L}\,x(t) \quad \text{and} \quad x(t) = \mathcal{L}^{-1}X(s)$$

Alternatively,

$$X(s) \leftrightarrow x(t)$$

A common practice in the choice of symbols for the Laplace transform and its inverse is to use upper case for the s domain and lower case for the time domain.

On applying the Laplace transform to the nth derivative of some function of time $y(t)$, we find that

$$\mathcal{L}\left[\frac{d^n y(t)}{dt^n}\right] = s^n Y(s) - s^{n-1}y(0) - s^{n-2}\left.\frac{dy(t)}{dt}\right|_{t=0} - \cdots - \left.\frac{d^{n-1}y(t)}{dt^{n-1}}\right|_{t=0}$$

Now, on applying the Laplace transform to an nth-order differential equation with constant coefficients, we obtain

$$\left(b_n s^n + b_{n-1}s^{n-1} + \cdots + b_0\right)Y(s) + \Psi_y(s) = \left(a_n s^n + a_{n-1}s^{n-1} + \cdots + a_0\right)X(s) + \Psi_x(s)$$

where $X(s)$ and $Y(s)$ are the Laplace transforms of the input and output, respectively, and $\Psi_x(s)$ and $\Psi_y(s)$ are functions that combine all the initial-condition terms that depend on $x(t)$ and $y(t)$, respectively.

The Transfer Function

An important s-domain characterization of an analog filter is its *transfer function*, as for any other linear system. This is defined as the ratio of the Laplace transform of the response to the Laplace transform of the excitation.

An arbitrary linear, time-invariant, continuous-time filter, which may or may not be causal, can be represented by the convolution integral

$$y(t) = \int_{-\infty}^{\infty} h(t-\tau)x(\tau)d\tau = \int_{-\infty}^{\infty} h(\tau)x(t-\tau)d\tau$$

where $h(t)$ is the impulse response of the filter. The Laplace transform yields

$$\begin{aligned} Y(s) &= \int_{-\infty}^{\infty}\left[\int_{-\infty}^{\infty} h(t-\tau)x(\tau)d\tau\right]e^{-st}dt \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t-\tau)e^{-st}x(\tau)d\tau\,dt \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t-\tau)e^{-st}\cdot e^{s\tau}\cdot e^{-s\tau}x(\tau)d\tau\,dt \end{aligned}$$

Changing the order of integration, we obtain

$$\begin{aligned} Y(s) &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t-\tau)e^{-s(t-\tau)}\cdot x(\tau)e^{-s\tau}dt\,d\tau \\ &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t-\tau)e^{-s(t-\tau)}dt\cdot x(\tau)e^{-s\tau}\,d\tau \end{aligned}$$

© 2003 by CRC Press LLC

Now, if we let $t = t' + \tau$, then $dt/dt' = 1$ and $t - \tau = t'$; hence,

$$\begin{aligned} Y(s) &= \int_{-\infty}^{\infty}\int_{-\infty}^{\infty} h(t')e^{-st'}dt' \cdot x(\tau)e^{-s\tau}d\tau \\ &= \int_{-\infty}^{\infty} h(t')e^{-st'}dt' \cdot \int_{-\infty}^{\infty} x(\tau)e^{-s\tau}d\tau \\ &= H(s)X(s) \end{aligned}$$

Therefore, the transfer function is given by

$$H(s) = \frac{Y(s)}{X(s)} = \mathcal{L}h(t) \tag{69.1}$$

In effect, the transfer function is equal to the Laplace transform of the impulse response.

Some authors define the transfer function as the Laplace transform of the impulse response. Then through the use of the convolution integral, they show that the transfer function is equal to the ratio of the Laplace transform of the response to the Laplace transform of the excitation. The two definitions are, of course, equivalent.

Typically, in analog filters the input and output are voltages, e.g., $x(t) \equiv v_i(t)$ and $y(t) \equiv v_o(t)$. In such a case the transfer function is given by

$$\frac{V_o(s)}{V_i(s)} = H_v(s)$$

or simply by

$$\frac{V_o}{V_i} = H_V(s)$$

However, on occasion the input and output are currents, in which case

$$\frac{I_o(s)}{I_i(s)} \equiv \frac{I_o}{I_i} = H_I(s)$$

The transfer function can be obtained through network analysis using one of several classical methods,[3] e.g., by using:

- Kirchhoff's voltage and current laws
- Matrix methods
- Flow graphs
- Mason's gain formula
- State-space methods

A transfer function is said to be *realizable* if it characterizes a stable and causal network. Such a transfer function must satisfy the following constraints:

1. It must be a rational function of s with real coefficients.
2. Its poles must lie in the left-half s plane.
3. The degree of the numerator polynomial must be equal to or less than that of the denominator polynomial.

[3]See Chapters 17 to 26 of this volume.

© 2003 by CRC Press LLC

A transfer function may represent a network comprising elements with real parameters only if its coefficients are real. The poles must be in the left-half s plane to ensure that the network is stable and the numerator degree must not exceed the denominator degree to assure the existence of a causal network.

69.3 Time-Domain Response

From (69.1),

$$Y(s) = H(s)X(s)$$

Therefore, the time-domain response of a filter to some arbitrary excitation can be deduced by obtaining the inverse Laplace transform of $Y(s)$, i.e.,

$$y(t) = \mathcal{L}^{-1}\{H(s)X(s)\}$$

General Inversion Formula

If

1. the singularities of $Y(s)$ in the finite plane are poles,[4] and
2. $Y(s) \to 0$ uniformly with respect to the angle of s as $|s| \to \infty$ with $\sigma \le C$, where C is a positive constant, then [3]

$$y(t) = \begin{cases} 0 & \text{for } t < 0 \\ \dfrac{1}{2\pi j}\displaystyle\int_{C-j\infty}^{C+j\infty} Y(s)e^{st}\,ds = \frac{1}{2\pi j}\int_{\Gamma} Y(s)e^{st}\,ds & \text{for } t \ge 0 \end{cases} \tag{69.2}$$

where Γ is a contour in the counterclockwise sense make up of the part of the circle $s = Re^{j\theta}$ to the left of line $s = C$ and the segment of the line $s = C$ that overlaps the circle, as depicted in Fig. 69.1; C and R are sufficiently large to ensure that Γ encloses all the finite poles of $Y(s)$.

From the residue theorem [2] and (69.2), we have

$$y(t) = \begin{cases} 0 & \text{for } t < 0 \\ \dfrac{1}{2\pi j}\displaystyle\int_{\Gamma} Y(s)e^{st}\,ds = \sum_{i=1}^{K} \operatorname*{res}_{s=p_i} Y_0(s) & \text{for } t \ge 0 \end{cases}$$

where $Y_0(s) = Y(s)e^{st}$ and K is the number of poles in $Y(s)$. If $Y_0(s)$ has a pole p_i of order m_i, the residue can be obtained by using the general formula [2]

$$\operatorname*{res}_{z=p_i} Y_0(s) = \frac{1}{(m_i - 1)!}\lim_{s \to p_i} \frac{d^{m_i-1}}{ds^{m_i-1}}\left[(s - p_i)^{m_i} Y_0(s)\right]$$

Note that complex poles yield complex residues. Hence, like the poles of $Y_0(s)$, its residues occur in complex-conjugate pairs. For this reason, $y(t)$ is found to be a real function of t, as can be easily verified.

Condition 1 listed previously may not be satisfied sometimes, for example, if

$$\lim_{s \to \infty} Y(s) = A_0$$

where A_0 is a constant. In such a case, we can express $Y(s)$ as

[4] Such a function is said to be meromorphic [2], [3].

© 2003 by CRC Press LLC

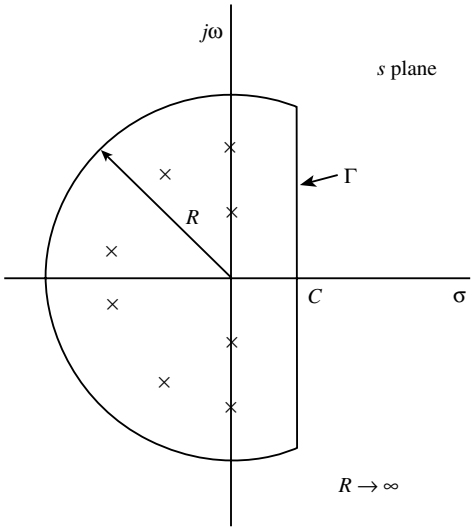

FIGURE 69.1 Contour Γ for the evaluation of the inverse Laplace transform.

$$Y(s) = A_0 + Y'(s)$$

where $Y'(s)$ satisfies conditions 1 and 2. Thus,

$$y(t) = A_0\delta(t) + \mathcal{L}^{-1}Y(s)$$

The inverse Laplace transform of $Y'(s)$ can now be obtained by using the inversion formula.

Inverse by Using Partial Fractions

The simplest way to obtain the time-domain response of a filter is to express $H(s)X(s)$ as a partial-fraction expansion and then invert the resulting fractions individually. If $Y(s)$ has simple poles, we can write

$$Y(s) = A_0 + \sum_{i=1}^{K} \frac{A_i}{s - p_i}$$

where A_0 is a constant and

$$A_i = \lim_{s \to p_i} \left[(s - p_i) Y(s) \right]$$

is the residue of pole $s = p_i$. On applying the general inversion formula to each partial fraction, we obtain

$$y(t) = A_0\delta(t) + u(t)\sum_{i=1}^{K} A_i e^{p_i t}$$

where $\delta(t)$ and $u(t)$ are the impulse function and unit step, respectively.

Impulse and Step Responses

The response of a filter to an impulse $\delta(t)$ designated as

$$y(t) = \mathcal{R}\,\delta(t) \equiv h(t)$$

© 2003 by CRC Press LLC

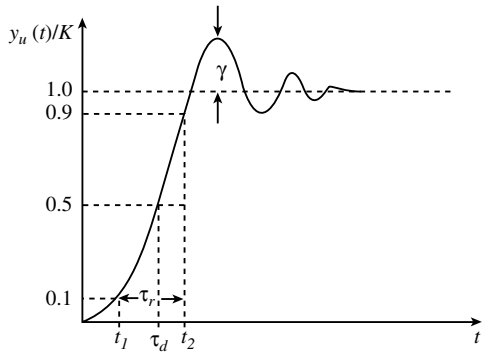

FIGURE 69.2 Overshoot, delay time, and rise time.

where $\mathcal{R}$ is an operator, is of considerable importance. Its absolute integrability guarantees the stability of the filter[5] and its Laplace transform, namely, $H(s)$, is the transfer function as has been shown in the section on the transfer function.

For an Nth-order, causal, linear, and time-invariant filter

$$H(s) = \frac{a_0 + a_1 s + a_2 s^2 + \cdots + a_M s^M}{b_0 + b_1 s + b_2 s^2 + \cdots + b_N s^N}$$

where $M \le N$.

The step (or unit-step) response is the output of a filter to the signal

$$u(t) = \begin{cases} 1 & \text{for } t \ge 0 \\ 0 & \text{for } t < 0 \end{cases}$$

The Laplace transform of $u(t)$ is $1/s$. Hence, the step response of an arbitrary filter is obtained as

$$y(t) = \mathcal{R}u(t) \equiv y_u(t) = \mathcal{L}^{-1}\left[\frac{H(s)}{s}\right]$$

Overshoot, Delay Time, and Rise Time

Three time-domain parameters of a filter are usually associated with the step response [4], namely, the overshoot, delay time and rise time. The *overshoot* γ is the difference between the peak value and the asymptotic value of the step response in percent as $t \to \infty$. The *delay time* τ_d is the time required for the step response to reach 50% of the asymptotic value. The *rise time* τ_r is the time required for the step response to increase from 10 to 90% of the asymptotic value. These three parameters are illustrated in Fig. 69.2, where $K = a_0/b_0$ is a scaling constant that normalizes the asymptotic value of the step response as $t \to \infty$ to unity.

The delay and rise times defined in terms of the step response entail quite a bit of computation. Alternative definitions of these parameters that are easier to use have been proposed by Elmore [4]. These are based on the impulse response and give accurate results if the overshoot is small. The delay time is defined as

$$\tau_D = \int_0^\infty th(t)\,dt$$

[5]See Chapter 21 of this volume, contribution of J. Vlach.

© 2003 by CRC Press LLC

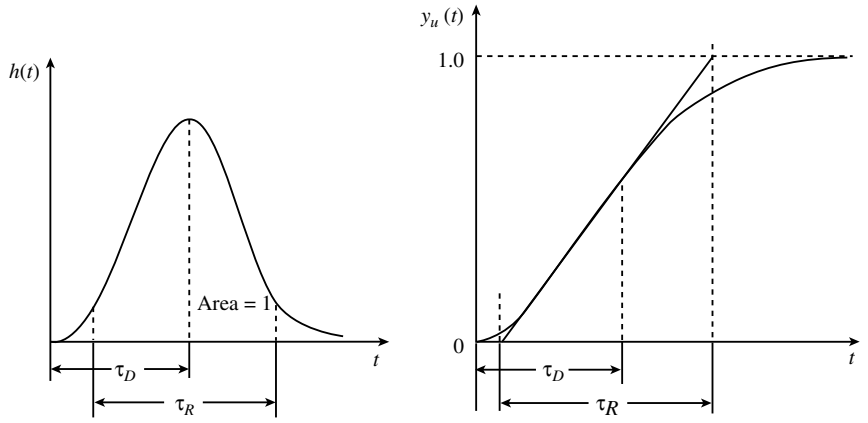

FIGURE 69.3 Physical interpretation of Elmore's definitions of delay and rise times: (a) impulse response $h(t)$, (b) unit-step response $y_u(t)$.

and the rise time assumes the form

$$\tau_R = \left[2\pi \int_0^\infty \left(t - \tau_D\right)^2 h(t)\, dt \right]^{1/2} = \sqrt{2\pi} \left[\int_0^\infty t^2 h(t)\, dt - \tau_D^2 \right]^{1/2}$$

The physical interpretation of these parameters is illustrated in Fig. 69.3(a) and (b). If the overshoot is small, say less than 1%, then

$$\tau_D \approx \tau_d \text{ and } \tau_R \approx \tau_r$$

The simplification brought about by Elmore's definitions can be easily demonstrated. Consider a filter whose step response approaches unity as $t \to \infty$. Such a filter has a transfer function of the form

$$H(s) = \frac{1 + a_1 s + a_2 s^2 + \cdots + a_M s^M}{1 + b_1 s + b_2 s^2 + \cdots + b_N s^N} \tag{69.3}$$

that is, $a_0 = b_0 = 1$. From the definition of the Laplace transform,

$$\begin{aligned} H(s) &= \int_0^\infty h(t) e^{-st} dt \\ &= \int_0^\infty h(t) \left(1 - st + \frac{s^2 t^2}{2!} - \cdots \right) dt \\ &= \int_0^\infty h(t)\, dt - s \int_0^\infty t h(t) dt + \frac{s^2}{2!} \int_0^\infty t^2 h(t) dt - \cdots \\ &= \int_0^\infty h(t)\, dt - s\tau_D + \frac{s^2}{2!} \left(\frac{\tau_R^2}{2\pi} + \tau_D^2 \right) - \cdots \end{aligned} \tag{69.4}$$

Alternatively, from (69.3), direct division gives

$$H(s) = 1 - \left(b_1 - a_1\right)s + \left(b_1^2 - a_1 b_1 + a_2 - b_2\right)s^2 + \cdots \tag{69.5}$$

© 2003 by CRC Press LLC

Now by comparing (69.4) and (69.5), we deduce

$$\int_0^\infty h(t)\ dt = 1, \tau_D = b_1 - a_1$$

and

$$\tau_R = \left\{2\pi\left[b_1^2 - a_1^2 + 2(a_2 - b_2)\right]\right\}^{1/2}$$

The previous definitions are based on the assumption that the unit-step response approaches unity as $t \to \infty$. If this is not the case, i.e., coefficients a_0 and b_0 are not equal to unity, then we can write

$$H(s) = KH'(s)$$

where $K = a_0/b_0$ and

$$H'(s) = \frac{1 + a_1's + a_2's^2 + \cdots + a_M's^M}{1 + b_1's + b_2's^2 + \cdots + b_N's^N}$$

Using the coefficients of $H'(s)$ in the formulas for τ_D and τ_R yields approximate values for the delay time and rise time, since these parameters are independent of the absolute value of the step response.

69.4 Frequency-Domain Analysis

The frequency response of an analog filter is deduced by finding its steady-state sinusoidal response, as we shall now demonstrate.

Sinusoidal Response

Consider an Nth-order analog filter characterized by a transfer function $H(s)$. The sinusoidal response of such a filter is

$$y(t) = \mathcal{L}^{-1}\left[H(s)X(s)\right]$$

where

$$X(s) = \mathcal{L}\left[u(t)\sin\omega t\right] = \frac{\omega}{(s + j\omega)(s - j\omega)} \tag{69.6}$$

The product $H(s)X(s)$ satisfies conditions 1 and 2 imposed on the general inversion formula of (69.2). Hence, for $t \geq 0$, we have

$$y(t) = \frac{1}{2\pi j}\int_\Gamma Y(s)e^{st}ds = \sum \text{res}\left[H(s)X(s)e^{st}\right] \tag{69.7}$$

where Γ is a contour enclosing the poles of $H(s)$and $X(s)$ as in Fig. 69.1.

Assuming simple poles for the transfer function, (69.6) and (69.7) give

$$y(t) = \sum_{i=1}^{N} X(p_i)e^{p_i t} \operatorname*{res}_{s=p_i} H(s) + \frac{1}{2j}\left[H(j\omega)e^{j\omega t} - H(-j\omega)e^{-j\omega t}\right. \tag{69.8}$$

© 2003 by CRC Press LLC

If the filter is assumed to be stable, then the poles are in the left-half s plane, i.e., $p_i = \sigma_i + j\omega_i$ with $\sigma_i < 0$.[6] As a consequence

$$\lim_{t\to\infty} e^{p_i t} = \lim_{t\to\infty}\left(e^{\sigma_i t}\cdot e^{j\omega_i t}\right) = 0$$

and since the residues of $H(s)$ are finite, the steady-state sinusoidal response is obtained from (69.8) as

$$\tilde{y}(t) = \lim_{t\to\infty} y(t) = \frac{1}{2j}\left[H(j\omega)e^{j\omega t} - H(-j\omega)e^{-j\omega t}\right] \tag{69.9}$$

Equation (69.9) was deduced on the assumption that the poles of the transfer function are simple. However, it also applies for transfer functions with higher-order poles.

Now from the definition of the Laplace transform

$$H(s) = \int_{-\infty}^{\infty} h(t)e^{-st}dt$$

and hence

$$H(-j\omega) = \int_{-\infty}^{\infty} h(t)e^{j\omega t}dt = \left[\int_{-\infty}^{\infty} h(t)e^{-j\omega t}dt\right]^{*} = H^{*}(j\omega) \tag{69.10}$$

If we write

$$H(j\omega) = M(\omega)e^{j\theta(\omega)} \tag{69.11}$$

where

$$M(\omega) = \left|H(j\omega)\right| \text{ and } \theta(\omega) = \arg H(j\omega) \tag{69.12}$$

the steady-state sinusoidal response of the filter is obtained from (69.9)–(69.12) as

$$\begin{aligned}\tilde{y}(t) &= \frac{1}{2j}\left[M(\omega)e^{j\theta(\omega)}e^{j\omega t} - M(\omega)e^{-j\theta(\omega)}e^{-j\omega t}\right]\\ &= M(\omega)\frac{1}{2j}\left[e^{j[\omega t+\theta(\omega)]} - e^{-j[\omega t+\theta(\omega)]}\right]\\ &= M(\omega)\sin\left[\omega t + \theta(\omega)\right]\end{aligned}$$

The preceding analysis has shown that the steady-state response of an analog filter to a sinusoid of unit amplitude is a sinusoid of amplitude $M(\omega)$, shifted by an angle $\theta(\omega)$. In effect, for a given frequency ω, the filter introduces a *gain* $M(\omega)$ and a *phase shift* $\theta(\omega)$.

As functions of frequency, $M(\omega)$ and $\theta(\omega)$ are known as the **amplitude** (or **magnitude**) **response** and **phase response** of the filter, respectively. The transfer function evaluated on the imaginary axis, namely, $H(j\omega)$ is the **frequency response** and, as was shown, its magnitude and angle are the amplitude response and phase response, respectively.

Two other quantities of a filter, which are of significant interest, are its *phase* and *group delays* These are defined as

[6]See Chapter 21 of this volume.

© 2003 by CRC Press LLC

$$\tau_p(\omega) = -\frac{\theta(\omega)}{\omega} \quad \text{and} \quad \tau_g(\omega) = -\frac{d\theta(\omega)}{d\omega}$$

respectively. For filters, the group delay is the more important of the two. As a function of frequency, $\tau_g(\omega)$ is usually referred to as the delay characteristic.

Graphical Construction

Consider a filter characterized by a transfer function of the form

$$H(s) = H_0 \frac{N(s)}{D(s)} = H_0 \frac{\prod_{i=1}^{M}(s - z_i)}{\prod_{i=1}^{N}(s - p_i)^{m_i}} \tag{69.13}$$

where H_0 is a constant. The frequency response of the filter is obtained as

$$H(j\omega) = M(\omega)e^{j\theta(\omega)} = \frac{H_0 \prod_{i=1}^{M}(j\omega - z_i)}{\prod_{i=1}^{N}(j\omega - p_i)^{m_i}}$$

By letting

$$j\omega - z_i = M_{z_i} e^{j\psi_{z_i}} \tag{69.14}$$

$$j\omega - p_i = M_{p_i} e^{j\psi_{p_i}} \tag{69.15}$$

we obtain

$$M(\omega) = \frac{|H_0| \prod_{i=1}^{M} M_{z_i}}{\prod_{i=1}^{N} M_{p_i}^{m_i}} \tag{69.16}$$

and

$$\theta(\omega) = \arg H_0 + \sum_{i=1}^{M} \psi_{z_i} - \sum_{i=1}^{N} m_i \psi_{p_i} \tag{69.17}$$

where arg $H_0 = \pi$ *if* H_0 is negative.

The gain and phase shift $M(\omega)$ and $\theta(\omega)$ for some frequency $\omega = \omega_i$ can be determined graphically by using the following procedure:

1. Mark the zeros and poles of the filter in the *s* plane.
2. Draw the phasor $s = j\omega_i$, where ω_i is the frequency of interest.
3. Draw a phasor of the type in (69.14) for each simple zero of $H(s)$.
4. Draw m_i phasor of the type in (69.15) for each pole of order m_i.
5. Measure the magnitudes and angles of the phasors in steps 3 and 4 and use them in (69.16) and (69.17) to calculate the gain $M(\omega_i)$ and phase shift $\theta(\omega_i)$, respectively.

© 2003 by CRC Press LLC

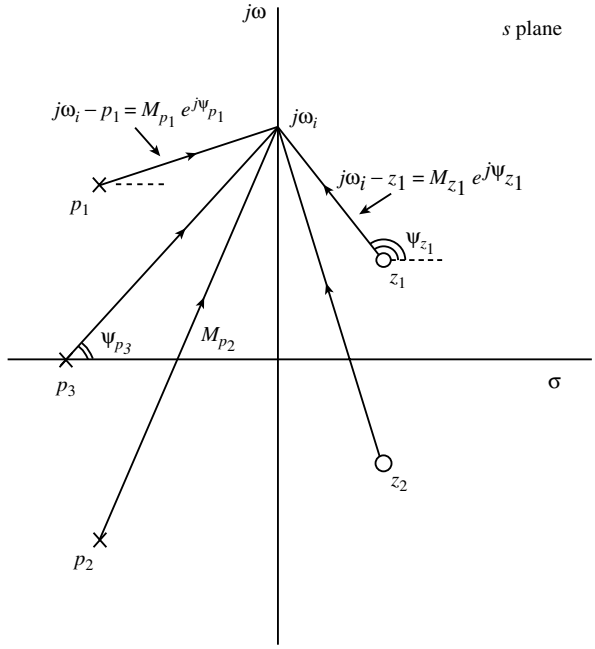

FIGURE 69.4 Graphical method for the evaluation of the frequency response.

The amplitude and phase responses of a filter can be determined by repeating the preceding procedure for frequencies $\omega = \omega_1, \omega_2, \ldots$, in the range 0 to ∞. The procedure is illustrated in Fig. 69.4.

It should be mentioned that the modern approach for the analysis of filters is through the use of the many circuit analysis programs such as SPICE.[7] Nevertheless, the above graphical method is of interest and merits consideration for two reasons. First, it illustrates some of the fundamental properties of filters. Second, it provides a certain degree of intuition about the expected amplitude or phase response of a filter. For example, if a filter has pole close to the $j\omega$ axis, then as ω approaches the neighborhood of the pole, the magnitude of the phasor from the pole to the $j\omega$ axis decreases rapidly to a very small value and then increases as ω increases above this value. As a result, the amplitude response will exhibit a large peak in the frequency range close to the pole. On the other hand, a zero close to or on the jω axis will lead to a notch in the amplitude response when ω is in the neighborhood of the zero.

Other situations are of interest, for example, if the poles of a filter are located in a band of the *s* plane below the horizontal line $s = \omega_c$ and its zeros are located above this line, then the filter will pass low-frequency and attenuate high-frequency components since $M_{zi} < M_{pi}$ if $\omega > \omega_c$ for all *i*. Such a filter is said to be a *low-pass* filter. If the zeros are located below the line $s = \omega_c$ and the poles above it, then the filter will pass high-frequency and attenuate low-frequency components, i.e., the filter will be a *high-pass* one.

Loss Function

Quite often, it is desirable to represent a filter in terms of its loss function. Consider a filter represented by the voltage transfer function

$$\frac{V_O(s)}{V_i(s)} = H(s) = \frac{N(s)}{D(s)}$$

[7]See Chapter 53 of this volume, contribution of J.G. Rollins.

© 2003 by CRC Press LLC

where $V_i(s)$ and $V_O(s)$ are the Laplace transforms of the input and output voltages, respectively, and $N(s)$ and $D(s)$ are polynomials in s. The loss (or attenuation) of the filter in decibels is defined as

$$A(\omega) = 20 \log \left| \frac{V_i(j\omega)}{V_O(j\omega)} \right| = 20 \log \frac{1}{|H(j\omega)|} = 10 \log L(\omega^2) \tag{69.18}$$

where

$$L(\omega^2) = \frac{1}{H(j\omega)H(-j\omega)}$$

$A(\omega)$ as a function of ω is the *loss characteristic.*

With $\omega = s/j$ in (69.18), the function

$$L(-s^2) = \frac{D(s)D(-s)}{N(s)N(-s)}$$

can be formed. This is called the *loss function* of the filter and, as is evident, its zeros are the poles of $H(s)$ and their negatives, whereas its poles are the zeros of $H(s)$ and their negatives.

69.5 Ideal and Practical Filters

An ideal low-pass filter is one that will pass only low-frequency components. Its loss characteristic is given by

$$A(\omega) = \begin{cases} 0 & \text{for} \quad 0 \le \omega < \omega_c \\ \infty & \text{for} \quad \omega_c < \omega < \infty \end{cases}$$

The frequency ranges 0 to ω_c and ω_c to ∞ are the *passband* and *stopband*, respectively. The boundary between the passband and stopband, namely, ω_c, is the *cutoff frequency.* An ideal high-pass filter will pass all components with frequencies above the cutoff frequency and reject all components with frequencies below the cutoff frequency, i.e.,

$$A(\omega) = \begin{cases} \infty & \text{for} \quad 0 \le \omega < \omega_c \\ 0 & \text{for} \quad \omega_c < \omega < \infty \end{cases}$$

Idealized loss characteristics can similarly be identified for bandpass and bandstop filters as

$$A(\omega) = \begin{cases} \infty & \text{for} \quad 0 \le \omega < \omega_{c1} \\ 0 & \text{for} \quad \omega_{c1} < \omega < \omega_{c2} \\ \infty & \text{for} \quad \omega_{c2} \le \omega < \infty \end{cases}$$

and

$$A(\omega) = \begin{cases} 0 & \text{for} \quad 0 \le \omega < \omega_{c1} \\ \infty & \text{for} \quad \omega_{c1} < \omega < \omega_{c2} \\ 0 & \text{for} \quad \omega_{c2} \le \omega < \infty \end{cases}$$

respectively.

© 2003 by CRC Press LLC

Practical filters differ from ideal ones in that the passband loss is not zero, the stopband loss is not infinite, and the transition between passband and stopband is gradual. Practical loss characteristics for low-pass, high-pass, bandpass, and bandstop filters assume the forms

$$A_{\mathrm{LP}}(\omega)\begin{cases}\le A_p & \text{for} \quad 0 \le \omega \le \omega_p \\ \ge A_a & \text{for} \quad \omega_a \le \omega \le \infty\end{cases}$$

$$A_{\mathrm{HP}}(\omega)\begin{cases}\ge A_a & \text{for} \quad 0 \le \omega \le \omega_a \\ \le A_p & \text{for} \quad \omega_p \le \omega \le \infty\end{cases}$$

$$A_{\mathrm{BP}}(\omega)\begin{cases}\ge A_a & \text{for} \quad 0 \le \omega \le \omega_{a1} \\ \le A_p & \text{for} \quad \omega_{p1} \le \omega \le \omega_{p2} \\ \ge A_a & \text{for} \quad \omega_{a2} \le \omega \le \infty\end{cases}$$

and

$$A_{\mathrm{BS}}(\omega) = \begin{cases}\le A_p & \text{for} \quad 0 \le \omega \le \omega_{p1} \\ \ge A_a & \text{for} \quad \omega_{a1} \le \omega \le \omega_{a2} \\ \le A_p & \text{for} \quad \omega_{p2} \le \omega \le \infty\end{cases}$$

respectively, where ω_p, ω_{p1}, and ω_{p2} are passband edges, ω_a, ω_{a1}, and ω_{a2} are stopband edges, A_P is the maximum passband loss, and A_a is the minimum stopband loss. In practice, A_p is determined from the allowable amplitude distortion (see Section 69.6) and A_a is dictated by the allowable adjacent channel interference and the desirable signal-to-noise ratio.

It should be mentioned that in practical filters the cutoff frequency ω_c is not a very precise term. It is often used to identify some hypothetical boundary between passband and stopband such as the 3-dB frequency in Butterworth filters, the passband edge in Chebyshev filters, the stopband edge in inverse-Chebyshev filters, or the geometric mean of the passband and stopband edges in elliptic filters.

If a filter is required to have a piecewise constant loss characteristic (or amplitude response) and the shape of the phase response is not critical, the filter can be fully specified by its band edges, the minimum passband and maximum stopband losses A_p and A_a, respectively.

69.6 Amplitude and Delay Distortion

In practice, a filter can distort the information content of the signal. Consider a filter characterized by a transfer function $H(s)$ and assume that its input and output signal are $v_i(t)$ and $v_o(t)$. The frequency response of the filter is given by

$$H(j\omega) = M(\omega)e^{j\theta(\omega)}$$

where $M(\omega)$ and $\theta(\omega)$ are the amplitude and phase responses, respectively.

The frequency spectrum of $v_i(t)$ is its Fourier transform, namely, $V_i(j\omega)$. Assume that the information content of $v_i(t)$ is concentrated in frequency band B given by

$$B = \{\omega : \omega_L \le \omega \le \omega_H\}$$

and that its frequency spectrum is zero elsewhere.

© 2003 by CRC Press LLC

Let us assume that the amplitude response is constant with respect to band B, i.e.,

$$M(\omega) = G_0 \quad \text{for} \quad \omega \in B \tag{69.19}$$

and that the phase response is linear, i.e.,

$$\theta(\omega) = -\tau_g \omega + \theta_o \quad \text{for} \quad \omega \in B \tag{69.20}$$

where τ_g is a constant. This implies that the group delay is constant with respect to band B, i.e.,

$$\tau(\omega) = -\frac{d\theta(\omega)}{d\omega} = \tau_g \quad \text{for} \quad \omega \in B$$

The frequency spectrum of the output signal $v_o(t)$ can be obtained from (69.19) and (69.20) as

$$\begin{aligned} V_o(j\omega) &= H(j\omega)V_i(j\omega) = M(\omega)e^{j\theta(\omega)}V_i(j\omega) \\ &= \left[G_0 e^{-j\omega\tau_g + j\theta_0}\right]V_i(j\omega) = G_0 e^{j\theta_0}\left[e^{-j\omega\tau_g}V_i(j\omega)\right] \end{aligned}$$

and from the time-shifting theorem of the Fourier transform

$$v_o(t) = G_0 e^{j\theta_0} v_i(t - \tau_g)$$

We conclude that the amplitude response of the filter is flat and its phase response is a linear function of ω (i.e., the delay characteristic is flat) in band B, then the output signal is a delayed replica of the input signal except that a gain G_o and a constant phase shift θ_0 are introduced.

If the amplitude response of the filter is not flat in band B, then *amplitude distortion* will be introduced since different frequency components of the signal will be amplified by different amounts.

If the delay characteristics is not flat in band B, then *delay* (or *phase*) *distortion* will be introduced since different frequency components will be delayed by different amounts.

Amplitude distortion can be quite objectionable in practice and, consequently, in each frequency band that carries information, the amplitude response is required to be constant to within a prescribed tolerance. The amount of amplitude distortion allowed determines the maximum passband loss A_p.

If the ultimate receiver of the signal is the human ear, e.g., when a speech or music signal is to be processed, delay distortion is quite tolerable. However, in other applications it can be as objectionable as amplitude distortion and the delay characteristic is required to be fairly flat. Applications of this type include data transmission, where the signal is to be interpreted by digital hardware, and image processing, where the signal is used to reconstruct an image that is to be interpreted by the human eye. The allowable delay distortion dictates the degree of flatness in the delay characteristic.

69.7 Minimum-Phase, Nonminimum-Phase, and Allpass Filters

Filters satisfying prescribed loss specifications for applications where delay distortion is unimportant can be readily designed with transfer functions whose zeros are on the $j\omega$ axis or in the left-half s plane. Such transfer functions are said to be **minimum-phase** since the phase response at a given frequency ω is increased if any one of the zeros is moved into the right-half s plane, as will now be demonstrated.

Minimum-Phase Filters

Consider a filter where the zeros z_i for $i = 1, 2, \ldots, M$ are replaced by their mirror images and let the new zeros be located at $z = \bar{z}_i$, where

© 2003 by CRC Press LLC

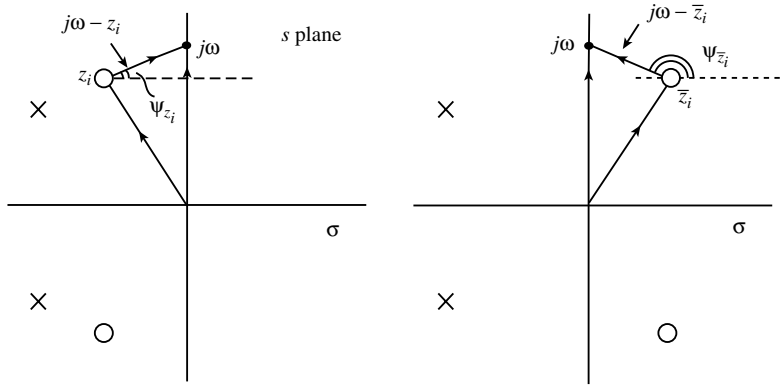

FIGURE 69.5 Zero-pole plots of minimum-phase and corresponding nonminimum-phase filter.

$$\text{Re}\ \bar{z}_i = -\text{Re}\ z_i \quad \text{and} \quad \text{Im}\,\bar{z}_i = \text{Im}\,z_i$$

as depicted in Fig. 69.5. From the geometry of the new zero-pole plot, the magnitude and angle of each phasor $j\omega - \bar{z}_i$ are given by

$$M_{\bar{z}_i} = M_{z_i} \quad \text{and} \quad \psi_{\bar{z}_i} = \pi - \psi_{z_i}$$

respectively. The amplitude response of the modified filter is obtained from (69.16) as

$$\overline{M}(\omega) = \frac{|H_0|\prod_{i=1}^{M} M_{\bar{z}_i}}{\prod_{i=1}^{N} M_{p_i}^{m_i}} = \frac{|H_0|\prod_{i=1}^{M} M_{z_i}}{\prod_{i=1}^{N} M_{p_i}^{m_i}} = M(\omega)$$

Therefore, replacing the zeros of the transfer function by their mirror images leaves the amplitude response unchanged.

The phase response of the original filter is given by (69.17) as

$$\theta(\omega) = \arg H_0 + \sum_{i=1}^{M} \psi_{z_i} - \sum_{i=1}^{N} m_i \psi_{p_i} \tag{69.21}$$

and since $\psi_{\bar{z}_i} = \pi - \psi_{z_i}$, the phase response of the modifier filter is given by

$$\begin{aligned} \bar{\theta}(\omega) &= \arg H_0 + \sum_{i=1}^{M} \psi_{\bar{z}_i} - \sum_{i=1}^{N} m_i \psi_{p_i} \\ &= \arg H_0 + \sum_{i=1}^{M} (\pi - \psi_{z_i}) - \sum_{i=1}^{N} m_i \psi_{p_i} \end{aligned} \tag{69.22}$$

that is, the phase response of the modified filter is different from that of the original filter. Furthermore, from (69.21) and (69.22)

$$\bar{\theta}(\omega) - \theta(\omega) = \sum_{i=1}^{M} (\pi - 2\psi_{z_i})$$

© 2003 by CRC Press LLC

and since $-\pi/2 \le \psi_{z_i} \le \pi/2$, we have

$$\bar{\theta}(\omega) - \theta(\omega) \ge 0$$

or

$$\bar{\theta}(\omega) \ge \theta(\omega)$$

As a consequence, the phase response of the modified filter is equal to or greater than that of the original filter for all ω.

A frequently encountered requirement in the design of filters is that the delay characteristic be flat to within a certain tolerance within the passband(s) in order to achieve tolerable delay distortion, as was demonstrated in Section 69.6. In these and other filters in which the specifications include constraints on the phase response or delay characteristic, a nonminimum-phase transfer function is almost always required.

Allpass Filters

An **allpass filter** is one that has a constant amplitude response. Consider a transfer function of the type given by (69.13). From (69.10), $H(-j\omega)$ is the complex conjugate of $H(j\omega)$, and hence a constant amplitude response can be achieved if

$$M^2(\omega) = H(s)H(-s)\big|_{s=j\omega} = H_0^2 \frac{N(s)}{D(s)} \times \frac{N(-s)}{D(-s)}\bigg|_{s=j\omega} = H_0^2$$

Hence, an allpass filter can be obtained if

$$N(-s) = D(s)$$

that is, the zeros of such a filter must be the mirror images of the poles and vice versa. A typical zero-pole plot for an allpass filter is illustrated in Fig. 69.6. A second-order allpass transfer function is given by

$$H_{AP}(s) = \frac{s^2 - bs + c}{s^2 + bs + c}$$

where $b > 0$ for stability. As described previously, we can write

$$M^2(\omega) = H_{\mathrm{AP}}(s)H_{\mathrm{AP}}(-s)\big|_{s=j\omega} = \frac{s^2 - bs + c}{s^2 + bs + c} \times \frac{s^2 + bs + c}{s^2 - bs + c}\bigg|_{s=j\omega} = 1$$

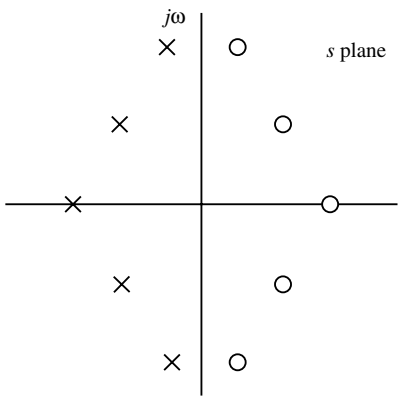

FIGURE 69.6 Typical zero-pole plot of an allpass filter.

© 2003 by CRC Press LLC

Allpass filters can be used to modify the phase responses of filters without changing their amplitude responses. Hence, they are used along with minimum-phase filters to obtain nonminimum-phase filters that satisfy amplitude and phase response specifications simultaneously.

Decomposition of Nonminimum-Phase Transfer Functions

Some methods for the design of filters satisfying amplitude and phase response specifications, usually methods based on optimization, yield a nonminimum-phase transfer function. Such a transfer function can be easily decomposed into a product of a minimum-phase and an allpass transfer function, i.e.,

$$H_N(s) = H_M(s)H_{AP}(s)$$

Consequently, a nonminimum-phase filter can be implemented as a cascade arrangement of a minimum-phase and an allpass filter.

The preceding decomposition can be obtained by using the following procedure:

1. For each zero in the right-half s plane, augment the transfer function by a zero and a pole at the mirror image position of the zero.
2. Assign the left-half s-plane zeros and the original poles to the minimum-phase transfer function $H_M(s)$.
3. Assign the right-half s-plane zeros and the left-hand s-plane poles generated in step 1 to the allpass transfer function $H_{AP}(s)$.

This procedure is illustrated in Fig. 69.7. For example, if

$$H_N(s) = \frac{(s^2+4s+5)(s^2-3s+7)(s-5)}{(s^2+2s+6)(s^2+4s+9)(s+2)}$$

then, we can write

$$H_N(s) = \frac{(s^2+4s+5)(s^2-3s+7)(s-5)}{(s^2+2s+6)(s^2+4s+9)(s+2)} \times \frac{(s^2+3s+7)(s+5)}{(s^2+3s+7)(s+5)}$$

Hence,

$$H_N(s) = \frac{(s^2+4s+5)(s^2+3s+7)(s+5)}{(s^2+2s+6)(s^2+4s+9)(s+2)} \times \frac{(s^2-3s+7)(s-5)}{(s^2+3s+7)(s+5)}$$

or

$$H_N(s) = H_M(s)H_{AP}(s)$$

where

$$H_M(s) = \frac{(s^2+4s+5)(s^2+3s+7)(s+5)}{(s^2+2s+6)(s^2+4s+9)(s+2)}$$

$$H_{AP}(s) = \frac{(s^2-3s+7)(s-5)}{(s^2+3s+7)(s+5)}$$

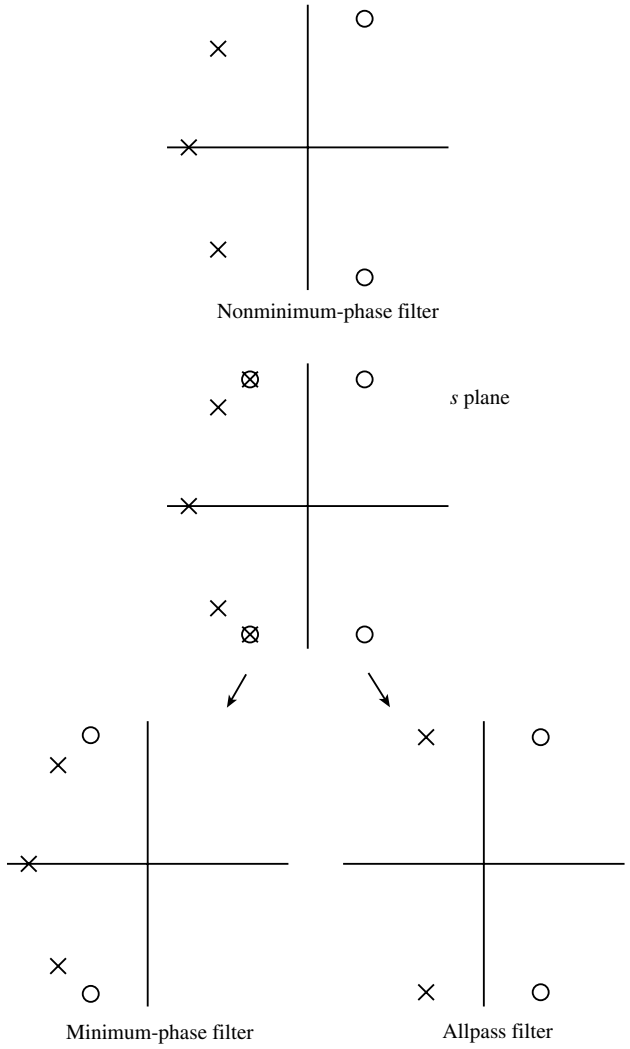

FIGURE 69.7 Decomposition of nonminimum-phase transfer function.

69.8 Introduction to the Design Process

The design of filters starts with a set of specifications and ends with the implementation of a prototype. It comprises four general steps, as follows:

1. approximation
2. realization
3. study of imperfections
4. implementation

The Approximation Step

The **approximation step** is the process of generating a transfer function that satisfies the desired specifications, which may concern the amplitude, phase, and possibly the time-domain response of the filter.

The available methods for the solution of the approximation problem can be classified as **closed-form** or **iterative**. In closed-form methods, the problem is solved through a small number of design steps using

© 2003 by CRC Press LLC

a set of closed-form formulas or transformations. In iterative methods, an initial solution is assumed and, through the application of optimization methods, a series of progressively improved solutions are obtained until some design criterion is satisfied. Closed-form solutions are very precise and entail a minimal amount of computation. However, the available solutions are useful in applications where the loss characteristic is required to be piecewise constant to within some prescribed tolerances. Iterative methods, on the other hand, entail a considerable amount of computation but can be used to design filters with arbitrary amplitude and phase response characteristics (see [1, ch. 14] for the application of these methods for the design of digital filters). Some classical closed-form solutions are the so-called Butterworth, Chebyshev, and elliptic[8] approximations to be described in Chapter 70 by A. M. Davis.

In general, the designer is interested in simple and reliable approximation methods that yield precise designs with the minimum amount of computation.

The Realization Step

The *synthesis* of a filter is the process of converting some characterization of the filter into a network. The process of converting the transfer function into a network is said to be the **realization step** and the network obtained is sometimes called the **realization**.

The realization of a transfer function can be accomplished by expressing it in some form that allows the identification of an interconnection of elemental filter subnetworks and/or elements. Many realization methods have been proposed in the past that lead to structures of varying complexity and properties. In general, the designer is interested in realizations that are economical in terms of the number of elements, do not require expensive components, and are not seriously affected by variations in the element values such as may be caused by variations in temperature and humidity, and drift due to element aging.

Study of Imperfections

During the approximation step, the coefficients of the transfer function are determined to a high degree of precision and the realization is obtained on the assumption that elements are ideal, i.e., capacitors are lossless, inductors are free of winding capacitances, amplifiers have infinite bandwidths, and so on. In practice, however, the filter is implemented with nonideal elements that have finite tolerances and are often nonlinear. Consequently, once a realization is obtained, sometimes referred to as a *paper design*, the designer must embark on the study of the effects of element imperfections. Several types of analysis are usually called for ranging from tolerance analysis, study of parasitics, time-domain analysis, sensitivity analysis, noise analysis, etc. Tight tolerances result in high-precision filters but the cost per unit would be high. Hence the designer is obliged to determine the highest tolerance that can be tolerated without violating the specifications of the filter throughout its working life. Sensitivity analysis is a related study that will ascertain the degree of dependence of a filter parameter, e.g., the dependence of the amplitude response on a specific element. If the loss characteristic of a filter is not very sensitive to certain capacitance, then the designer would be able to use a less precise and cheaper capacitor, which would, of course, decrease the cost of the unit.

Implementation

Once the filter is thoroughly analyzed and found to meet the desired specifications under ideal conditions, a prototype is constructed and tested. Decisions to be made involve the type of components and packaging, and the methods are to be used for the manufacture, testing, and tuning of the filter. Problems may often surface at the implementation stage that may call for one or more modifications in the paper design. Then the realization and possibly the approximation may have to be redone.

[8]To be precise, the elliptic approximation is not a closed-form method, since the transfer function coefficients are given in terms of certain infinite series. However, these series converge very rapidly and can be treated as closed-form formulas for most practical purposes (see [1, ch. 5]).

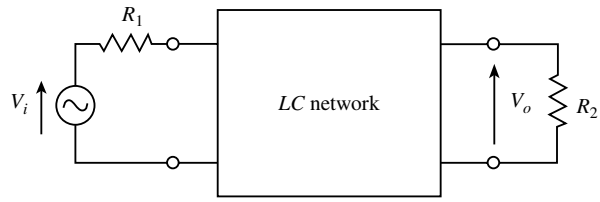

FIGURE 69.8 Passive *RLC* filter.

69.9 Introduction to Realization

Realization tends to depend heavily on the type of filter required. The realization of passive *RLC* filters differs quite significantly from that of active filters which, in turn, is entirely different from the realization of microwave filters.

Passive Filters

Passive *RLC* filters have been the mainstay of communications since the 1920s and, furthermore, they continue to be of considerable importance today for frequencies in the range 100–500 kHz.

The realization of passive *RLC* filters has received considerable attention through the years and it is, as a consequence, highly developed and sophisticated. It can be accomplished by using available filter-design packages such as FILSYN [5] and FILTOR [6]. In addition, several filter-design handbooks and published design tables are available [7]–[10].

The realization of passive *RLC* filters starts with a resistively terminated *LC* two-port network such as that in Fig. 69.8. Then through one of several approaches, the transfer function is used to generate expressions for the *z* or *y* parameters of the *LC* two-port. The realization of the *LC* two-port is achieved by realizing the *z* or *y* parameters. The realization of passive filters is considered in Section XI by L. Huelsman and W. K. Chen.

Active Filters

Since the reactance of an inductor is ωL, increased inductance values are required to achieve reasonable reactance values at low frequencies. For example, an inductance of 1 mH which will present a reactance of 6.28 kΩ at 1 MHz will present only 0.628 Ω at 100 Hz. Thus, as the frequency range of interest is reduced, the inductance values must be increased if a specified impedance level is to be maintained. This can be done by increasing the number of turns on the inductor coil and to some extent by using ferromagnetic cores of high permeability. Increasing the number of turns increases the resistance, the size, and the cost of the inductor. The resistance is increased because the length of the wire is increased [$R = (\rho \times length)/Area$], and hence the *Q* factor is reduced. The cost goes up because the cost of materials as well as the cost of labor go up, since an inductor must be individually wound. For these reasons, inductors are generally incompatible with miniaturization or microcircuit implementation.

The preceding physical problem has led to the invention and development of a class of inductorless filters known collectively as **active filters**. Sensitivity considerations, which will be examined in Chapter 73 by I. Filanovsky, have led to two basic approaches to the design of active filters. In one approach, the active filter is obtained by simulating the inductances in a passive *RLC* filter or by realizing a signal flow graph of the passive *RLC* filter. In another approach, the active filter is obtained by cascading a number of low-order filter sections of some type, as depicted in Fig. 69.9(a) where Z_{o0} is the output impedance of the signal source.

Each filter section is made up of an interconnection of resistors, capacitors, and active elements, and by Thévenin's theorem, it can be represented by its input impedance, open-circuit voltage transfer

© 2003 by CRC Press LLC

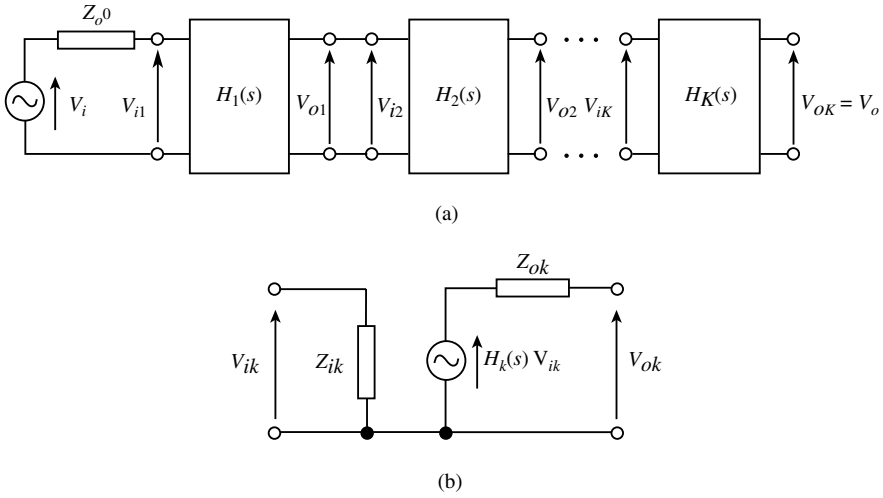

FIGURE 69.9 (a) Cascade realization, (b) Thévenin equivalent circuit of filter section.

function, and output impedance as shown in Fig. 69.9(b). The voltage transfer function of the configuration is given by

$$H(s) = \frac{V_o}{V_i}$$

and since the input voltage of section k is equal to the output voltage of section $k-1$, i.e., $V_{ik} = V_{o(k-1)}$ for $k = 2, 3, \ldots, K$, and $V_o = V_{oK}$ we can write

$$H(s) = \frac{V_o}{V_i} = \frac{V_{i1}}{V_i} \times \frac{V_{o1}}{V_{i1}} \times \frac{V_{o2}}{V_{i2}} \times \cdots \times \frac{V_{oK}}{V_{iK}} \tag{69.23}$$

where

$$\frac{V_{i1}}{V_i} = \frac{Z_{i1}}{Z_{o0} + Z_{i1}} \tag{69.24}$$

and

$$\frac{V_{ok}}{V_{ik}} = \frac{Z_{i(k+1)}}{Z_{ok} + Z_{i(k+1)}} H_k(s) \tag{69.25}$$

is the transfer function of the kth section. From (69.23)–(69.25), we obtain

$$H(s) = \frac{V_o}{V_i} = \frac{Z_{i1}}{Z_{o0} + Z_{i1}} \prod_{k=1}^{K} \frac{Z_{i(k+1)}}{Z_{ok} + Z_{i(k+1)}} H_k(s)$$

Now if

$$|Z_{ik}| \gg |Z_{o(k-1)}|$$

© 2003 by CRC Press LLC

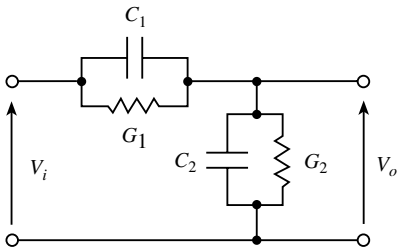

FIGURE 69.10 First-order *RC* network.

for $k = 1, 2, \ldots, K$, then the loading effect produced by section $k + 1$ on section k can be neglected and hence

$$H(s) = \frac{V_o}{V_i} = \prod_{k-1}^{K} H_k(s)$$

Evidently, a highly desirable property in active filter sections is that the magnitude of the input impedance be large and/or that of the output impedance be small since in such a case the transfer function of the cascade structure is equal to the product of the transfer functions of the individual sections.

An arbitrary *N*th-order transfer function obtained by using the Butterworth, Bessel, Chebyshev, inverse-Chebyshev, or elliptic approximation can be expressed as

$$H(s) = H_0(s)\prod_{k=1}^{K} \frac{a_{2k}s^2 + a_{1k}s + a_{0k}}{s^2 + b_{1k}s + b_{0k}}$$

where

$$H_0(s) = \begin{cases} \dfrac{a_{10}s + a_{00}}{b_{10}s + b_{00}} & \text{for odd } N \\ 1 & \text{for even } N \end{cases}$$

The first-order transfer function $H_0(s)$ for the case of an odd-order can be readily realized using the *RC* network of Fig. 69.10.

Biquads

From the above analysis, we note that all we need to be able to realize an arbitrary transfer function is a circuit that realizes the biquadratic transfer function

$$H_{BQ}(s) = \frac{a_2s^2 + a_1s + a_0}{s^2 + b_1s + b_0} = \frac{a_2(s + z_1)(s + z_2)}{(s + p_1)(s + p_2)} \tag{69.26}$$

where zeros and poles occur in complex conjugate pairs, i.e., $z_2 = z_1^*$ and $p_2 = p_1^*$. Such a circuit is commonly referred to as a *biquad*.

After some, manipulation, the transfer function in (69.26) can be expressed as

$$H_{BQ}(s) = K\frac{s^2 + (2\text{Re } z_1)s + (\text{Re } z_1)^2 + (\text{Im } z_1)^2}{s^2 + (2\text{Re } p_1)s + (\text{Re } p_1)^2 + (\text{Im } p_1)^2}$$

$$= K\frac{s^2 + (\omega_z/Q_z)s + \omega_z^2}{s^2 + (\omega_P/Q_P)s + \omega_p^2}$$

© 2003 by CRC Press LLC

where $K = a_2$, ω_z, and ω_p are the zero and pole frequencies, and Q_z and Q_p are the zero and pole *quality factors* (or Q factors for short), respectively. The formulas for the various parameters are as follows:

$$\omega_z = \sqrt{(\text{Re } z_1)^2 + (\text{Im } z_1)^2}$$

$$\omega_p = \sqrt{(\text{Re } p_1)^2 + (\text{Im } p_1)^2}$$

$$Q_z = \frac{\omega_z}{2 \text{ Re } z_1}$$

$$Q_p = \frac{\omega_p}{2 \text{ Re } p_1}$$

The zero and pole frequencies are approximately equal to the frequencies of minimum gain and maximum gain, respectively. The zero and pole Q factors have to do with the selectivity of the filter. A high zero Q factor results in a deep notch in the amplitude response, whereas a high pole Q factor results in a very peaky amplitude response.

The dc gain and the gain as $\omega \to \infty$ in dB are given by

$$M_0 = 20 \log|H_{BQ}(0)| = 20 \log\left(K \frac{\omega_z^2}{\omega_p^2}\right)$$

and

$$M_\infty = 20 \log|H_{BQ}(j\infty)| = 20 \log K$$

respectively.

Types of Basic Filter Sections

Depending on the values of the transfer function coefficients, five basic types of filter sections can be identified, namely, low-pass, high-pass, bandpass, notch (sometimes referred to as bandreject), and allpass. These sections can serve as building blocks for the design of filters that can satisfy arbitrary specifications. They are actually sufficient for the design of all the standard types of filters, namely, Butterworth, Chebyshev, inverse-Chebyshev, and elliptic filters.

Low-Pass Section

In a *low-pass* section, we have $a_2 = a_1 = 0$ and $a_0 = K\omega_p^2$. Hence, the transfer function assumes the form

$$H_{LP}(s) = \frac{a_0}{s^2 + b_1 s + b_0} = \frac{K\omega_p^2}{s^2 + (\omega_p/Q_p)s + \omega_p^2}$$

[See Fig. 69.11(a).]

High-Pass Section

In a *high-pass* section, we have $a_2 = K$ and $a_1 = a_0 = 0$. Hence, the transfer function assumes the form

$$H_{HP}(s) = \frac{a_2 s^2}{s^2 + b_1 s + b_0} = \frac{Ks^2}{s^2 + (\omega_p/Q_p)s + \omega_p^2}$$

[See Fig. 69.11(b).]

© 2003 by CRC Press LLC

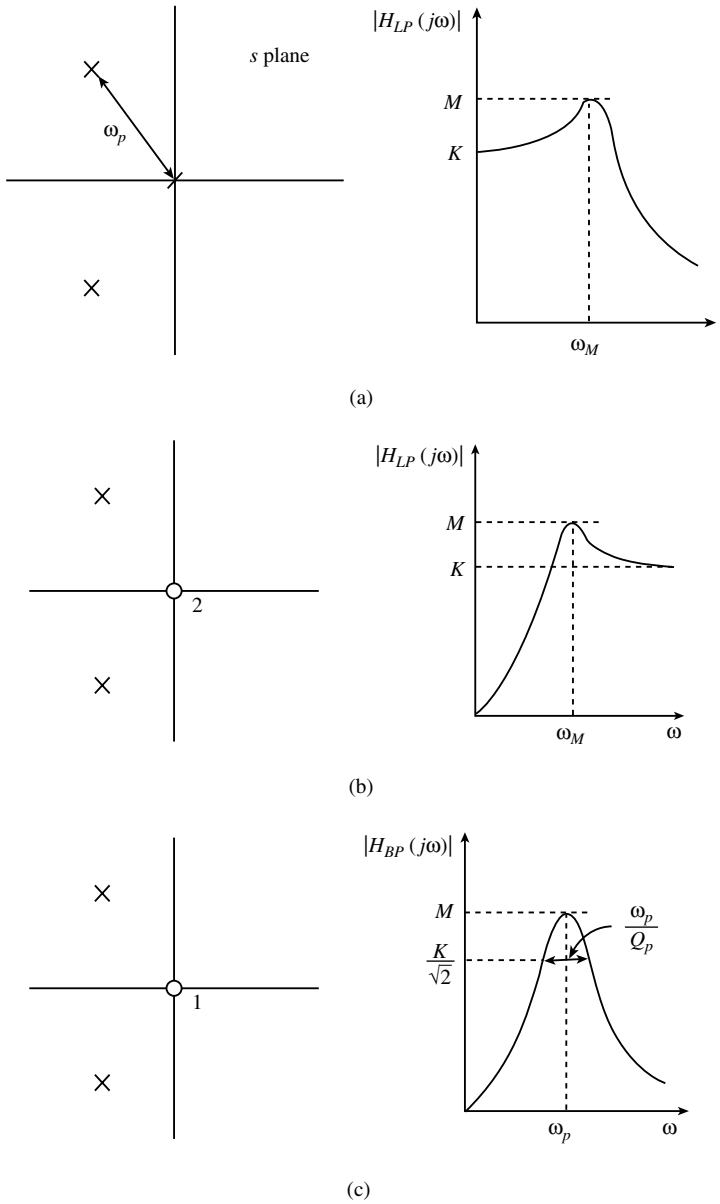

FIGURE 69.11 Basic second-order filter sections: (a) low-pass, (b) high-pass, (c) bandpass.

Bandpass Section

In a *bandpass* section, we have $a_1 = K\omega_p/Q_p$ and $a_2 = a_0 = 0$. Hence the transfer function assumes the form

$$H_{\mathrm{BP}}(s) = \frac{a_1 s}{s^2 + b_1 s + b_0} = \frac{K\left(\omega_p/Q_p\right)s}{s^2 + \left(\omega_p/Q_p\right) + \omega_p^2}$$

[See Fig. 69.11(c).]

Notch Section

In a *notch* section, we have $a_2 = K$, $a_1 = 0$, and $a_0 = K\omega_z^2$. Hence, the transfer function assumes the form

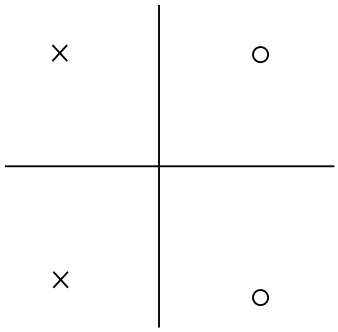
(d)



(e)

FIGURE 69.11 (Continued) Basic second-order filter sections: (d) notch, (e) allpass.

$$H_N(s) = \frac{a_2 s^2 + a_0}{s^2 + b_1 s + b_0} = \frac{K\left(s^2 + \omega_z^2\right)}{s^2 + \left(\omega_p / Q_p\right)s + \omega_p^2}$$

[See Fig. 69.11(d).]

Allpass Section

In an *allpass* section, we have $a_2 = K$, $a_1 = -K\omega_p/Q_p$, and $a_0 = K\omega_p^2$. Hence the transfer function assumes the form

$$H_{AP}(s) = \frac{a_2 s^2 + a_1 s + a_0}{s^2 + b_1 s + b_0} = \frac{K\left[s^2 - \left(\omega_p / Q_p\right)s + \omega_p^2\right]}{s^2 + \left(\omega_p / Q_p\right)s + \omega_p^2}$$

[See Fig. 69.11(e).]

The design of active and switched-capacitor filters is treated in some detail in Section XII.

70.1 Introduction

The approximation problem for filters is illustrated in Fig. 70.1. A filter is often desired to produce a given slope of gain over one or more frequency intervals, to remain constant over other intervals, and to completely reject signals having frequencies contained in still other intervals. Thus, in the example shown in the figure, the desired gain is zero for very low and very high frequencies. The center line, shown dashed, is the nominal behavior and the shaded band shows the permissible variation in the gain characteristic. Realizable circuits must always generate smooth curves and so cannot exactly meet the piecewise linear specification represented by the center line. Thus, the realizable behavior is shown by the smooth, dark curve that lies entirely within the shaded tolerance band.

What type of frequency response function can be postulated that will meet the required specifications and — at the same time — be realizable: constructible with a specified catalog of elements? The answer depends upon the types of elements allowed. For instance, if one allows pure delays with a common delay time, summers, and scalar multipliers, a trigonometric polynomial will work; this, however, will cause the gain function to be repeated in a periodic manner. If this is permissible, one can then realize the filter in the form of an FIR digital filter or as a commensurate transmission line filter — and, in fact, it can be realized in such a fashion that the resulting phase behavior is precisely linear. If one fits the required behavior with a rational trigonometric function, a function that is the ratio of two trigonometric polynomials, an economy of hardware will result. The phase, however, will unfortunately no longer be linear. These issues are discussed at greater length in [1].

Another option would be to select an ordinary polynomial in ω as the approximating function. Polynomials, however, behave badly at infinity. They approach infinity as $\omega \to \pm\infty$, a highly undesirable solution. For this reason, one must discard polynomials. A rational function of ω, however, will work nicely for the ratio of two polynomials will approach zero as $\omega \to \pm\infty$ if the degree of the numerator polynomial is selected to be of lower degree than that of the denominator. Furthermore, by the Weierstrass theorem, such a function can approximate any continuous function arbitrarily closely over any closed interval of finite length [2]. Thus, one sees that the rational functions in ω offer a suitable approximation for analog filter design and — in fact — do not have the repetitive nature of the trigonometric rational functions.

Suppose, therefore, that the gain function is of the form

$$A(\omega) = \frac{N(\omega)}{D(\omega)} = \frac{a_0 + a_1\omega + a_2\omega^2 + \cdots + a_r\omega^r}{b_0 + b_1\omega + b_2\omega^2 + \cdots + b_q\omega^q} \tag{70.1}$$

© 2003 by CRC Press LLC

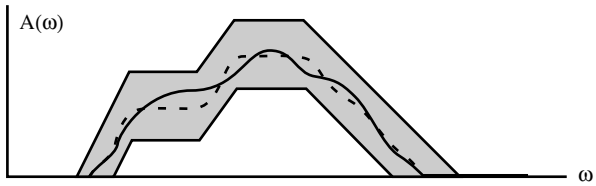

FIGURE 70.1 The general approximation problem.

where $r \le q$ for reasons mentioned above. Assuming that the filter to be realized is constrained to be constructable with real[1] elements, one must require that $A(-\omega) = A(\omega)$ — that is, that the gain be an event function of frequency. But then, as it is straightforward to show, one must require that all the odd coefficients of both numerator and denominator be zero. This means that the gain is a function of ω^2:

$$A(\omega) = \frac{N(\omega^2)}{D(\omega^2)} = \frac{a_0 + a_1\omega^2 + \cdots + a_m\omega^{2m}}{b_0 + b_1\omega^2 + \cdots + b_n\omega^{2n}} = A(\omega^{-2}) \tag{70.2}$$

The expression has been reindexed and the constants redefined in an obvious manner. The net result is that one must approximate the desired characteristic by the ratio of two polynomials in ω^2; the objective is to determine the numerator and denominator coefficients to meet the stated specifications. Once this is accomplished one must compute the filter transfer function $G(s)$ in order to synthesize the filter [4], [5]. Assuming that $G(s)$ is real (has real coefficients), then its complex conjugate satisfies $G^*(s) = G(s^*)$, from which it follows that $G(s)$ is related to $A(\omega^2)$ by the relationship

$$\left[G(s)G(-s)\right]_{s=j\omega} = G(j\omega)G^*(j\omega) = \left|G(j\omega)\right|^2 = A^2(\omega^2) \tag{70.3}$$

In fact, it is more straightforward to simply cast the original approximation problem in terms of $A^2(\omega^2)$, rather than in terms of $A(\omega)$. In this case, (70.2) becomes

$$A^2(\omega^2) = \frac{N(\omega^2)}{D(\omega^2)} = \frac{a_0 + a_1\omega^2 + \cdots + a_m\omega^{2m}}{b_0 + b_1\omega^2 + \cdots + b_n\omega^{2n}} \tag{70.4}$$

Thus, one can assume that the approximation process produces $A^2(\omega^2)$ as the ratio of two real polynomials in ω^2. Since (70.3) requires the substitutions $s \to j\omega$, one also has $s^2 \to -\omega^2$, and conversely. Thus, (70.3) becomes

$$G(s)G(-s) = A^2(-s^2) \tag{70.5}$$

Though this has been shown to hold only on the imaginary axis, it continues to hold for other complex values of s as well by analytic continuation.[2]

The problem now is to compute $G(s)$ from (70.5), a process known as the **factorization problem**. The solution is not unique; in fact, the phase is arbitrary — subject only to certain realizability conditions. To see this, just let $G(j\omega) = A(\omega)e^{j\phi(\omega)}$, where $\phi\omega$ is an arbitrary phase function. Them, (70.3) implies that

$$G(j\omega)G^*(j\omega) = A(\omega)e^{j\phi(\omega)} \cdot A(\omega)e^{-j\phi(\omega)} = A^2(\omega) \tag{70.6}$$

[1]Complex filters are quite possible to construct, as recent work [3] shows.

[2]A function analytic in a region is completely determined by its values along any line segment in that region — in this case, by its value along the $j\omega$ axis.

© 2003 by CRC Press LLC

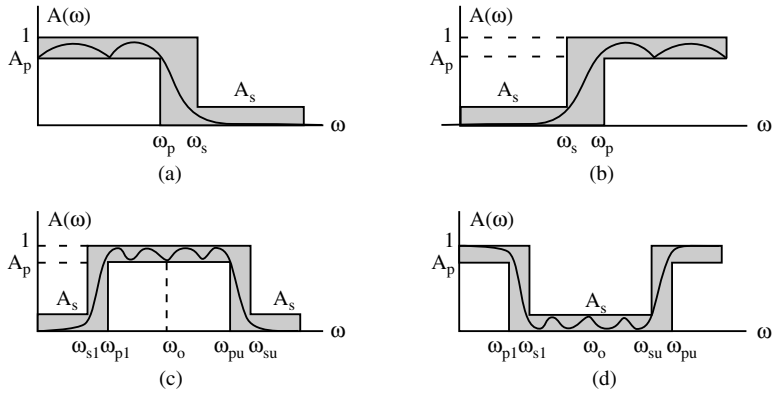

FIGURE 70.2 Catalog of basic filter types: (a) lowpass, (b) highpass, (c) bandpass, (d) bandreject.

If the resulting structure is to have the property of minimum phase [6], the phase function is determined completely by the gain function. If not, one can simply perform the factorization and accept whatever phase function results from the particular process chosen. As has been pointed out earlier in this chapter, it is often desirable that the phase be a linear function of frequency. In this case, one must follow the filter designed by the above process with a phase equalization filter, one that has constant gain and a phase characteristic that, when summed with that of the first filter, produces linear phase. As it happens, the human ear is insensitive to phase nonlinearity, so the phase is not of much importance for filters designed to operate in the audio range. For those intended for video applications, however, it is vitally important. Nonlinear phase produces, for instance, the phenomenon of multiple edges in a reproduced picture.

If completely arbitrary gain characteristics are desired, computer optimization is necessary [6]. Indeed, if phase is of great significance, computer algorithms are available for the simultaneous approximation of both gain and phase. These are complex and unwieldy to use, however, so for more modest applications the above approach relying upon gain approximation only suffices. In fact, the approach arose historically in the telephone industry in its earlier days in which voice transmission was the only concern, data and video transmission being unforeseen at the time. Furthermore, the frequency division multiplexing of voice signals was the primary concern; hence, a number of standard desired shapes of frequency response were generated: low-pass, high-pass, bandpass, and band-reject (or notch). Typical but stylized specification curves are shown in Fig. 70.2. This figure serves to define the following parameters: the minimum passband gain A_p, the maximum stopband gain A_s, the passband cutoff frequency ω_p, the stopband cutoff frequency ω_s (the last two parameters are for low-pass and high-pass filters only), the center frequency ω_o, upper passband and stopband cutoff frequencies ω_{pu} and ω_{su} and lower passband and stopband cutoff frequencies ω_{pl} and ω_{sl} (the last four parameters are for the bandpass and band-reject filters only). As shown in the figure, the maximum passband gain is usually taken to be unity. In the realization process, the transfer function scale factor is often allowed to be a free parameter that is resolved in the design procedure. The resulting "flat gain" (frequency independent) difference from unity is usually considered to be of no consequence — as long as it is not too small, thus creating signal-to-noise ratio problems. There is a fifth standard type that we have not shown: the allpass filter. It has a constant gain for all frequencies, but with a phase characteristic that can be tailored to fit a standard specification in order to compensate for phase distortion. Frequency ranges where the gain is relatively large are called **passbands** and those where the gain is relatively small, **stopbands**. Those in between — where the gain is increasing or decreasing — are termed **transition bands**.

In order to simplify the design even more, one bases the design of all other types of filter in terms of only one: the low pass. In this case, one says that the low-pass filter is a **prototype**. The specifications of the desired filter type are transformed to those of an equivalent low-pass prototype, and the transfer

© 2003 by CRC Press LLC

function for this filter is determined to meet the transformed specifications. Letting the low-pass frequency be symbolized by Ω and the original by ω, one sets

$$\Omega = f(\omega) \tag{70.7}$$

The approximation problem is then solved in terms of Ω. Letting

$$p = j\Omega \tag{70.8}$$

one then has $G(p)$, the desired transfer function.

Two approaches are now possible. One is to apply the inverse transformation, letting

$$s = j\omega = jf^{-1}(\Omega) = jf^{-1}(p/j) \tag{70.9}$$

thus obtaining the desired transfer function

$$G(s) = G(j\omega) = G\left[jf^{-1}(\Omega)\right] = G\left[jf^{-1}(p/j)\right] \tag{70.10}$$

The other consists of designing the circuit to realize the low-pass prototype filter, then transform *each of the elements* from functions of p to functions of s by means of the complex frequency transformation

$$s = j\omega = jf^{-1}(\Omega) = jf^{-1}(p/j) \tag{70.11}$$

As it happens, the transformation $p = f(s)$ has a special form. It can be shown that if f is real for real values of s, thereby having real parameters, and maps the imaginary axis of the p plane into the imaginary axis of the s plane then it must be an odd function; furthermore, if it is to map *positive real rational functions* into those of like kind (necessary for realizability with *R, L,* and *C* elements, as well as possibly ideal transformers[3]), it must be a *reactance function*. (See [11] for details.) Since it is always desirable from an economic standpoint to design filters of minimum order, it is desirable that the transformation be of the smallest possible degree. As a result, the following transformations are used:

$$(\text{lpp} \leftrightarrow \text{lp}) \qquad p = ks \tag{70.12}$$

$$(\text{lpp} \leftrightarrow \text{hp}) \quad p = \frac{k}{s} \tag{70.13}$$

$$(\text{lpp} \leftrightarrow \text{bp}) \quad p = \frac{s^2 + \omega_0^2}{Bs} \tag{70.14}$$

$$(\text{lpp} \leftrightarrow \text{br}) \quad p = \frac{Bs}{s^2 + \omega_o^2} \tag{70.15}$$

where the parameters k, B, and ω_o are real constants to be determined by the particular set of specifications. We have used the standard abbreviations of lpp for *low-pass prototype,* lp for *low pass,* hp for *high pass,* bp for *bandpass,* and br for *bandreject*. Often the letter *f* is added; for example, one might use the acronym brf for *bandreject filter.* The reason for including the transformation in (70.12) is to allow standardization of the lpp. For instance one can transform from an lpp with, say, a passband cutoff frequency of 1 rad/s to a low-pass filter with a passband cutoff of perhaps 1 kHz.

[3]For active realizations — those containing dependent sources — this condition is not necessary.

© 2003 by CRC Press LLC

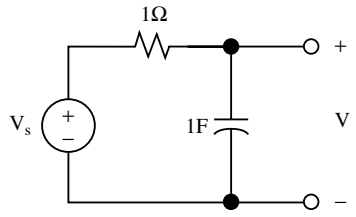

FIGURE 70.3 Low-pass prototype.

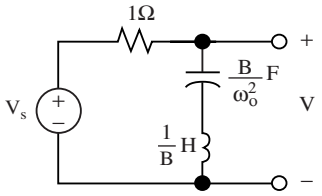

FIGURE 70.4 Resulting bandreject filter.

As a simple example, suppose a bandreject filter were being designed and that the result of the approximation process were

$$H(p) = \frac{1}{p+1} \tag{70.16}$$

Then the br transfer function would be

$$H(s) = \left[H(p)\right]_{p=\left[Bs/\left(s^2+\omega_o^2\right)\right]} = \frac{1}{\dfrac{Bs}{s^2+\omega_o^2}+1} = \frac{s^2+\omega_o^2}{s^2+Bs+\omega_o^2} \tag{70.17}$$

(The parameters ω_o and B would be determined by the bandreject specifications.) As one can readily see, a first-order lpp is transformed into a second-order brf. In general, for bandpass and bandreject design, the object transfer function is of twice the order of the lpp. Since the example is so simple, it can readily be seen that the circuit in Fig. 70.3 realizes the lpp voltage gain function in (70.16). If one applies the transformation in (70.15) the 1-Ω resistor maps into a 1-Ω resistor, but the 1 F capacitor maps into a combination of elements having the admittance

$$Y(p) = p = \frac{1}{\dfrac{s}{B}+\dfrac{\omega_o^2}{Bs}} \tag{70.18}$$

But this is simply the series connection of a capacitor of value B/ω_o^2 farads and an inductor of value $1/B$ henrys. The resulting bandreject filter is shown in Fig. 70.4.

The only remaining "loose end" is the determination of the constant(s) in the appropriate transformation equation selected appropriately from (70.12)–(70.15). This will be done here for the lpp ↔ bp transformation, (70.14). It is typical, and the reader should have no difficulty working out the other cases. Substituting $p = j\Omega$ and $s = j\omega$ in (70.14), one gets

$$j\Omega = \frac{-\omega^2+\omega_o^2}{jB\omega} \tag{70.19}$$

or

$$\Omega = \frac{\omega^2-\omega_o^2}{B\omega} = \frac{\omega}{B} - \frac{\omega_o^2}{B\omega} \tag{70.20}$$

© 2003 by CRC Press LLC

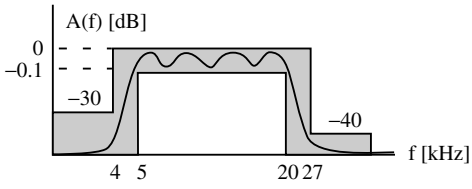

FIGURE 70.5 Bandpass filter specifications.

This clearly shows that $\omega = \pm\omega_o$ maps into $\Omega = 0$ and $\omega = \pm\infty$ into $\Omega = \pm\infty$. However, as $\omega \to 0+$, $\Omega \to -\infty$ and as $\omega \to 0-$, $\Omega \to +\infty$. Of perhaps more interest is the inverse transformation. Solving (70.20) for ω in terms of Ω, one finds that[4]

$$\omega = \frac{B\Omega}{2} + \sqrt{\left[\frac{B\Omega}{2}\right] + \omega_o^2} \tag{70.21}$$

Now, consider pairs of values of Ω, of which one is the negative of the other. Letting ω_+ be the image of Ω with $\Omega > 0$ and $\omega\angle$ be the image of $-\Omega$, one has

$$\omega_+ = \frac{B\Omega}{2} + \sqrt{\left[\frac{B\Omega}{2}\right] + \omega_o^2} \tag{70.22}$$

and

$$\omega_- = \frac{-B\Omega}{2} + \sqrt{\left[\frac{B\Omega}{2}\right] + \omega_o^2} \tag{70.23}$$

Subtracting, one obtains

$$\omega_+ - \omega_- = B\Omega \tag{70.24}$$

$$\omega_+\omega_- = \omega_o^2 \tag{70.25}$$

Thus, the geometric mean of ω_+ and $\omega\angle$ is the parameter ω_o; furthermore, the lpp frequencies Ω = 1 rad/s map into points whose difference is the parameter B. Recalling that $A(\Omega)$ has to be an even function of Ω, one sees that the gain magnitudes at these two points must be identical. If the lpp is designed so that Ω = 1 rad/s is the "bandwidth" (single-sided), then the object bpf will have a (two-sided) bandwidth of B rad/s.

An example should clarify things. Figure 70.5 shows a set of bandpass filter gain specifications. Some slight generality has been allowed over those shown in Fig. 70.2 by allowing the maximum stopband gains to be different in the two stopbands.

The graph is semilog: the vertical axis is linear with a dB scale and the horizontal axis is a log scale (base 10). The –0.1-dB minimum passband gain, by the way, is called the *passband ripple* because actual realized response is permitted to "ripple" back and forth between 0 and –0.1 dB. Notice that the frequency has been specified in terms of kHz — often a practical unit. Equation (70.20), however, can be normalized to any unit without affecting Ω. Thus, by normalizing ω to $2\pi \times 10^3$, one can substitute f in kHz for ω; the parameters ω_o (replaced of f_o symbolically) and B will then be in kHz also.

Now, notice that $5 \times 20 = 100 \neq 4 \times 27 = 108$, so the specifications are not geometrically symmetric relative to any frequency. Somewhat arbitrarily choosing $f_o = \sqrt{5 \times 20} = 10$ kHz, one can force the specifications to have geometric symmetry by the following device: simply reduce the upper stopband

[4]The negative sign on the radical gives $\omega < 0$ and the preceding treatment only considers positive ω.

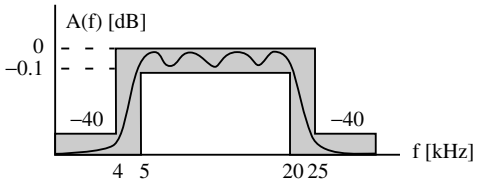

FIGURE 70.6 Bandpass filter specifications.

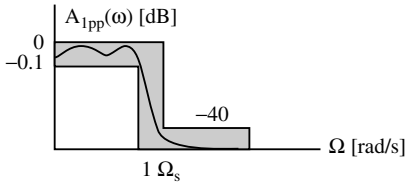

FIGURE 70.7 Bandpass filter specifications.

cutoff frequency from 27 to 25 kHz. Then force the two stopband attenuations to be identical by decreasing the –30-dB lower stopband figure to –40 dB. This results in the modified specifications shown in Fig. 70.6. If one chooses to map the upper and lower passband cutoff frequencies to $\Omega = 1$ rad/s (a quite typical choice, as many filter design catalogs are tabulated under this assumption), one then has

$$B = 20 - 5 = 15 \text{ kHz} \tag{70.26}$$

This fixes the parameters in the transformation and the lpp stopband frequency can be determined from (70.20):

$$\Omega_s = \frac{25^2 - 10^2}{15 \times 25} = \frac{25}{15} - \frac{100}{375} = 1.498 \text{ rad/s} \tag{70.27}$$

The lpp specifications then assume the form shown in Fig. 70.7. Once the lpp approximation problem is solved, one can then transform either the derived transfer function or the synthesized circuit back up to bandpass form since the parameters of the transformation are known.

70.2 The Butterworth LPP Approximation

For performing lpp approximations, it is more convenient to work with the *characteristic function* $k(\omega)$ than with the gain function. It is defined by the equation

$$A^2(\omega) = \frac{1}{1 + K^2(\omega)} \tag{70.28}$$

Although Ω was used in the last subsection to denote lpp frequency, the lower case ω is used here and throughout the remainder of the section. No confusion should result because frequency will henceforth always mean lpp frequency. The main advantage in using the characteristic function is simply that it approximates zero over any frequency interval for which the gain function approximates unity. Further, it becomes infinitely large when the gain becomes zero. These ideas are illustrated in Fig. 70.8. Notice that $K(\omega)$ can be either positive or negative in the passband for it is squared in the defining equation. The basic problem in lpp filter approximation is therefore to find a characteristic function that approximates zero in the passband, approximates infinity in the stopband, and makes the transition from one to the other rapidly. Ideally, it would be exactly zero in the passband, then become abruptly infinity for frequencies in the stopband.

© 2003 by CRC Press LLC

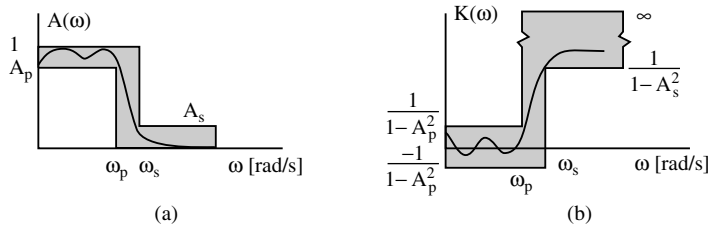

FIGURE 70.8 Filter specifications in terms of the characteristic function: (a) gain, (b) characteristic function.

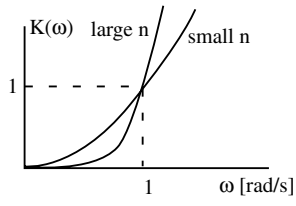

FIGURE 70.9 The Butterworth characteristic function.

The *n*th-order Butterworth approximation is defined by

$$K(\omega) = \omega^n \tag{70.29}$$

This characteristic function is sketched in Fig. 70.9 for two values of n — one small and the other large. As is easily seen, the larger order provides a better approximation to the idea "brick wall" lpp response. Notice, however, that $K(1) = 1$ regardless of the order; hence $A(1) = 0.5$ (–3 dB) regardless of the order.

It is conventional to define the *loss function* $H(s)$ to be reciprocal of the gain function:

$$H(s) = \frac{1}{G(s)} \tag{70.30}$$

Letting $s = j\omega$ and applying (70.28) results in

$$\left|H(j\omega)\right|^2 - K^2(\omega) = 1 \tag{70.31}$$

which is one form of *Feldtkeller's equation*, a fundamental equation in the study of filters. The loss approximates unity wherever the characteristic function approximates zero and infinity when the latter approximates infinity.

The loss function can be used to illustrate a striking property of the Butterworth approximation. Taking the kth derivative of (70.31), one has

$$\frac{d^k\left|H(j\omega)\right|^2}{d\omega^k} = \frac{d^k K^2(\omega)}{d\omega^k} = \frac{d^k\omega^{2n}}{d\omega^k} = \frac{(2n)!}{k!}\omega^{2n-k} \tag{70.32}$$

This has the value zero at $\omega = 0$ for $k \le 2n - 1$. It is the unique polynomial having this property among the set of all monic[5] polynomials of order $2n$ or lower having the value zero at the origin. But this means that the square of the Butterworth characteristic function $K(\omega)$ is the flattest of all such polynomials at $\omega = 0$. Since adding one to $K^2(\omega)$ produces the loss function $|H(j\omega)|^2$, the same is true of it relative to

[5]A monic polynomial is one where the leading coefficient (highest power of ω) is unity.

© 2003 by CRC Press LLC

the set of all loss functions having the value unity at the origin. For this reason, the Butterworth approximation is often called the *maximally flat magnitude* (or MFM) approximation.

The passband ripple parameter A_p is always $1/\sqrt{2}$ for a Butterworth lpp; note that if a different ripple parameter is desired, one must treat the corresponding filter as a general low-pass filter, then apply (65.12) in the introduction to Chapter 65. The value of the parameter in that frequency transformation is determined by the requirement that the frequency at which the desired filter assumes the value $1/\sqrt{2}$ map into a lpp passband frequency of 1 rad/s. The required order is determined from the equation

$$\frac{1}{\sqrt{1+\omega_s^{2n}}} \leq A_s \tag{70.33}$$

or, rearranged,

$$n \geq \frac{\log\left[\dfrac{1}{A_s^2}-1\right]}{2\ \log(\omega_s)} \tag{70.34}$$

The value of n is, of course, chosen to be the smallest integer greater than the expression on the right-hand side of (70.34).

Since only one parameter is in the Butterworth approximation, (70.34) completely determines $A(\omega)$. That is, the MFM is a one-parameter approximation. The only remaining item of concern is the determination of $G(s)$, for synthesis of the actual filter requires knowledge of the transfer function. As was pointed out in the last subsection, this is the factorization problem. In general, the solution is given by (70.5), repeated here for convenience as (70.35):

$$G(s)G(-s) = A^2(-s^2) \tag{70.35}$$

In the present case, we have

$$G(s)G(-s) = \frac{1}{1+(-s^2)^n} = \frac{1}{1+(-1)^n s^{2n}} \tag{70.36}$$

How does one find $G(s)$ from this equation? The solution merely lies in applying the restriction that the resulting filter is to be stable. This means that the poles of $G(s)G(-s)$ that lie in the right-half plane must be discarded and the remaining ones assigned to $G(s)$. In this connection, observe that any poles on the imaginary axis must be off even multiplicity since $G(s)G(-s)$ is an even function (or, equivalently, since $A^2(\omega^2) = |G(j\omega)|^2$ is nonnegative). Furthermore, any even-order poles of $G(s)G(-s)$ on the imaginary axis could only result from one or more poles of $G(s)$, itself, at the same location. But such a $G(s)$ represents a filter that is undesirable because, at best, it is only marginally stable. As will be shown, this situation does not occur for Butterworth filters.

The problem now is merely to find all the poles of $G(s)G(-s)$, then to sort them. These poles are located at the zeros of the denominator in (70.36). Thus, one must solve

$$1+(-s^2)^n = 0 \tag{70.37}$$

or, equivalently,

$$s^{2n} = (-1)^{n-1} \tag{70.38}$$

© 2003 by CRC Press LLC

Representing s in polar coordinates by

$$s = \rho e^{j\phi} \tag{70.39}$$

one can write (70.38) in the form

$$\rho^{2n} e^{j2n\phi} = e^{j(n-1)\pi} \tag{70.40}$$

This has the solution

$$\rho = 1 \tag{70.41}$$

and

$$\phi = \frac{\pi}{2} + (2k-1)\frac{\pi}{2n} \tag{70.42}$$

where k is any integer. Of course, only those values of ϕ between 0 and 2π radians are to be considered unique.

As an example, suppose that $n = 2$; that is, one is interested in determining the transfer function of a second-order Butterworth filter. Then the unique values of ϕ determined from (70.42) are $\pi/4$, $3\pi/4$, $5\pi/4$, and $7\pi/4$. All other values are simply these four with integer multiples of 2π added. The last two represent poles in the right-half plane, so are simply discarded. The other two correspond to poles at $s = -0.707 \pm j0.707$. Letting $D(s)$ be the numerator polynomial of $G(s)$, then, one has

$$D(s) = s^2 + \sqrt{2}s + 1 \tag{70.43}$$

The poles of $G(s)G(-s)$ are sketched in Fig. 70.10. Notice that if one assigns the left-half plane poles to $G(s)$, then those in the right-half plane will be those of $G(-s)$.

Perhaps another relatively simple example is in order. To this end, consider the third-order Butterworth transfer function: $n = 3$. In this case, the polar angles of the poles of $G(s)$ are at $\pi/3$, $2\pi/3$, π, $4\pi/3$, $5\pi/3$, and 2π. This pole pattern is shown in Fig. 70.11. The denominator polynomial corresponds to those in the left-half plane. It is

$$D(s) = (s+1)(s^2 + s + 1) = s^3 + 2s^2 + 2s + 1 \tag{70.44}$$

The pattern for the general nth order case is similar — all the poles of $G(s)G(-s)$ lie on the unit circle and are equally spaced at intervals of π/n radians, but are offset by $\pi/2$ radians relative to the positive real axis. A little thought will convince one that this means that no poles ever fall on the imaginary axis.

The factorization procedure determines the denominator polynomial in $G(s)$. But what about the numerator? Since the characteristic function is a polynomial, it is clear that $G(j\omega)$ — and hence $G(s)$ itself — will have a constant numerator. For this reason, the Butterworth approximation is referred to as an *all-pole* filter. Sometimes it is also called a *polynomial* filter, referring to the fact that the characteristic function is a polynomial. As was mentioned earlier, the constant is usually allowed to float freely in the

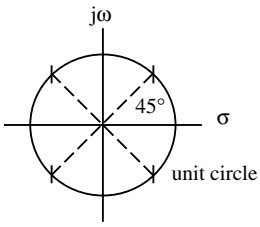

FIGURE 70.10 Poles of the second-order Butterworth transfer function.

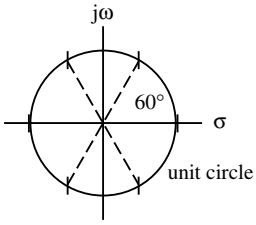

FIGURE 70.11 Poles of the third-order Butterworth transfer function.

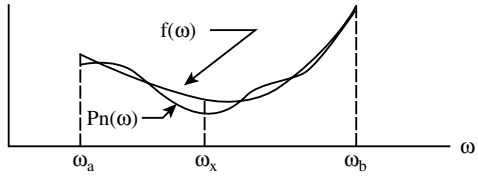

FIGURE 70.12 The minimax error criterion.

synthesis process and is determined only at the conclusion of the design process. However, more can be said. Writing

$$G(s) = \frac{a}{D(s)} \tag{70.45}$$

one can apply (70.36) to show that $a^2 = 1$, provided that $|G(0)|$ is to be one, as is the case for the normalized lpp. This implies that

$$a = \pm 1 \tag{70.46}$$

If a passive unbalanced (grounded) filter is desired the positive sign must be chosen. Otherwise, one can opt for either.

70.3 The Chebyshev LPP Approximation

The main advantage of the Butterworth approximation is that it is simple. It does not, however, draw upon the maximum approximating power of polynomials. In fact, a classical problem in mathematics is to approximate a given continuous function on a closed bounded interval with a polynomial of a specified maximum degree. One can choose to define the error of approximation in many ways, but the so-called *minimax* criterion seems to be the most suitable for filter design. It is the minimum value, computed over all polynomials of a specified maximum degree, of the maximum difference between the polynomial values and those of the specified function. This is illustrated in Fig. 70.12. The minimax error in this case occurs at ω_x. It is the largest value of the magnitude of the difference between the function values $f(\omega)$ and those of a given candidate polynomial $p_n(\omega)$. The polynomial of best fit is the one for which this value is the smallest.

The basic lpp approximation problem is to pick the characteristic function to be that polynomial of a specified maximum degree no more than, say, n, which gives the smallest maximum error of approximation *to the constant value* 0 over the interval $0 \le \omega \le 1$ (arbitrarily assuming that the passband cutoff is to be 1 rad/s). In this special case, the solution is known in closed form: it is the Chebyshev[6] polynomial of degree n. Then, $K(\omega)$ is polynomial $\varepsilon T_n(\omega)$, where

[6]If the name of the Russian mathematician is transliterated from the French, in which the first non-Russian translations were given, it is spelled Tchebychev.

© 2003 by CRC Press LLC

$$T_n(\omega) = \cos\left[n\cos^{-1}(\omega)\right] \tag{70.47}$$

and ε is the minimax error (a constant).

It is perhaps not clear that $T_n(\omega)$ is actually a polynomial; however, upon computing the first few by applying simple trigonometric identities one has the results shown in Table 70.1. In fact, again by calling upon simple trigonometric identities, one can derive the general recurrence relation

TABLE 70.1

n	$T_n(\omega)$
0	1
1	ω
2	$2\omega^2 - 1$
3	$4\omega^3 - 3\omega$
4	$8\omega^4 - 8\omega^2 + 1$

$$T_n(\omega) = 2\omega T_{n-1}(\omega) - T_{n-2}(\omega); \qquad n \geq 2 \tag{70.48}$$

The Chebyshev polynomials have an enormous number of interesting properties and to explore them all would require a complete monograph. Among those of the most interest for filtering applications, however, are these. First, from the recursion relationship (70.48) one can see that $T_n(\omega)$ is indeed a polynomial of order n; furthermore, its leading coefficient is 2^{n-1}. If n is even, $T_n(\omega)$ is an even polynomial in ω and if n is odd, $T_n(\omega)$ is an odd polynomial. The basic definition in (70.47) clearly shows that the extreme values of $T_n(\omega)$ over the interval $0 \leq \omega \leq 1$ are ±1. Some insight into the behavior of the Chebyshev polynomials can be obtained by making the transformation $\phi = \cos^{-1}(\omega)$. Then, $T_n(\phi) = \cos(n\phi)$, a trigonometric function that is quite well known. The behavior of T_{15}, for example, is shown in Fig. 70.13. The basic idea is this: the Chebyshev polynomial of nth order is merely a cosine of "frequency" $n/4$, which "starts" at $\omega = 1$ and "runs backward" to $\omega = 0$. Thus, it is always 1 at $\omega = 1$ and — as ω goes from 1 rad/s to 0 rad/s backward, it goes through n quarter-periods (or $n/4$ full periods). Thus, at $\omega = 0$ the value of this polynomial will be either 0 or ±1, depending upon the specific value of n. If n is even, an integral number of half-periods will have been described and the resulting value will be ±1; if n is odd, an integral number of half-periods plus a quarter-period will have been described and the value will be zero.

Based on the foregoing theory, one sees that the best approximation to the ideal lpp characteristic over the passband is, for a given passband tolerance, ε, given by

$$A^2(\omega) = \frac{1}{1 + \varepsilon^2 T_n^2(\omega)} \tag{70.49}$$

It is, of course, known as the Chebyshev approximation and the resulting filter as the Chebyshev lpp of order n. The gain magnitude $A(\omega)$ is plotted for $n = 5$ and $\varepsilon = 0.1$ in Fig. 70.14. The passband behavior looks like ripples in a container of water, and since the crests are equally spaced above and below the average value, it is called **equiripple** behavior. In the passband, the maximum value is 1 and the minimum value is

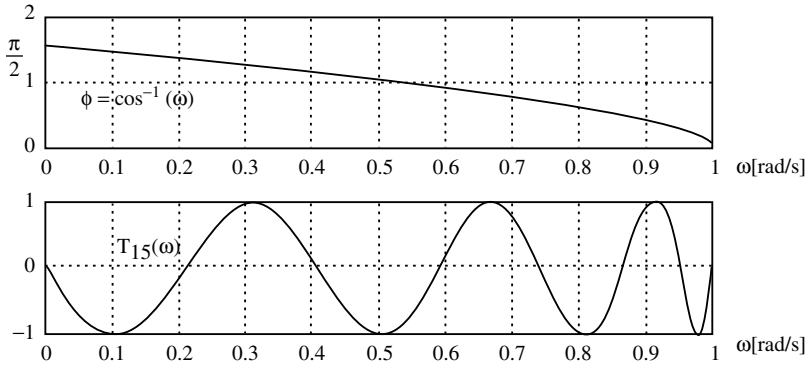

FIGURE 70.13 Behavior of the Chebyshev polynomials.

© 2003 by CRC Press LLC

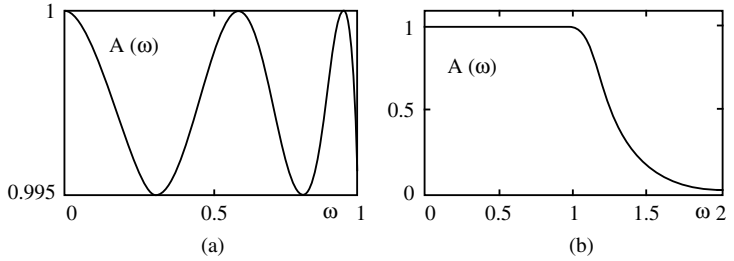

FIGURE 70.14 Frequency response of a fifth-order Chebyshev lpp: (a) passband, (b) overall.

$$A_{\min} = \frac{1}{\sqrt{1+\varepsilon^2}} \tag{70.50}$$

The passband ripple is usually specified as the peak to peak variation in dB. Since the maximum value is one, that is 0 dB, this quantity is related to the *ripple parameter* ε through the equation

$$\text{passband ripple in dB} = 20 \log \sqrt{1+\varepsilon^2} \tag{70.51}$$

The Chebyshev approximation is the best possible among the class of all-pole filters — *over the passband*. But what about its stopband behavior? As was pointed out previously, it is desirable that — in addition to approximating zero in the passband — the characteristic function should go to infinity as rapidly as possible in the stopband. Now it is a happy coincidence that the Chebyshev polynomial goes to infinity for $\omega > 1$ faster than any other polynomial of the same order. Thus, the Chebyshev approximation is the best possible among the class of polynomial, or all-pole, filters.

The basic definition of the Chebyshev polynomial works fine for values of ω in the passband, where $\omega \le 1$. For larger values of ω, however, $\cos^{-1}(\omega)$ is a complex number. Fortunately, there is an alternate form that avoids complex arithmetic. To derive this form, simply recognize the complex nature of $\cos^{-1}(\omega)$ explicitly and write

$$x = \cos^{-1}(\omega) \tag{70.52}$$

One then has[7]

$$\omega = \cos(x) = \cos[j(jx)] = \cosh(jx) \tag{70.53}$$

so

$$jx = \cosh^{-1}(\omega) \tag{70.54}$$

Thus, one can also write

$$T_n(\omega) = \cos[jn(jx)] = \cosh[n(jx)] = \cosh[n\ \cosh^{-1}(\omega)] \tag{70.55}$$

This result is used to compute the required filter order. Assuming as usual that A_s is the maximum allowed stopband gain, one uses the square root of (70.49) to get

$$A(\omega_s) = \frac{1}{\sqrt{1+\varepsilon^2 T_n^2(\omega_s)}} \le A_s \tag{70.56}$$

[7]Since $\cos(x) = \cosh(jx)$.

© 2003 by CRC Press LLC

Solving, one has

$$T_n(\omega_s) \geq \frac{1}{\varepsilon}\sqrt{\frac{1}{A_s^2}-1} \tag{70.57}$$

Since $\omega_s \geq 1$, it is most convenient to use the hyperbolic form in (70.55):

$$n \geq \frac{\cosh^{-1}\left[\frac{1}{\varepsilon}\sqrt{\frac{1}{A_s^2}-1}\right]}{\cosh^{-1}(\omega_s)} \tag{70.58}$$

To summarize, one first determines the parameter ε from the allowed passband ripple, usually using (70.51); then one determines the minimum order required using (70.58). The original filter specifications must, of course, be mapped into the lpp domain through appropriate choice(s) of the constant(s) in the transformation equations (70.12)–(70.15). Notice that the definition of passband for the Chebyshev filter differs from that of the Butterworth unless the passband ripple is 3 dB. For the Chebyshev characteristic, the passband cutoff frequency is that frequency at which the gain goes through the value $1/\sqrt{1+\varepsilon^2}$ for the last time as ω increases.

The only remaining item is the determination of the transfer function $G(s)$ by factorization. Again, this requires the computation of the poles of $G(s)G(-s)$. Using (70.49), one has

$$G(s)G(-s) = \left[A^2(\omega)\right]_{s=j\omega} = \frac{1}{1+\varepsilon^2\left[T_n^2(\omega)\right]_{s=j\omega}} \tag{70.59}$$

Thus, the poles are at those values of s for which

$$\left[T_n^2(\omega)\right]_{s=j\omega} = \frac{-1}{\varepsilon^2} \tag{70.60}$$

or[8]

$$\cos\left[n\ \cos^{-1}\left(\frac{s}{j}\right)\right] = \pm j\frac{1}{\varepsilon} \tag{70.61}$$

Letting

$$\cos^{-1}(s/j) = a + jb, \text{ there results} \tag{70.62}$$

$$\cos(na)\cosh(nb) - j\sin(na)\sinh(nb) = \pm j\frac{1}{\varepsilon} \tag{70.63}$$

Equating real and imaginary parts, one has

$$\cos(na)\cos(nb) = 0 \tag{70.64a}$$

and

[8]Since s is complex anyway, nothing is to be gained from using the hyperbolic form.

© 2003 by CRC Press LLC

$$\sin(na)\sinh(nb) = \pm\frac{1}{\varepsilon} \tag{70.64b}$$

Since $\cosh(nb) > 0$ for any b, one must have

$$\cos(na) = 0 \tag{70.65}$$

which can hold only if

$$a = (2k+1)\frac{\pi}{2n};\ k \text{ any integer} \tag{70.66}$$

But, in this case, $\sin[(2k+1)\pi/2] = \pm 1$, so application of (70.64b) gives

$$\sinh(nb) = \pm\frac{1}{\varepsilon} \tag{70.67}$$

One can now solve for b:

$$b = \pm\frac{1}{n}\sinh^{-1}\left[\frac{1}{\varepsilon}\right] \tag{70.68}$$

Equations (70.66) and (70.68) together determine a and b, hence $\cos^{-1}(s/j)$. Taking the cosine of both sides of (70.62) and using (70.65) and (70.68) gives

$$\begin{aligned} s = &\pm\sin\left[(2k+1)\frac{\pi}{2n}\right]\sinh\left(\frac{1}{n}\sinh^{-1}\left[\frac{1}{\varepsilon}\right]\right) \\ &+ j\cos\left[(2k+1)\frac{\pi}{2n}\right]\cosh\left(\frac{1}{n}\sinh^{-1}\left[\frac{1}{\varepsilon}\right]\right) \end{aligned} \tag{70.69}$$

Letting $s = \sigma + j\omega$ as usual, one can rearrange (70.69) into the form

$$\left[\frac{\sigma}{\sinh\left[\frac{1}{n}\sinh^{-1}\left[\frac{1}{\varepsilon}\right]\right]}\right]^2 + \left[\frac{\omega}{\cosh\left[\frac{1}{n}\sinh^{-1}\left[\frac{1}{\varepsilon}\right]\right]}\right]^2 = 1 \tag{70.70}$$

which is the equation of an ellipse in the s-plane with real axis intercepts of

$$\sigma_o = \pm\sinh\left[\frac{1}{n}\sinh^{-1}\left[\frac{1}{\varepsilon}\right]\right] \tag{70.71}$$

and imaginary axis intercepts of

$$\omega_o = \pm\cosh\left[\frac{1}{n}\sinh^{-1}\left[\frac{1}{\varepsilon}\right]\right] \tag{70.72}$$

This is shown in Fig. 70.15.

© 2003 by CRC Press LLC

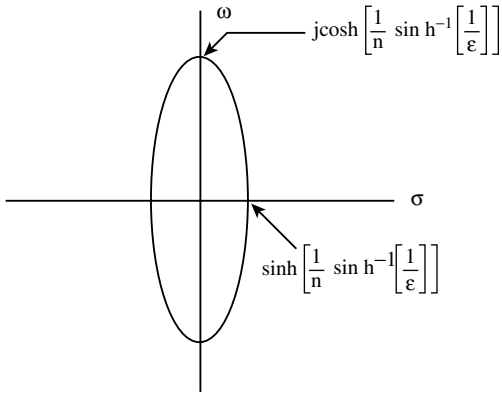

FIGURE 70.15 Pole locations for $G(s)G(-s)$ for the Chebyshev filter.

As an example, suppose that a Chebyshev lpp is to be designed that has a passband ripple of 0.1 dB, a maximum stopband gain of –20 dB, and $\omega_s = 2$ rad/s. Then, one can use (70.51) to find[9] the ripple parameter ε:

$$\varepsilon = \sqrt{10^{0.1/10} - 1} = 0.1526 \tag{70.73}$$

Equation (70.58) gives the minimum order required:

$$n \geq \frac{\cosh^{-1}\left[\dfrac{1}{0.1526}\sqrt{\dfrac{1}{(0.1)^2} - 1}\right]}{\cosh^{-1}(2)} = \frac{\cosh^{-1}(65.20)}{\cosh^{-1}(2)} = 3.70 \tag{70.74}$$

In doing this computation by hand, one often uses the identity

$$\cosh^{-1}(x) = \ln\left[x + \sqrt{x^2 - 1}\right] \tag{70.75}$$

which can be closely approximated by

$$\cosh^{-1}(x) = \ln(2x) \tag{70.76}$$

if $x \gg 1$. In the present case, a fourth-order filter is required. The poles are shown in Table 70.2 and graphed in Fig. 70.16.

By selecting the left-half plane poles and forming the corresponding factors, then multiplying them, one finds the denominator polynomial of $G(s)$ to be

$$D(s) = s^4 + 1.8040s^3 + 2.2670s^2 + 2.0257s + 0.8286 \tag{70.77}$$

As for the Butterworth example of the last subsection, one finds the scale factor:

$$k = 0.8286 \tag{70.78}$$

Therefore, the complete transfer function is

[9]For practical designs, a great deal of precision is required for higher-order filters.

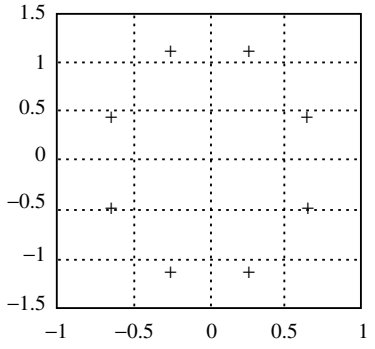

FIGURE 70.16 Pole locations for example filter.

$$G(s) = \frac{k}{D(s)} = \frac{0.8286}{s^4 + 1.8040s^3 + 2.2670s^2 + 2.0257s + 0.8286} \tag{70.79}$$

Of course, if completely automated algorithms are not being used to design such a filter as the one in our example, numerical assistance is required. The computation in the preceding example was performed in MATLAB — a convenient package for many computational problems in filter design.

70.4 The Bessel–Thompson LPP Approximation

Thus far, two all-pole approximations have been presented. As was pointed out in the preceding subsection, the Chebyshev is better than the Butterworth — in fact, it is the best all-pole approximation available. So why bother with the Butterworth at all, other than as an item of historical interest? The answer lies in the phase. The Chebyshev filter has a phase characteristic that departs farther from linearity than that of the Butterworth; put differently, its group delay deviates from a constant by a greater amount. Thus, the Butterworth approximation is still a viable approximation in applications where phase linearity is of some importance.

The question naturally arises as to whether there is an lpp approximation that has better phase characteristics than that of the Butterworth. The answer is yes, and that is the topic of this section, which will follow [7] — perhaps the simplest development of all.

Recall that the gain function $G(s)$ is the inversion of the loss function $H(s)$:

$$G(s) = \frac{1}{H(s)} \tag{70.80}$$

Also, recall that it was the loss function $|h(j\omega)| = 1/A(\omega)$ (or, rather, its square $|h(j\omega)|^2$) that was required to have the maximally flat magnitude (MFM) property: at $\omega = 0$,

© 2003 by CRC Press LLC

$$\left[\frac{d^k\left|H(j\omega)\right|^2}{d\omega^k}\right]_{\omega=0} = \left[\frac{d^k\omega^{2n}}{d\omega^k}\right]_{\omega=0} = \left[\frac{(2n)!}{k!}\omega^{2n-k}\right]_{\omega=0} = 0 \tag{70.81}$$

for $k = 0, 1, \ldots, 2n-1$. The question to be asked and answered in this section is whether there exists a similar approximation for the group delay $\tau_g(\omega)$: a maximally flat delay (MFD) approximation.

To answer this question, the phase will be written in terms of the loss function $H(j\omega)$. Since the latter quantity can be written in polar form as

$$H(j\omega) = \frac{1}{G(j\omega)} = \frac{1}{A(\omega)e^{j\phi(\omega)}} = \frac{1}{A(\omega)}e^{-j\phi(\omega)} \tag{70.82}$$

the (complex) logarithm is

$$\ln H(j\omega) = -\ln A(\omega) - j\phi(\omega) \tag{70.83}$$

Thus,

$$\phi(\omega) = -\mathrm{Im}\left\{\ln H(j\omega)\right\} \tag{70.84}$$

The group delay is merely the negative of the derivative of the phase, so one has

$$\begin{aligned}\tau_g(\omega) &= -\frac{d\phi}{d\omega} = \frac{d}{d\omega}\mathrm{Im}\left\{\ln H(j\omega)\right\} = \mathrm{Im}\left\{\frac{d}{d\omega}\ln H(j\omega)\right\} \\ &= \mathrm{Im}\left\{j\frac{d}{d(j\omega)}\ln H(j\omega)\right\} = \mathrm{Re}\left\{\frac{d}{d(j\omega)}\ln H(j\omega)\right\}\end{aligned} \tag{70.85}$$

Recalling that the even part of a complex function $F(s)$ is given by

$$Ev\left\{F(s)\right\} = \frac{F(s)+F(-s)}{2} \tag{70.86}$$

one can use the symmetry property for real $F(s)$ (in the present context, $F(s)$ is assumed to be a rational function, so a real $F(s)$ is one with real coefficients) to show that

$$Ev\left\{F(s)\right\}_{s=j\omega} = \frac{F(j\omega)+F(-j\omega)}{2} = \frac{F(j\omega)+F^*(j\omega)}{2} = \mathrm{Re}\left\{F(j\omega)\right\} \tag{70.87}$$

In this manner, one can analytically extend the group delay function $\tau_g(j\omega)$ so that it becomes a function of s:

$$\tau_g(s) = Ev\left\{\frac{d}{ds}\ln H(s)\right\} = Ev\left[\frac{H'(s)}{H(s)}\right] = \frac{1}{2}\left[\frac{H'(s)}{H(s)} + \frac{H'(-s)}{H(-s)}\right] \tag{70.88}$$

In the present case, it will be assumed that $H(s)$ is a polynomial. In this manner, an all-pole (or polynomial) filter will result. Thus, one can write

$$H(s) = \sum_{k=0}^{n} a_k^n s^k \tag{70.89}$$

© 2003 by CRC Press LLC

The superscript on the (assumed real) coefficient matches the upper limit on the sum and is the assumed filter order. The group delay function is, thus, a real rational function:

$$\tau_g(s) = \frac{N(s)}{D(s)} \tag{70.90}$$

where $N(s)$, the numerator polynomial, and $D(s)$, the denominator polynomial, have real coefficients and are of degrees no greater than $2n - 1$ and $2n$, respectively, by inspection of (70.88). But, again according to (70.88), $\tau_g(s)$ is an even function. Thus,

$$\tau_g(-s) = \frac{N(-s)}{D(-s)} = \tau_g(s) = \frac{N(s)}{D(s)} \tag{70.91}$$

The last equation, however, implies that

$$\frac{N(-s)}{N(s)} = \frac{D(-s)}{D(s)} = 1 \tag{70.92}$$

The last equality is arrived at by the following reasoning. $N(s)$ and $D(s)$ are assumed to have no common factors — any such have already been cancelled in the formation of $\tau_g(s)$. Thus, the two functions of s in (70.92) are independent; since they must be equal for s, they must therefore equal a constant. But this constant is unity, as is easily shown by allowing s to become infinite and noting that the degrees and leading coefficients of $N(-s)$ and $N(s)$ are the same.

The implication of the preceding development is simply that $N(s)$ and $D(s)$ consist of only even powers of s. Looking at $N(s)$, for example, and letting it be written

$$N(s) = \sum_{k=0}^{2n-1} \rho_k s^k \tag{70.93}$$

one has

$$N(-s) = \sum_{k=0}^{2n-1} \rho_k (-s)^k = N(s) = \sum_{k=0}^{m} \rho_k (s)^k \tag{70.94}$$

This, however implies that the ρ_k are zero for odd k. Hence $N(s)$ consists of only even powers of s. The same is true of $D(s)$ and therefore of $\tau_g(s)$. Clearly, therefore $\tau_g(\omega)$ will consist of only even powers of ω — that is, it will be a function of ω^2. Now there is to be an MFD approximation one must have by analogy with the MFM approximation in the section on the Butterworth LPP approximation,

$$\frac{d^k \tau_g(\omega)}{d(\omega^2)^k} = 0 \tag{70.95}$$

for $k = 1, 2, \ldots, n - 1$. The constraint is, of course, that τ_g must come from a polynomial loss function $H(s)$ whose zeros [poles of $G(s)$] all lie in the left-half plane.

It is convenient to normalize time so that the group delay T, say, at $\omega = 0$ is 1 second; this is equivalent to scaling the frequency variable ω to be ωT. Here, it will be assumed that this has been performed already already. A slight difference exists between the MFD and MFM approximations; the latter approximates zero at $\omega = 0$, while the former approximates $T = 1s$ at $\omega = 0$. The two become the same, however, if one considers the function

© 2003 by CRC Press LLC

$$\tau_g(s) - 1 = \frac{P(s)}{2H(s)H(-s)} \tag{70.96}$$

where $P(s)$ has a maximum order of $2n$. The form on the right-hand side of this expression can be readily verified by consideration of (70.88), the basic result for the following derivation. Furthermore, writing $P(s)$ in the form

$$P(s) = \sum_{k=0}^{n} P_k\left(s^2\right)^k \tag{70.97}$$

it is readily seen that

$$p_o = p_1 = \cdots = p_{n-1} = 0 \tag{70.98}$$

The lowest-order coefficient is clearly zero because $\tau_g(0) = 1$; furthermore, all odd coefficients are zero since τ_g is even. Finally, all other coefficients in (70.98) have to be zero if one imposes the MFD condition in (70.95).[10]

At this stage, one can write the group delay function in the form

$$\tau_g(s) = \frac{N(s)}{D(s)} = 1 + \frac{p_n s^{2n}}{2H(s)H(-s)} = \frac{2H(s)H(-s) + p_n s^{2n}}{2H(s)H(-s)} \tag{70.99}$$

It was pointed out immediately after (70.90), however, that the degree of $N(s)$ is at most $2n - 1$. Hence, the coefficient of s^{2n} in the numerator of (70.99) have vanish, and one therefore also has

$$2(-1)^n a_n + p_n = 0 \tag{70.100}$$

or, equivalently,

$$p_n = 2(-1)^{n+1} a_n \tag{70.101}$$

Finally, this allows one to write (70.99) in the form

$$\tau_g(s) = \frac{H(s)H(-s) + (-1)^{n+1} a_n s^{2n}}{H(s)H(-s)} \tag{70.102}$$

If one now equates (70.102) and (70.88) and simplifies, there results

$$H'(s)H(-s) + H'(-s)H(s) - 2H(s)H(-s) = 2(-1)^{n+1} a_n s^{2n} \tag{70.103}$$

Multiplying both sides by s^{-2n}, taking the derivative (noting that $(d/ds)H(-s) = -H'(-s)$, one obtains (after a bit of algebra)

$$Ev\left\{\left[sH''(s) - 2(s+n)H'(s) + 2nH(s)\right]H(-s)\right\} = 0 \tag{70.104}$$

[10]The derivatives are easy to compute, but this is omitted here for reasons of space.

© 2003 by CRC Press LLC

Now, if s_o is a zero of this even function, the $-s_o$ will also be a zero. Further, since all of the coefficients in $H(s)$ are real, s_o^* and $-s_o^*$ must also be zeros as well; that is, the zeros must occur in a *quadrantally symmetric* manner. Each zero must belong either to $H(-s)$, or to the factor it multiplies, or to both. The degree of the entire expression in (70.40) is $2n$ and $H(-s)$ has n zeros. Thus, the expression in square brackets must have n zeros. Now here is the crucial step in the logic: if the filter being designed is to be stable, then all n zeros $H(-s)$ must be in the (open) right-half plane. This implies that the factor in square brackets must have n zeros in the (open) left-half plane. Since the expression has degree n, these zeros can be found from the equation

$$sH''(s) - 2(s+n)H'(s) + 2nH(s) = 0 \tag{70.105}$$

This differential equation can be transformed into that of Bessel; here, however, the solution will be derived directly by recursion. Using (70.89) for $H(s)$, computing its derivatives, reindexing, and using (70.105), one obtains, for $0 \le k \le n-1$,

$$(k+1)ka_{k+1}^n - 2n(k+1)a_{k+1}^n - 2ka_k^n + 2na_k^n = 0 \tag{70.106}$$

This produces the recursion formula

$$a_{k+1}^n = \frac{2(n-k)}{(2n-k)(k+1)}a_k^n; \qquad 0 \le k \le n-1 \tag{70.107}$$

or, normalizing the one free constant so that $a_n^n = 1$ and reindexing, gives

$$a_{k+1}^n = \frac{2(n-k)}{(2n-k)(k+1)}; \qquad 0 \le k \le n-1 \tag{70.108}$$

The resulting polynomials for $H(s)$ are closely allied with the Bessel polynomials. The first several are given in Table 70.3 and the corresponding gain and group delay characteristics are plotted (using MATLAB) in Fig. 70.17. Notice that the higher the order, the more accurately the group delay approximates a constant and the better the gain approximates the ideal lpp; the latter behavior, however, is fairly poor. A view of the group delay behavior in the passband is shown for the third-order filter in Fig. 70.18.

TABLE 70.3

n	$H(s)$
1	$s + 1$
2	$s^2 + 3s + 3$
3	$s^3 + 6s^2 + 15s + 15$
4	$s^4 + 10s^3 + 45s^2 + 105s + 105$

70.5 The Elliptic Approximation

The Butterworth approximation provides a very fine approximation to the ideal "brick wall" lpp response at $\omega = 0$, but is poor for other frequencies; the Chebyshev, on the other hand, spreads out the error of approximation throughout the passband and thereby achieves a much better amplitude approximation. This is one concrete application of a general result in approximation theory known as the Weierstrass theorem [2], which asserts the possibility of uniformly approximating a continuous function on a compact set by a polynomial or by a rational function.

A compact set is the generalization of a closed and bounded interval — the setting for the Chebyshev approximation sketched in Fig. 70.19. The compact set is the closed interval $[-1, 1]$,[11] the continuous function to be approximated is the constant 0, and the approximating function is a polynomial of degree n (in the figure n is three). A careful inspection of this figure reveals that the maximum error of approximation

[11]Here, we are explicitly observing that the characteristic function to be approximated is even in ω.

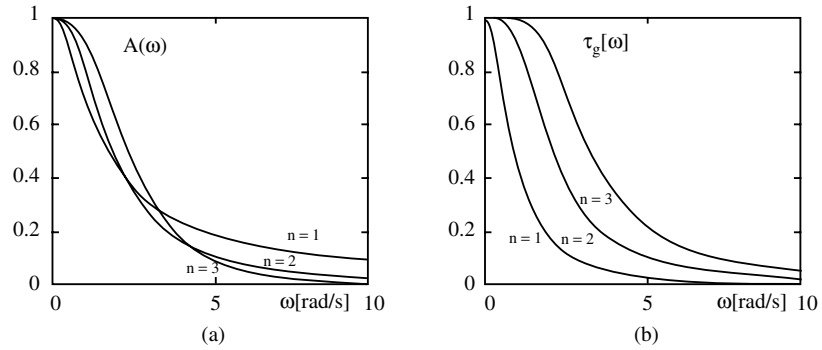

FIGURE 70.17 Gain and group delay characteristics for the Bessel–Thompson filters of orders one through three: (a) gain, (b) group delay.

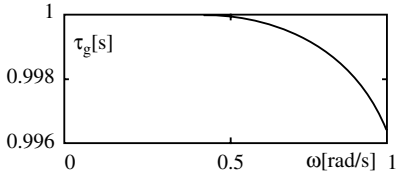

FIGURE 70.18 Group delay of third-order Bessel filter.

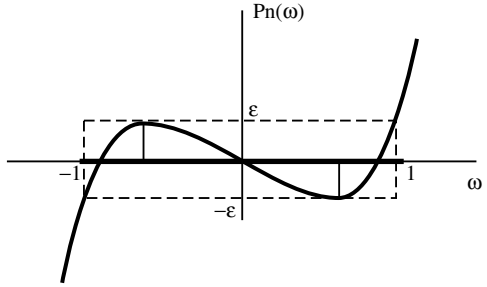

FIGURE 70.19 Chebyshev approximation.

occurs exactly four times on a set of four discrete points within the interval and the *sign* of this maximum error alternates from one such point to its adjacent neighbor. This is no coincidence; in fact, the polynomial of best approximation of degree n is characterized by this alternation or *equiripple* property: the error function achieves its maximum value exactly $n + 1$ times on the interval of approximation and the signs at these points alternate. If one finds a polynomial by any means that has this property it is the unique polynomial of best approximation.

In the present case, one simply notes that the cosine function has the required equiripple behavior. That is, as ϕ varies between $-\pi/2$ and $\pi/2$, $\cos(n\phi)$ varies between its maximum and minimum values of ± 1 a total of $n + 1$ times. But $\cos(n\phi)$ is not a polynomial, and the problem (for reasons stated in the introduction) is to determine a *polynomial* having this property. At this point, one observes that if one makes the transformation

$$\phi = \cos^{-1}(\omega) \tag{70.109}$$

then, as ω varies from -1 to $+1$, ϕ varies from $-\pi/2$ to $+\pi/2$. This transformation is, fortunately, one-to-one over this range; furthermore, even more fortunately, the overall function

© 2003 by CRC Press LLC

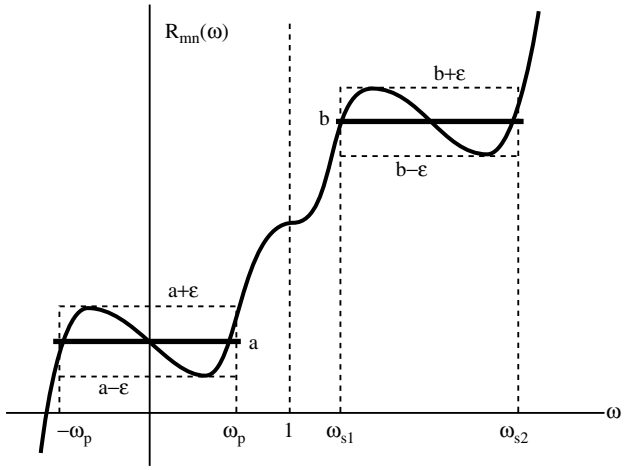

FIGURE 70.20 Chebyshev rational approximation.

$$T_n(\omega) = \cos\left[n \cos^{-1}(\omega)\right] \tag{70.110}$$

is a polynomial as desired. Of course, the maximum error is ±1, an impractically large value. This is easily rectified by requiring that the approximating polynomial be

$$p_n(\omega) = \varepsilon T_n(\omega) = \varepsilon \cos\left[n \cos^{-1}(\omega)\right] \tag{70.111}$$

In terms of gain and characteristic functions, therefore, one has

$$G(\omega) = \frac{1}{1 + K^2(\omega)} = \frac{1}{1 + \varepsilon^2 T_n^2(\omega)} \tag{70.112}$$

That is, $p_n(\omega) = \varepsilon T_n(\omega)$ is the best approximation to the characteristic function $K(\omega)$.

Since the gain function to be approximated is even in ω, $K(\omega)$ — and, therefore, $p_n(\omega) = \varepsilon T_n(\omega)$ — must be either even or odd. As one can recall, the Chebyshev polynomials have this property. For this reason, it is only necessary to discuss the situation for $\omega \geq 0$ for the extension to negative ω is then obvious.

The foregoing sets the stage for the more general problem, which will now be addressed. As noted previously, the Weierstrass theorem holds for more general compact sets. Thus, as a preliminary exercise, the approximation problem sketched in Fig. 70.20 will be discussed. That figure shows two closed intervals as the compact set on which the approximation is to occur. The function to be approximated is assumed to be the constant a on the first interval and the constant b on the second.[12] In order to cast this into the filtering context, it will be assumed that the constant a is small and the constant b large. The sharpness of the transition characteristic can then be set to any desired degree by allowing ω_p to approach unity from below and ω_s^1 to approach unity from above. Notice that the frequency scaling will be different here than for the all-pole case in which the right-hand interval endpoint was allowed to be unity.

In addition to more general compact sets, the Weierstrass theorem allows the approximating function to be a general real rational function, which has been denoted by $R_{mn}(\omega)$ in the figure. This notation means that the numerator and denominator polynomials have maximum degree m and n respectively. Now suppose that one specifies that $b = 1/a$ and suppose $R_{mn}(\omega)$ is a reciprocal function, that is, one having the property that

[12]One should note that this function is continuous on the compact set composed of the two closed intervals.

© 2003 by CRC Press LLC

$$R_{mn}\left(\frac{1}{\omega}\right)=\frac{1}{R_{mn}(\omega)} \tag{70.113}$$

Then, if one determines its coefficients such that the quiripple property holds on the interval $-\omega_p \le \omega \le \omega_p$, it will also hold on the interval $\omega_{s1} \le \omega \le \omega_{s2}$. Of course, this interval is constrained such that $\omega_{s1} = 1/\omega_p$. The other interval endpoint will then extend to $+\infty$ (and, by symmetry, there will also be an interval on the negative frequency axis with one endpoint at $-1/\omega_p$ and the other at $-\infty$). This is, of course, not a compact set — but the approximation theorem continues to hold anyway because it is equivalent to approximating $a = 1/b$ on the lowpass interval $[-\omega_p, \omega_p)$. Thus, one can let $a = 0$ and $b = \infty$ and simultaneously approximate the ideal characteristic function

$$K(\omega)=\begin{cases}0; & |\omega|\le\omega_p\\ \infty; & |\omega|\ge\dfrac{1}{\omega_p}\end{cases} \tag{70.114}$$

with the real and even or odd (for realizability) rational function $R_{mn}(\omega)$ having the aforementioned reciprocal property. The Weierstrass theorem equiripple property for such rational functions demands that the total number of error extrema[13] on the compact set be $m + n + 2$. (This assumes the degree of both polynomials to be relative to the variable ω^2.)

Based on the preceding discussion, one has the following form for $R_{mn}(\omega)$:

$$R_{2n,2n}(\omega)\equiv R_{2n}(\omega)=\frac{\left(\omega_1^2-\omega^2\right)\left(\omega_3^2-\omega^2\right)\cdots\left(\omega_{2n-1}^2-\omega^2\right)}{\left(1-\omega_1^2\omega^2\right)\left(1-\omega_2^2\omega^2\right)\cdots\left(1-\omega_{2n-1}^2\omega^2\right)} \tag{70.115}$$

$$R_{2n+1,2n}(\omega)\equiv R_{2n+1}(\omega)=\frac{\omega\left(\omega_2^2-\omega^2\right)\left(\omega_4^2-\omega^2\right)\cdots\left(\omega_{2n}^2-\omega^2\right)}{\left(1-\omega_2^2\omega^2\right)\left(1-\omega_4^2\omega^2\right)\cdots\left(1-\omega_{2n}^2\omega^2\right)} \tag{70.116}$$

The first is clearly an even rational function and latter odd. The problem now is to find the location of the pole and zero factors such that equiripple behavior is achieved in the passband. The even case is illustrated in Fig. 70.21 for $n = 2$. Notice that the upper limit of the passband frequency interval has been taken for convenience to be equal to $\sqrt{k}$; hence, the lower limit of the stopband frequency interval is $1/\sqrt{k}$. Thus,

$$k=\frac{\omega_p}{\omega_s} \tag{70.117}$$

is a measure of the sharpness of the transition band rolloff and is always less than unity. The closer it is to one, the sharper the rolloff. It is an arbitrarily specified parameter in the design. Notice that equiripple behavior in the passband implies equiripple behavior in the stopband — in the latter, the approximation is to the constant whose value is infinity and the minimum value (which corresponds to a maximum value of gain) is $1/\varepsilon$, while the maximum deviation from zero in the passband is ε. The zeroes are all in the passband and are mirrored in poles, or infinite values, in the stopband. The notation ω_0 and ω_2 for the passband frequencies of maximum error has been introduced. In general, their indices will be even for even approximations and odd for odd approximations.

[13]There can be degeneracy in the general approximation problem, but the constraints of the problem being discussed here preclude this from occurring.

© 2003 by CRC Press LLC

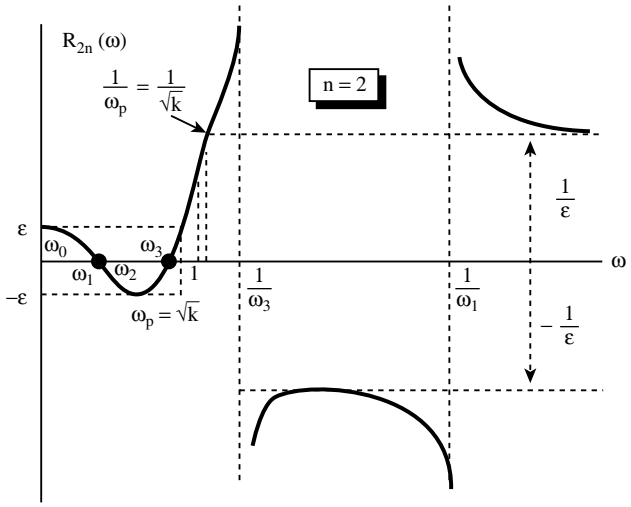

FIGURE 70.21 Typical plot of an even-order Chebyshev rational function.

A sketch for the odd case would differ only in that the plot would go through the origin, that is the origin would be a zero rather than a point of maximum error. Notice that the resulting filter will have finite gain unlike the Butterworth or Chebyshev, which continue to rolloff toward zero as ω becomes infinitely large. As noted in the figure the approximating functions are called the *Chebyshev rational functions*.

The procedure [8] now is quite analogous to the Chebyshev polynomial approximation, though rather more complicated. One looks for a continuous, periodic waveform that possess the desired equiripple behavior. Since the Jacobian elliptic functions are generalizations of the more ordinary sinusoids, it is only natural that they be investigated with an eye toward solving the problem under attack. With that in mind, some of the more salient properties will now be reviewed.

Consider the function

$$I(\phi,k) = -\frac{1}{\sqrt{1-k^2\sin^2(\phi)}} \tag{70.118}$$

which is plotted for two values of k in Fig. 70.22. If $k = \pm 1$, the peak value is infinite; in this case, $I(\phi, k) = \sec(\phi)$. For smaller values of k the peak value depends upon k with smaller values of k resulting lower

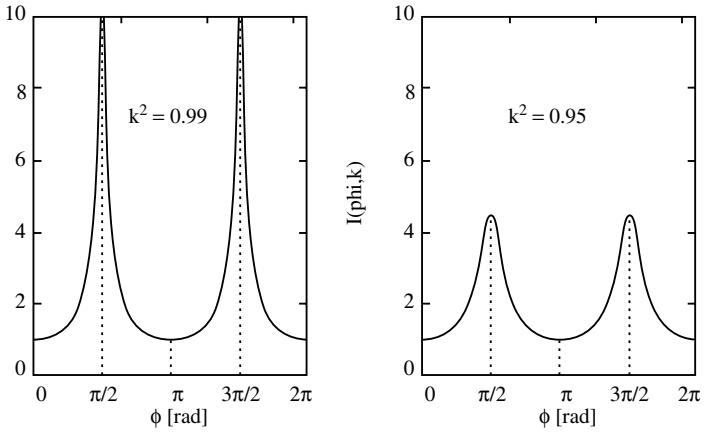

FIGURE 70.22 Plot of $I(\phi, k)$.

© 2003 by CRC Press LLC

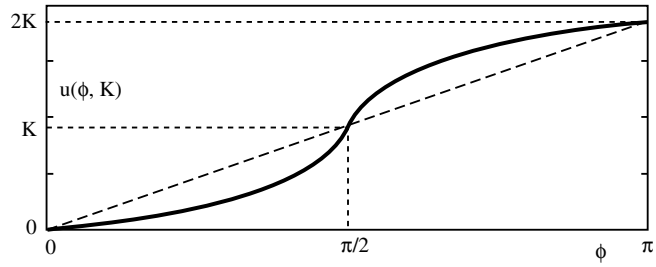

FIGURE 70.23 Running integral of I normalized to K.

peak values. The peaks occur at odd multiples of $\pi/2$. Note that $I(\phi, k)$ has the constant value one for $k = 0$. Figure 70.23 shows the running integral of $I(\phi, k)$ for $k^2 = 0.99$ and for $k^2 = 0$. For $k^2 = 0$ the curve is a straight line (shown dashed); or other values of k^2, it deviates from a straight line by an amount that depends upon the size of k^2. Observe that the running integral has been plotted over one full period of $I(k, \phi)$ — that is, from 0 to π. The running integral is given in analytical form by

$$u(\phi,k) = \int_0^{\phi} I(\alpha, k)\, d\alpha = \int_0^{\phi} \frac{1}{\sqrt{1-k^2 \sin^2(\alpha)}}\, d\alpha \tag{70.119}$$

The quantity K, shown by the lowest dashed horizontal line in Fig. 70.23, is the integral of $I(\phi, k)$ from 0 to $\pi/2$; that is, it is the area beneath the $I(\phi, k)$ curve in Fig. 70.22 from 0 to $\pi/2$. Thus, it is the area beneath the curve to the left of the first vertical dashed line in that figure. It is given by

$$u\left(\frac{\pi}{2}, k\right) = \int_0^{\pi/2} I(\alpha, k) d\alpha = \int_0^{\pi/2} \frac{1}{\sqrt{1-k^2 \sin^2(\alpha)}}\, d\alpha = K \tag{70.120}$$

and is referred to as the *complete elliptic integral of the first kind.*

The sine generalization sought can now be defined. Since the running integral $u(\phi, k)$ is monotonic, it can be inverted and thereby solved for ϕ in terms of u; for each value of u there corresponds a unique value of ϕ. The **elliptic sine function** is defined to be the ordinary sine function of ϕ:

$$sn(u, k) = \sin(\phi, k) \tag{70.121}$$

Now, inspection of Fig. 70.23 shows that, as ϕ progresses from 0 to 2π, $u(\phi, k)$ increases from 0 to $4K$; since angles are unique only to within multiples of 2π, therefore, it is clear that $sn(u, k)$ is periodic with period $4K$. Hence, K is a quarter-period of the elliptic sine function.

The integral in (70.119) cannot be evaluated in closed form; thus, there is not a simple, compact expression for the required inverse. Therefore, the elliptic sine function can only be tabulated in numerical form or computer using numerical techniques. It is shown for $k^2 = 0.99$ in Fig. 70.24 and compared with a conventional sine function having the same period ($4K$).

Recall, now, the objective of exploring the preceding generalization of the sinusoid: one is looking for a transformation that will convert the characteristic function given by (70.115) and (70.116) into equivalent waveforms having the equiripple property. As one might suspect (since so much time has been spent on developing it), the elliptic sine function is precisely the transformation desired. The crucial aspect of showing this is the application of a fundamental property of $sn(u, k)$, known as an **additional formula**:

$$sn(u+a,k)sn(u-a,k) = \frac{sn^2(u,k) - sn^2(a,k)}{1-k^2 sn^2(u,k) sn^2(a,k)} \tag{70.122}$$

© 2003 by CRC Press LLC

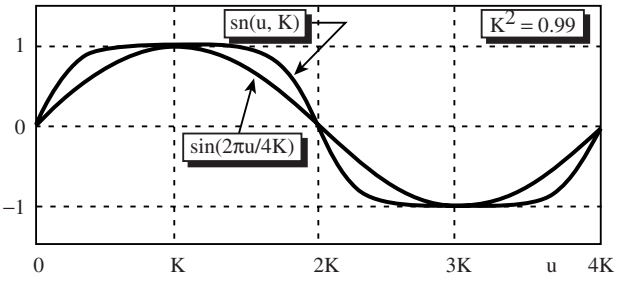

FIGURE 70.24 Plots of the elliptic and ordinary sine functions.

The right-hand side of this identity has the same form as one factor in (70.115) and (70.116), that is of one zero factor coupled with its corresponding pole factor. This suggests the transformation

$$\omega = \sqrt{k}\ sn(u,k) \tag{70.123}$$

The passband zeros then are given by

$$\omega_i = \sqrt{k}\ sn(u_i,k) \tag{70.124}$$

and the factors mentioned previously map into

$$\frac{\omega_i^2-\omega^2}{1-\omega_i^2\omega^2} = \frac{k\left[sn^2(u_i,k)-sn^2(u,k)\right]}{1-k^2sn^2(u_i,k)sn^2(u,k)} = k\,sn(u+u_i)sn(u-u_i) \tag{70.125}$$

For specificity, the even-order case will be discussed henceforth. The odd-order case is the same if minor notational modifications are made. Thus, one sees that

$$R_{2n}(\omega) = \prod_{i=1,3,\cdots,2n-1} \frac{\omega_i^2-\omega^2}{1-\omega_i^2\omega^2} = \prod_{i=1,3,\cdots,2n-1} ksn(u+u_i)sn(u-u_i) \tag{70.126}$$

The u_i are to be chosen. Before doing this, it helps to simplify the preceding expression by defining $u_{-i} = -u_i$ and reindexing. Calling the resulting function $G(u)$, one has

$$G(u) = \prod_{i=-1,-3,\cdots,-(2n-1)}^{i=1,3,\cdots,2n-1} ksn(u+u_i) \tag{70.127}$$

Refer now to Fig. 70.24. Each of the *sn* functions is periodic with period $4K$ and is completely defined by its values over one quarter-period $[0, K)$. Suppose that one defines

$$u_i = i\frac{K}{2n} \tag{70.128}$$

Figure 70.25 shows the resulting transformation corresponding to (70.123) and (70.124). As u progresses from $-K$ to $+K$, ω increases from $-\sqrt{k}$ to $+\sqrt{k}$ as desired. Furthermore, because of the symmetry of $sn(u)$, the set $\{u_i\}$ forms an additive group — adding $K/2n$ to the index of any u_i results in another u_i in the set. This means that $G(u)$ in (70.127) is periodic with period $K/2n$. Thus, as ω increases from $-\sqrt{k}$ to $+\sqrt{k}$, $R_{2n}(\omega)$ achieves $2n + 2$ extrema, that is, positive and negative peak values. But this is sufficient for $R_{2n}(\omega)$ to be the Chebyshev rational function of best approximation.

© 2003 by CRC Press LLC

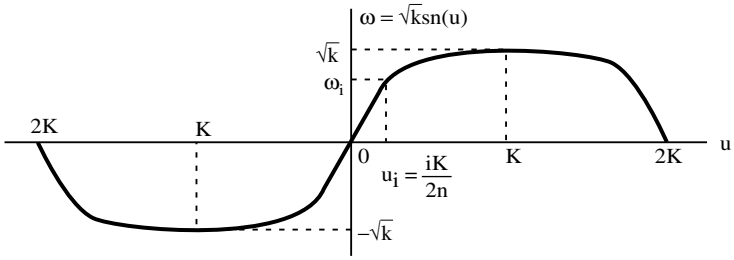

FIGURE 70.25 The elliptic sine transformation.

The symmetry of the zero distribution around the peak value of $sn(u)$, that is, around $u = K$, reveals that the peak values of $R_{2n}(\omega)$ occur between the zeros; that is, recalling that in Fig. 70.21 the peak values have been defined by the symbols ω_i for even i, one has

$$\omega_i = \sqrt{k}\, sn\left(\frac{iK}{2n}\right); i = 0, 1, 2, \cdots, 2n \tag{70.129}$$

where the odd indices correspond to the zeros and the even ones to the peak values. Note that $i = 0$ corresponds to $\omega = 0$ and $i = 2n$ to $\omega = \sqrt{k}$. This permits one to compute the minimax error:

$$\varepsilon = \left|R_{2n}(0)\right| = \left(\omega_1 \omega_3 \cdots \omega_{2n-1}\right)^2 \tag{70.130}$$

As pointed out previously, the analysis for odd-order filters proceeds quite analogously. The only difference lies in the computation of ε. In this case, $R_{2n+1}(0) = 0$; thus, $\omega = 0$ is a zero — not a point of maximum deviation. One can, however, note that the quantity $\varepsilon^2 - R_{2n+1}^2(\omega)$ has double zeroes at the frequencies of maximum deviation (except at $\omega = \omega_{2n+1} = \sqrt{k}$) and the same denominator as $R_{2n+1}^2(\omega)$. Hence,

$$\varepsilon^2 - R_{2n+1}^2(\omega) = \frac{\left(\omega_1^2 - \omega^2\right)^2 \left(\omega_3^2 - \omega^2\right)^2 \cdots \left(\omega_{2n+1}^2 - \omega^2\right)}{\left(1 - \omega_2^2 \omega^2\right)^2 \left(1 - \omega_4^2 \omega^2\right)^2 \cdots \left(1 - \omega_{2n}^2 \omega^2\right)^2} \tag{70.131}$$

Notice here that $\omega_{2n+1} = \sqrt{k}$. Since $R_{2n+1}(0) = 0$, one can evaluate this expression at $\omega = 0$ to get

$$\varepsilon = \left(\omega_1 \omega_3 \cdots \omega_{2n-1}\right)^2 \sqrt{k} \tag{70.132}$$

Note that one uses the zero frequencies in the even-order case and the frequencies of maximum deviation in the odd-order case.

As an example, suppose that the object is to design an elliptic filter of order $n = 2$. Further, suppose that the passband ripple cutoff frequency is to be 0.95. Then, one has

$$\omega_p = \sqrt{k} = 0.95 \tag{70.133}$$

The quarter period of the elliptic sine function is

$$K = 2.9083 \tag{70.134}$$

Evaluating the zeros and points of maximum deviation of the Chebyshev rational function numerically using (70.129), one obtains the values shown in Table 70.4. Thus, the required elliptic rational function is

© 2003 by CRC Press LLC

TABLE 70.4

i	ω_i
0	0.0000
1	0.5923
2	0.8588
3	0.9352
4	0.9500

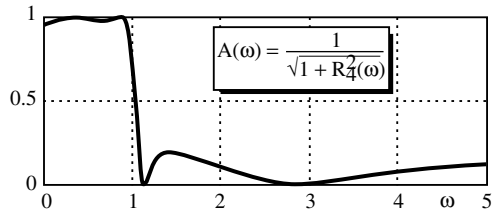

FIGURE 70.26 Gain plot for the example elliptic filter.

$$R_4(\omega) = \frac{(0.3508 - \omega^2)(0.8746 - \omega^2)}{(1 - 0.3508\omega^2)(1 - 0.8746\omega^2)} \tag{70.135}$$

Finally, the maximum error is given by (70.130):

$$\varepsilon = (\omega_1\omega_2)^2 = (0.5923 \times 0.9352)^2 = 0.3078 \tag{70.136}$$

Figure 70.26 shows the resulting gain plot. Observe the transmission zero at $\omega = 1/0.9352 = 1.069$, corresponding to the pole of the Chebyshev rational function located at the inverse of the largest passband zero. Also, as anticipated, the minimum gain in the passband is

$$A_p = \frac{1}{\sqrt{1+\varepsilon^2}} = \frac{1}{\sqrt{1+(0.3078)^2}} = 0.9558 \tag{70.137}$$

and the maximum stopband gain is

$$A_s = \frac{1}{\sqrt{1+\dfrac{1}{\varepsilon^2}}} = \frac{1}{\sqrt{1+\dfrac{1}{(0.3078)^2}}} = 0.2942 \tag{70.138}$$

Perhaps a summary of the various filter types is in order at this point. The elliptic filter has more flexibility than the Butterworth or the Chebyshev because one can adjust its transition band rolloff independently of the passband ripple. However, as the sharpness of this rolloff increases, as a more detailed analysis shows, the stopband gain increases and the passband ripple increases. Thus, if these parameters are to be independently specified — as is often the desired approach — one must allow the order of the filter to float freely. In this case, the design becomes a bit more involved. The reader is referred to [9], which presents a simple curve for use in determining the required order. It proceeds from the result that the filter order is the integer greater than or equal to the following ratio:

© 2003 by CRC Press LLC

$$n \geq \frac{f(M)}{f(\Omega)} \tag{70.139}$$

where

$$f(x) = \frac{K\left(\sqrt{1-x^{-2}}\right)}{K(1/x)} \tag{70.140}$$

Lin [9] presents a curve of this function $f(x)$. K is the complete elliptic integral given in (70.120). The parameters M and Ω are defined by

$$M = \sqrt{\frac{1-10^{-0.1A_s}}{1-10^{-0.1A_p}}} \tag{70.141}$$

and

$$\Omega = 1/k \tag{70.142}$$

Of course, there is still the problem of factorization. That is, now that the appropriate Chebyshev rational function is known, one must find the corresponding $G(s)$ transfer function of the filter. The overall design process is explained in some detail in [10], which develops a numerically efficient algorithm for directly computing the parameters of the transfer function.

The Butterworth and Chebyshev filters are of the all-pole variety, and this means that the synthesis of such filters is simpler than is the realization of elliptic filters, which requires the realization of transmission zeros on the finite $j\omega$ axis.

Finally, a word about phase (or group delay). Table 70.5 shows a rank ordering of the filters in terms of both gain and phase performance. As one can see, the phase behavior is inverse to the gain performance. Thus, the elliptic filter offers the very best standard approximation to be ideal lpp "brickwall" gain behavior, but its group delay deviates considerably from a constant. On the other end of the spectrum, one notes that the Bessel–Thompson filters offers excellent phase performance, but a quite high order is required to achieve a reasonable gain characteristic.

TABLE 70.5

Filter Type	Gain Rolloff	Phase Linear
Bessel	Worst	Best
Butterworth	Poor	Better
Chebyshev	Better	Poor
Elliptic	Best	Worst

If both excellent phase and gain performance are absolutely necessary, two approaches are possible. One either uses computer optimization techniques to simultaneously approximate gain and phase, or one uses one of the filters described in this section followed by an *allpass* filter, one having unity gain over the frequency range of interest, but whose phase can be designed to have the inverse characteristic to the filter providing the desired gain. This process is known as *phase compensation*.

71.1 Low-Pass Prototype

As discussed in Chapter 70, conventional approximation techniques (Butterworth, Chebyshev, Elliptic, Bessel, etc.) lead to a normalized transfer function denoted *low-pass prototype* (LPP). The LPP is characterized by a passband frequency $\Omega_P = 1.0$ rad/s, a maximum passband ripple A_P (or A_{max}), a minimum stopband attenuation A_s (or A_{min}), and a stopband frequency Ω_s. A_p and A_s are usually specified in dB. Tolerance bounds (also called box constraints) for the magnitude response of an LPP are illustrated in Fig. 71.1(a). The ratio Ω_s/Ω_p is called the **selectivity factor** and it has a value Ω_s for an LPP filter. The passband and stopband edge frequencies are defined as the maximum frequency with the maximum passband attenuation A_p and the minimum frequency with the minimum stopband attenuation A_s, respectively. The passband ripple and the minimum passband attenuation are expressed by

$$A_P = 20\log\left|\frac{K}{H(\omega_P)}\right| \qquad A_s = 20\log\left|\frac{K}{H(\omega_s)}\right| \tag{71.1}$$

where K is the maximum value of the magnitude response in the passband (usually unity). Figure 71.1(b) shows the magnitude response of a Chebyshev LPP transfer function with specifications $A_p = 2$ dB, $A_s = 45$ dB, and $\Omega_s = 1.6$.

Transformation of Transfer Function. Low-pass, high-pass, bandpass, and band-reject transfer functions (denoted in what follows LP, HP, BP, and BR, respectively) can be derived from an LPP transfer function through a transformation of the complex frequency variable. For convenience, the transfer function of the LPP is expressed in terms of the complex frequency variable s, where $s = u + j\Omega$ while the transfer functions obtained through the frequency transformation (low-pass, high-pass, bandpass, or band-reject) are expressed in terms of the transformed complex frequency variable $p = \sigma + j\omega$.

The approximation of a LP, HP, BP, or BR transfer function with passband ripple (s) A_p and stopband attenuation (s) A_s involves three steps:

© 2003 by CRC Press LLC

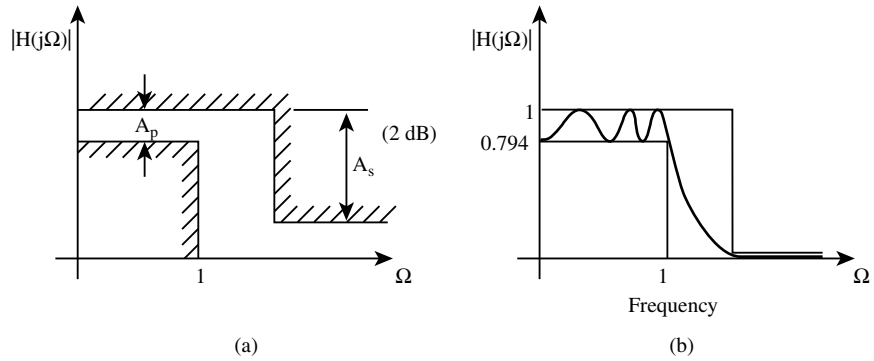

FIGURE 71.1 (A) Tolerance bounds for magnitude response of low-pass prototype. (b) Chebyshev LPP response.

1. Determination of the stopband edge frequency or selectivity factor Ω_s of an LPP, which can be transformed into the desired LP, HP, BP, or BR filter.
2. Approximation of an LPP transfer function $T_{LPP}(s)$ with selectivity factor Ω_s and with same passband ripple and stopband attenuation A_p and A_s as the desired LP, HP, BP, or BR filter, respectively
3. Transformation of the LPP transfer function $T_{LPP}(s)$ into the desired transfer function (LP, HP, BP, or BR) $T(p)$ through a frequency transformation of the form

$$s = f(p) \tag{71.2}$$

Transformation of a network with LPP magnitude response into a low-pass, high-pass, bandpass, or band-rejection network can be done directly on the elements of the network. This procedure is denoted **network transformation**. It is very convenient in practice because element values for double terminated lossless ladder networks with LPP specifications have been extensively tabulated for some common values of A_p, A_s, and Ω_s. Also, a host of personal computer programs have become available in recent years that allow one to determine the component values of LPP ladder networks for arbitrary values A_p, A_s, and Ω_s. In what follows we study the frequency transformation $s = f(p)$ for each specific type of filter response (LP, HP, BP, and BR). We show how to calculate the selectivity factor of the equivalent LPP based on box constraint specifications for each type of filter. We then show how mapping of the imaginary frequency axis from s to p leads to LP, HP, BP, or BR magnitude responses. We analyze how poles and zeros are mapped from the s-plane to the p-plane for each transformation and finally we show the element transformations required to directly transform LPP networks into any of the filter types addressed previously.

71.2 Frequency and Impedance Scaling

Frequency Scaling

The simplest frequency transformation is a scaling operation expressed by

$$s = \frac{p}{\omega_o} \tag{71.3}$$

where ω_o is a frequency scaling parameter. This transformation is denoted *frequency scaling* and it allows one to obtain a low-pass transfer function with a nonunity passband frequency edge from an LPP transfer function.

© 2003 by CRC Press LLC

Transformation of Poles and Zeros of Transfer Function. Consider an LPP factorized transfer function $T_{LPP}(s)$ with n poles $s_{p1}, s_{p2}, \ldots, s_{pn}$ and m zeros $s_{z1}, s_{z2}, \ldots, s_{zm}$

$$T_{LPP}(s) = K\frac{(1-s/s_{z1})(1-s/s_{z2})\cdots(1-s/s_{zm})}{(1-s/s_{sp1})(1-s/s_{p2})\cdots(1-s/s_{pn})} \tag{71.4}$$

Using (71.3), this transfer function becomes

$$T_{LP}(p) = K\frac{(1-p/p_{z1})(1-p/p_{z2})\cdots(1-p/p_{zm})}{(1-p/p_{p1})(1-p/p_{p2})\cdots(1-p/p_{pn})} \tag{71.5}$$

where poles and zeros (s_{zi} and s_{pj}) of the LPP transfer function $P_{LPP}(s)$ become simply poles and zeros in $T_{LP}(p)$, which are related to those of $T_{LPP}(s)$ by the scaling factor ω_o:

$$p_{pi} = \omega_o s_{pi} \qquad p_{zj} = \omega_o s_{zj} \tag{71.6}$$

To determine the magnitude (or frequency) response of the LP filter we evaluate the magnitude of the transfer function on the imaginary axis (for $s = j\Omega$). The magnitude response of the transformed transfer function $|T_{LP}(j\omega)|$ preserves a low-pass characteristic as illustrated in Fig. 71.2. The frequency range from 0 to ∞ in the Ω axis is mapped to the range 0 to ∞ in the ω axis. A frequency and its mirror image in the negative axis $\pm\Omega$ is mapped to frequencies $\omega = \pm\omega_o\Omega$ with the same magnitude response: $|T_{LPP}(j\Omega)| = |T_{LP}(j\omega_o\Omega)|$. The passband and stopband edge frequencies $\Omega_P = 1$ rad/s and Ω_s of the LPP are mapped into passband and stopband edge frequencies $\omega_p = \omega_o$ and $\omega_s = \omega_o\Omega_s$, respectively. From this, it can be seen that for given low-pass filter specifications ω_s, ω_p the equivalent LPP is determined based on the relation $\Omega_s = \omega_s/\omega_p$, while the frequency scaling parameter ω_o corresponds to the passband edge frequency of the desired LP.

LP Network Transformation. Capacitors and inductors are the only elements that are frequency dependent and that can be affected by a change of frequency variable. Capacitors and inductors in an LPP network have impedances $z_c = 1/sc_n$ and $z_1 = s1_n$, respectively. Using (71.3) these become $Z_c(p) = 1/pC$ and $Z_L(p) = pL$, where $C = c_n/\omega_o$ and $L = l_n/\omega_o$. The LPP to LP frequency transformation is performed directly on the network by simply dividing the values of all capacitors and inductors by the frequency scaling factor ω_o. This is illustrated in Fig. 71.3(a). The transformation expressed by (71.3) can be applied to any type of filter and it has the effect of scaling the frequency axis without changing the shape of its magnitude response. This is illustrated in Fig. 71.3, where the elements of an LPP with $A_p = 2$ dB, $A_s = 45$ dB, and selectivity $\Omega_s = 1.6$ rad/s are scaled [Fig. 71.3(b)] to transform the network into an LP network with passband and stopband edge frequencies $\omega_p = 2\pi$ 10 krad/s and $\omega_s = 2\pi$ 16 krad/s (or $f_p = 10$ kHz and $f_s = 16$ kHz), respectively.

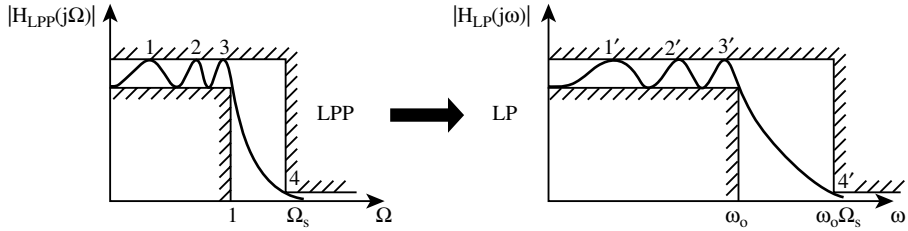

FIGURE 71.2 Derivation of low-pass response from a low-pass prototype by frequency scaling.

© 2003 by CRC Press LLC

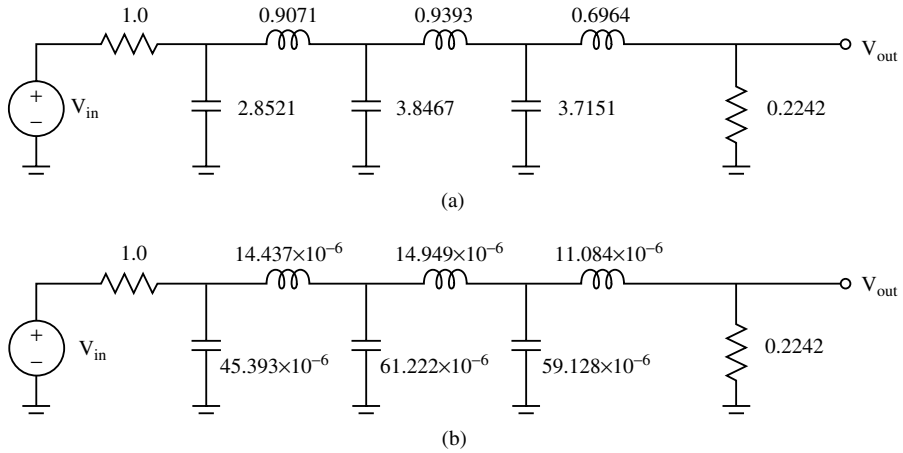

FIGURE 71.3 (a) Low-pass prototype ladder network. (b) LP network with passband frequency f_p = 10 kHZ derived from (a).

Impedance Scaling

Dimensionless transfer functions defined by ratios of voltages (V_{out}/V_{in}) or currents (I_{out}/I_{in}) remain unchanged if all impedances of a network are scaled by a common scaling factor "a". On the other hand, transfer functions of the transresistance type (V_{out}/I_{in}) or of the transconductance type (I_{out}/V_{in}) are simply modified by the impedance scaling factor a and $1/a$, respectively. If we denote a normalized impedance by z_n, then the impedance scaling operation leads to an impedance $Z = az_n$. When applied to resistors (r_n), capacitors (c_n), inductors (l_n), transconductance gain coefficients (g_n), and transresistance gain coefficients (r_n) result in the following relations for the elements (R, C, L, g, and r) of the impedance scaled network.

$$\begin{aligned} R &= ar_n \\ L &= al_n \\ C &= \frac{1}{a}c_n \\ g &= \frac{1}{a}g_n \\ r &= ar_n \end{aligned} \tag{71.7}$$

Dimensionless voltage-gain and current-gain coefficients are not affected by impedance scaling. Technologies for fabrication of microelectronic circuits (CMOS, bipolar, BiCMOS monolithic integrated circuits, thin-film and thick-film hybrid circuits) only allow elements values and time constants (or pole and zero frequencies) within certain practical ranges. Frequency and impedance scaling are very useful to scale normalized responses and network elements resulting from standard approximation procedures to values within the range achievable by the implementation technology. This is illustrated in the following example.

Example 1. The amplifier of Fig. 71.4. is characterized by a one-pole low-pass voltage transfer function given by $H(s) = V_{out}/V_{in} = K(1+s/\omega_p)$, where $K = g_m r_L r_1/(r_1 + r_2)$, and $\omega_p = 1/r_L C_L$. Perform frequency and impedance scaling so that the circuit pole takes a value $\omega_p = 2\pi 10$ Mrad/s (or f_p = 10 MHz) and resistance, capacitance, and transconductance gain values are in the range of kΩ, pF, and μA/V, which are appropriate for the implementation of the circuit as an integrated circuit in CMOS technology.

© 2003 by CRC Press LLC

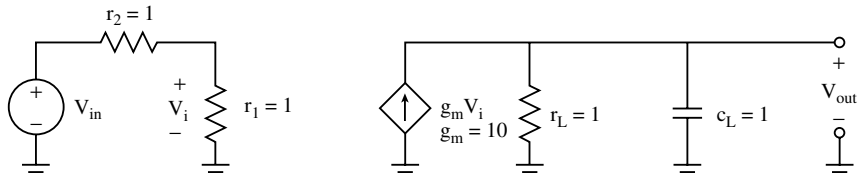

FIGURE 71.4 Normalized transconductance amplifier.

Solution. The required location of the pole and range of values for the circuit elements can be achieved using frequency and impedance scaling factors $\omega_0 = 2\pi \cdot 10^7$ and $a = 10^4$, respectively. These result in $R_1 = ar_1 = 10$ kΩ, $R_2 = ar_2 = 10$ kΩ, $g = g_m/a = 1000$ μA/V, $R_L = ar_L = 10$ kΩ, and $C_L = c_L/a\omega_o = 1.59$ pF.

71.3 Low-Pass to High-Pass Transformation

The LPP to high-pass transformation is defined by

$$s = \frac{\omega_o^2}{p} \tag{71.8}$$

Using this substitution in the LPP transfer function (71.4), it becomes

$$T_{\text{HP}}(P) = K\frac{p^{n-m}(p-p_{z1})(p-p_{z2})\cdots(p-p_{zm})}{(p-p_{p1})(p-p_{p2})\cdots(p-p_{pn})} \tag{71.9}$$

where the poles and zeros of (71.8) are given by

$$\begin{aligned} p_{zi} &= \frac{\omega_o^2}{s_{zi}} \quad \text{for } i \in \{1, 2, \ldots, m\} \\ p_{pj} &= \frac{\omega_o^2}{s_{pj}} \quad \text{for } j \in \{1, 2, \ldots. n\} \end{aligned} \tag{71.10}$$

It can be seen that zeros and poles of $T_{\text{HP}}(p)$ are reciprocal to those of $T_{\text{LPP}}(s)$ and scaled by the factor ω_o^2. $T_{\text{HP}}(p)$ has $n - m$ zeros at $s = 0$, which can be considered to originate from $n - m$ zeros at ∞ in $T_{\text{LPP}}(s)$.

Let us consider now the transformation of the imaginary axis in s to the imaginary axis in p. For $s = j\Omega$, p takes the form $p = j\omega$ where

$$\omega = -\omega_o^2/\Omega \tag{71.11}$$

From (71.11), it can be seen that positive frequencies in the LPP transform to reciprocal and scaled frequencies of the HP filter. Specifically, the frequency range from 0 to ∞ in Ω maps to the frequency range –∞ to 0 in ω, while the range –∞ to 0 in Ω maps to 0 to ∞ in ω. The passband edge frequency ($\Omega_p = \pm 1$) and the stopband edge frequency $\pm\,\Omega_s$ of the LPP is mapped to $\omega_p = \mp\omega_o^2$ and $\omega_s = \mp\omega_o^2/\Omega_s$ in the high-pass response. This is illustrated in Fig. 71.5.

The procedure to obtain the specifications of the equivalent LPP given specifications ω_p and ω_s for a HP circuit can be outlined as follows:

1. Calculate the selectivity factor of the LPP according to $\Omega_s = \omega_p/\omega_s$.
2. Approximate an LPP transfer function $T_{\text{LPP}}(s)$ with the selectivity Ω_s and the passband ripple and stopband attenuation of the desired high-pass response.
3. Perform an LPP to HP transformation either by direct substitution $p = \omega_o^2/s$ in $T_{\text{LPP}}(s)$ or by transforming poles and zeros of $T_{\text{LPP}}(s)$ using (71.10).

© 2003 by CRC Press LLC

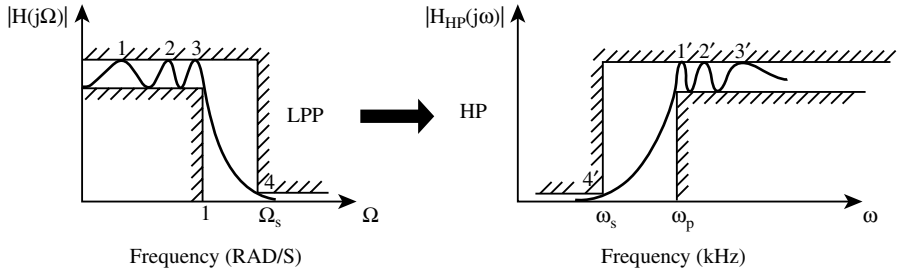

FIGURE 71.5 Transformation of a low-pass into a high-pass response.

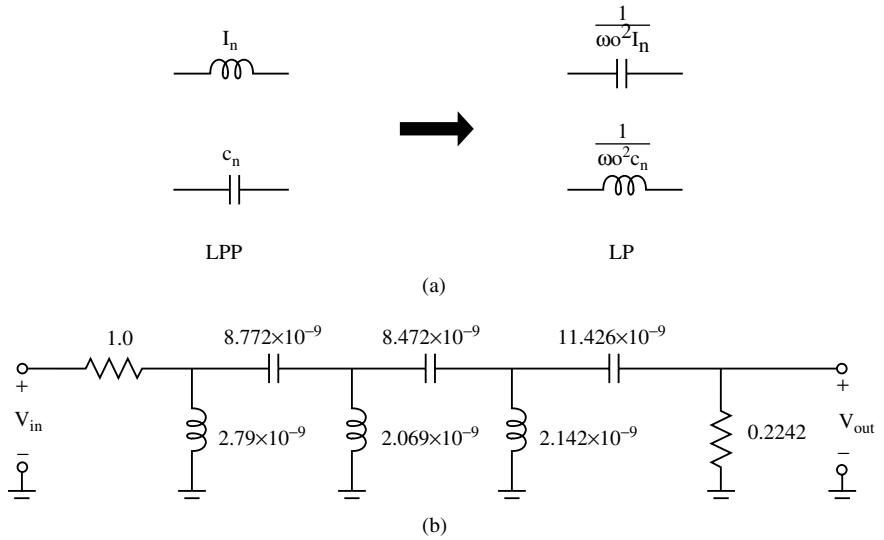

FIGURE 71.6 (a) LPP to high-pass network element transformations. (b) High-pass network derived from LPP of Fig. 71.3(a).

Network Transformation. Consider a capacitor c_n and an inductor l_n in an LPP network. They have impedances $z_c(s) = 1/sc_n$, $z_1(s) = sl_n$, respectively. Using (71.8), these become impedances $Z_L(p) = pL$ and $Z_c = 1/pC$ in the high-pass network, where $L = 1/\omega_o^2 c_n$ and $C = 1/\omega_o^2 l_n$. It can be seen that an LPP to HP transformation can be done directly on an LPP network by replacing capacitors by inductors and inductors by capacitors. For illustration, Fig. 71.6 shows a high-pass network with a passband edge frequency $\omega_p = 2\pi$ 20 Mrad/s or (fp = 20 MHz) derived from the LPP network shown in Fig. 71.6(a).

71.4 Low-Pass to Bandpass Transformation

If the LPP transfer function is expressed now as a rational function

$$H_{\text{LPP}}(s) = K\,\frac{b_o + b_1 s + b_2 s^2 + \cdots + b_m s_m}{a_o + a_1 s + a_2 s^2 + \cdots + a_n s^n} \tag{71.12}$$

then through the substitution

$$s = \frac{1}{\text{BW}}\,\frac{p^2 + \omega_o^2}{p} \tag{71.13}$$

© 2003 by CRC Press LLC

$H_{LPP}(s)$ transformed into a bandpass transfer function $H_{BP}(p)$ with the form

$$H_{BP}(P) = K'P^{n-m}\,\frac{1 + B_1 p + B_2 p^2 + \cdots + B_2 p^{2m-2} + B_1 p^{2m-1} + p^{2m}}{1 + A_1 p + A_2 p^2 + \cdots + A_2 p^{2m-2} + A_1 p^{2m-1} + p^{2m}} \tag{71.14}$$

From (71.14), it can be seen that the bandpass transfer function has twice as many poles and zeros as the LPP transfer function. In addition it has $n–m$ zeros at the origin. The coefficients of the numerator and denominator polynomials are symmetric and are a function of the coefficients of $H_{LPP}(s)$.

In order to obtain poles and zeros of the bandpass transfer function from the poles and zeros of $T_{LPP}(p)$, three points must be considered.

First, a real pole (or zero) $s_p = -u_p$ of $H_{LPP}(s)$ maps into a complex conjugate pair with frequency ω_o and Q (or selectivity) factor in $H_{BP}(p)$, where $Dq = \omega_o/(U_p BW)$.[1]

Second, a pair of complex conjugate pole (or zeros) of $H_{LPP}(s)$ with frequency Ω_o and pole-quality factor q denoted by (Ω_o, q) is mapped into two pairs of complex conjugate poles (or zeros) (ω_{o1}, Q) and (ω_{o2}, Q), where the following relations apply:

$$\begin{aligned} \omega_{o1} &= \omega_o M \\ \omega_{o2} &= \frac{\omega_o}{M} \\ Q &= \frac{a}{c}\left(M + \frac{1}{M}\right) \end{aligned} \tag{71.15a}$$

and the definitions

$$\begin{aligned} a &= \frac{\omega_o}{\mathrm{BW}} \\ b &= \frac{\Omega_o}{2a} \\ c &= \frac{\Omega_o}{q} \\ M &= \sqrt{b^2 + \sqrt{\left(1+b^2\right)^2 - \frac{c}{\left(2a\right)^2}} + \sqrt{2b}\,\sqrt{1 + b^2 - \frac{c}{2\Omega_o^2} + \sqrt{\left(1+b^2\right)^2 - \frac{c}{\left(2a\right)^2}}}} \end{aligned} \tag{71.15b}$$

apply.

Narrow-Band Approximation. If the condition $\mathrm{BW}/\omega_o \ll 1$ is satisfied, then following simple transformations known as the narrow band approximation[2] can be used to map directly poles (or zeros) from the s-plane to the p-plane

$$p_p \approx \frac{BW}{2} s_p + j\omega_o, \quad p_z \approx \frac{BW}{2} s_z + j\omega_o \tag{71.16}$$

[1]A complex conjugate pole pair can be expressed as s_p, $s_p^* = u_p \pm j\omega_p = \omega_c e^{\pm j\theta} = (\omega_c, Q)$, where the pole quality factor Q is given by $Q = \frac{1}{2}\cos\theta$ and $\omega_c = (G_p^2 + \omega_p^2)^{\frac{1}{2}}$, $\theta = tg^{-1}\frac{\omega_p}{G_p}$.

[2]L. P. Huelsman, "An algorithm for the low-pass to bandpass transformation," *IEEE Trans. Education,* vol. E-H, p. 72, March 1968.

© 2003 by CRC Press LLC

These approximations are valid only if the transformed poles and zeros are in the vicinity of $j\omega_o$, that is, if $|s_p - \omega_o|/\omega_o \ll 1$.

Third, in order to obtain poles and zeros of the bandpass transfer function, mapping of complex zeros on the imaginary Ω axis (s_2, $s_x^* = \pm j\Omega_z$) takes place using the same mapping relations discussed next.

Mapping of Imaginary Frequency Axis. Consider a frequency $s = j\Omega$ and its mirror image $s = -j\Omega$ in the LPP. Using (71.13), these two frequencies are mapped into four frequencies: $\pm\omega_1$ and $\pm\omega_2$, where ω_1 and ω_2 are given by

$$\omega_2 = \Omega\frac{\mathrm{BW}}{2} + \sqrt{\omega_o^2 + \left(\Omega\frac{\mathrm{BW}}{2}\right)^2}$$
$$\omega_1 = -\Omega\frac{\mathrm{BW}}{2} + \sqrt{\omega_o^2 + \left(\Omega\frac{\mathrm{BW}}{2}\right)^2} \tag{71.17}$$

From (71.17), the following relations can be derived:

$$\omega_2 - \omega_1 = \mathrm{BW}\Omega$$
$$\omega_1\omega_2 = \omega_o^2 \tag{71.18}$$

It can be seen that with the LPP to bandpass transformation *frequencies are mapped into bandwidths.* A frequency Ω and its mirror image $-\Omega$ are mapped into two pairs of frequency points that have ω_0 as center of geometry. The interval from 0 to ∞ in the positive Ω axis maps into two intervals in the ω axis: the first from ω_o to $+\infty$ on the positive ω axis and the second from $-\omega_o$ to 0 to in the negative ω axis. The interval $-\infty$ to 0 on the negative Ω axis maps into two intervals: from $-\infty$ to $-\omega_o$ in the negative ω axis and from 0 to ω_o in the positive ω axis. The LPP passband and stopband edge frequencies $\Omega_p = \pm 1$ and $+\Omega_s$ are mapped into passband edge frequencies ω_{p1}, ω_{p2} and into stopband edge frequencies ω_{s1}, ω_{s2} that satisfy

$$\omega_{p2} - \omega_{p1} = \mathrm{BW}$$
$$\omega_{s2} - \omega_{s1} = \mathrm{BW}\Omega_s \tag{71.19}$$

and

$$\omega_{p1}\omega_{p2} = \omega_{s1}\omega_{s2} = \omega_o^2 \tag{71.20}$$

Figure 71.7 shows mapping of frequency points 1, 2, 3, and 4 in the Ω axis to points 1′, 2′, 3′, and 4′ and 1″, 2″, 3″, 4″ in the ω axis of the bandpass response.

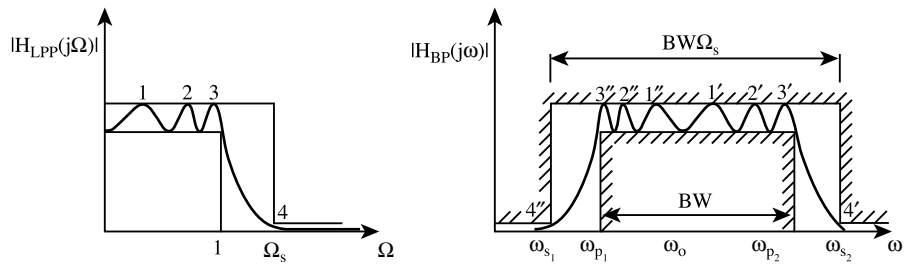

FIGURE 71.7 Low-pass to bandpass transformation.

© 2003 by CRC Press LLC

If the bandpass filter specifications do not satisfy (71.20) (which is usually the case), then either one of the stopband frequencies or one of the passband frequencies has to be redefined so that they become symmetric w.r.t. ω_o and an equivalent LPP filter can be specified. For given passband and stopband specifications ω_{p1}, ω_{p2}, ω_{s1}, ω_{s2}, A_p, A_s, the procedure to determine Ω_s for an equivalent LPP is as follows:

1. Calculate first the parameter ω_o in terms of the passband frequencies according to $\omega_o = \sqrt{\omega_{p1}\omega_{p2}}$.
2. Make the stopband frequencies geometrically symmetric with respect to ω_o determined in step 1 by redefining either ω_{s1} or ω_{s2} so that one of these frequencies becomes more constrained.[3] If $\omega_{s2} < \omega_o^2/\omega_{s2}$, then assign ω_{s1} the new value: $\omega_{s1} =< \omega_o^2/\omega_{s1}$. Otherwise assign ω_{s2} the new value $\omega_{s2} = \omega_o^2/\omega_{s1}$.
3. Calculate a selectivity factor of the LPP based on the redefined stopband frequency according to $\Omega_s = (\omega_{s2} - \omega_{s1})/(\omega_{p2} - \omega_{p1})$. This expression follows directly from (71.19) and (71.20).
4. Calculate now the parameter ω_o in terms of the stopband frequencies, according to $\omega_o = \sqrt{\omega_{s1}\omega_{s2}}$.
5. Symmetrize the passband frequencies w.r.t. the value of ω_o determined in step 4 by constraining either ω_{p1} or ω_{p2}. If $\omega_{p1} > \omega_o^2/\omega_{p2}$, then assign ω_{p1} the new value: $\omega_{p1} > \omega_o^2/\omega_{p2}$. Otherwise assign ω_{p2} the new value $\omega_{p2} > \omega_o^2/\omega_{p1}$.
6. Calculate the selectivity factor based on the new set of passband frequencies using the same expression as in step 3.
7. Select from step 3 or step 6 the maximum selectivity factor Ω_s and determine the transformation parameters ω_o and BW from the values calculated in steps 1 to 3 or in 4 to 6, whichever sequence leads to the maximum Ω_s, which leads to the lowest order n for $T_{\text{LPP}}(s)$ and with this to the least expensive filter implementation.

Example 2. Consider the following nonsymmetric specifications for a bandpass filter: $\omega_{s1} = 2\pi 9$, $\omega_{s2} = 2\pi 17$, $\omega_{p1} = 2\pi 10$ and $\omega_{p1} = 2\pi 14.4$ (all frequencies specified in krad/s). Application of the above procedure leads to a new value for the upper stopband frequency $\omega_{s2} = 16$ and from this to the following parameters: BW = $2\pi(14.4 - 10) = 2\pi 4.4$, $\omega_o^2 = 2\pi 9\ 2\pi 16 = 2\pi 10\ 2\pi 14.4 = (2\pi)^2\ 144$, and $\Omega_s = 16 - 9/(14.4 - 10) = 1.59$.

Bandpass Network Transformation. Consider now the transformation of capacitors and inductors in an LPP filter. An inductor in the LPP network has an impedance $z_l(s) = sl_n$. This becomes an impedance $z_s(p) = pL_s + 1/pC_s$, where $L_s = l_n/\text{BW}$ and $C_s = \text{BW}/l_n\omega_o^2$. Now consider a capacitor c_n in the LPP with admittance $Y_c(s) = sc_n$. Using the transformation (71.12), this becomes an admittance $Y_p(p) = pC_p + 1/pL_p$, where $C_p = c_n/\text{BW}$ and $L_p = \text{BW}/c_n\omega_o^2$. This indicates that to transform an LPP network into a bandpass network, inductors in the LPP network are replaced by the series connection of an inductor with value L_s and a capacitor with value C_s and capacitors in the LPP are replaced by the parallel combination of a capacitor C_p and inductor L_p. This is illustrated in Fig. 71.8. As with other transformations, resistors remain unchanged since they are not frequency dependent.

Example 3. Consider the LPP network shown in Fig. 71.3(a) with specifications $Ap = 2$ dB, $As = 45$ dB, and $\Omega_s = 1.6$. Derive a bandpass network using the parameters calculated in Example 2: $\omega_o^2 = (2\pi)^2\ 144$, BW = 2π 4.4 krad/s.

Solution. Straightforward application of the relations shown in Fig. 71.8(a) leads to the network of Fig. 71.8(b).

[3]The term "constraint specifications" is used here in the sense of redefining either a stopband frequency or a passband frequency so that one of the transition bands becomes narrower, which corresponds to tighter design specifications.

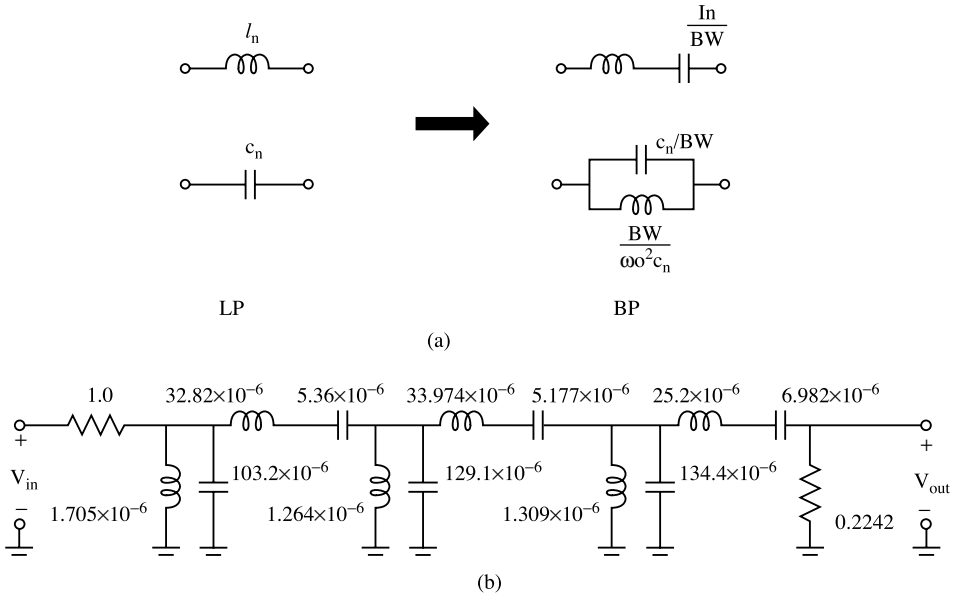

FIGURE 71.8 (a) LPP to bandpass network element transformations. (b) Bandpass network derived from LPP network of Fig. 71.3(a).

71.5 Low-Pass to Band-Reject Transformation

This transformation is characterized by

$$S = \mathrm{BW}\frac{p}{p^2 + \omega_o^2} \tag{71.21}$$

and it can be best visualized as a sequence of two transformations through the intermediate complex frequency variables $s' = u' + j\Omega' \cdot 1$. A normalized LPP to high-pass transformations

$$s = \frac{1}{s'} \tag{71.22}$$

followed by a bandpass transformation applied to s'

$$s' = \frac{1}{\mathrm{BW}}\frac{p^2 + \omega_o^2}{p} \tag{71.23}$$

Mapping of the imaginary ω axis to the Ω axis through this sequence of transformations leads to a band-rejection response in ω; frequency points 1, 2, 3, 4 have been singled out to better illustrate the transformation. Figure 71.9(a) shows the magnitude response of the LPP, Fig. 71.9(b) shows the high-pass response obtained through (71.22). This intermediate response is a normalized high-pass response with a passband extending from $\Omega'_p = 1$ to ∞ and a stopband extending from 0 to $\Omega'_s = 1/\Omega_s$. Figure 71.9(c) shows the magnitude response obtained by applying (71.23) to the variable s'. The frequency range from $\Omega' = 0$ to ∞ in Fig. 71.9(b) is mapped into the range from ω_o to ∞ and from $-\omega_o$ to 0. The frequency range from $-\infty$ to 0 in Ω' is mapped into the ranges from 0 to ω_o and from $-\infty$ to $-\omega_o$ in ω as indicated in Fig. 71.9(c). It can be seen that the bandpass transformation applied to a normalized high-pass response

© 2003 by CRC Press LLC

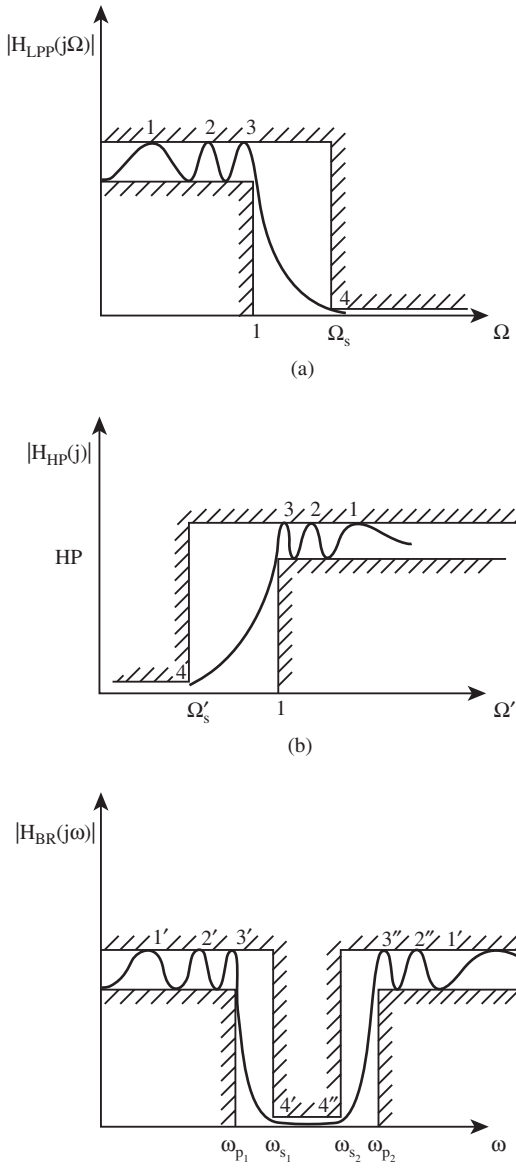

FIGURE 71.9 Low-pass to band-reject transformation: (a) Low-pass response, (b) normalized high-pass response, (c) band-reject response derived from (a) and (b).

creates two passbands with ripple A_p from $\omega = 0$ to ω_{p1} and from ω_{p2} to ∞ and a stopband with attenuation A_s from ω_{s1} to ωs_2. The following conditions are satisfied:

$$\begin{aligned} \omega_{s1}\omega_{s2} &= \omega_{p1}\omega_{p2} = \omega_o^2 \\ \omega_{s2} - \omega_{s1} &= \mathrm{BW}\ \Omega'_s = \mathrm{BW}/\Omega_s \\ \omega_{p2} - \omega_{p1} &= \mathrm{BW} \end{aligned} \tag{71.24}$$

© 2003 by CRC Press LLC

From (71.24), if ω_{s1}, ω_{s2}, ω_{p1}, ω_{p2} as well as A_p and A_s are specified for a band-rejection filter, then the selectivity factor of the equivalent LPP is calculated according to $\Omega_s = (\omega_{p2} - \omega_{p1})/(\omega_{s2} - \omega_{s1})$. Similar to the case of bandpass filters, the band-rejection specifications must be made symmetric with respect to ω_o so that an equivalent LPP can be specified. This is done following a similar procedure as for the bandpass transformation by constraining either one of the passband frequencies or one of the stopband frequencies so that the response becomes geometrically symmetric with respect to ω_o. The option leading to the largest selectivity factor (that corresponds in general to the least expensive network implementation) is then selected. In this case constraining design specifications refers to either increase ω_{p1} or ω_{s2} or to decrease ω_{p2} or ω_{s1}.

Example 4. Make following band-rejection filter specifications symmetric so that an equivalent LPP with the lowest Ω_s can be found: $\omega_{s1} = 2\pi\ 10$, $\omega_{s2} = 2\pi\ 14.4$, $\omega_{p1} = 2\pi\ 9$, $\omega_{p2} = 2\pi\ 17$.

Solution. Defining ω_o in terms of the passband frequencies the upper stopband frequency acquires the new value $\omega_{s2} = 2\pi\ 15.3$ and the selectivity factor $\Omega_s = 1.509$ is obtained. If ω_o is defined in terms of the stopband frequencies the upper passband frequency is assigned the new value $\omega_{p2} = 2\pi\ 16$ and the selectivity factor $\Omega_s = 1.59$ is obtained. Therefore, the second option with $\Omega_s = 1.59$ corresponds to the largest selectivity factor and the following transformation parameters result: $BW = \omega_{p2}–\omega_{p1} = 2\pi(16–9) = 2\pi\ 7$, $\omega_o^2 = \omega_{p1}\ \omega_{p1} = (2\pi)^2\ 144$ is made.

Transformation of Poles and Zeros of the LPP Transfer Function. To determine the poles and zeros of the band-rejection transfer function $H_{BR}(p)$ starting from those of $H_{LPP}(s)$, again a sequence of two transformations is required: 1) poles and zeros of the LPP (denoted s_{p1}, s_{p2}, …, *spn* and s_{z1}, s_{z2}, …, s_{zn}) are transformed into poles and zeros of $H_{HP}(s')s'_{p1}$, s'_{p2}, …, s'_{z1}, s'_{z2}, …, s'_{zm}, which are reciprocal to those of the LPP. The high-pass also acquires $n - m$ zeros at the origin as explained in Section 71.3; 2). The transformations described in Section 71.4 are then applied to the high-pass poles zeros s'_{p1}, s'_{p2}, …, s'_{z1}, s'_{z2}, …, s'_{zm}.

Band-Rejection Network Transformation. Using the transformation (71.21), an inductor in the LPP network with admittance $y_1(s) = 1/sl_n$ becomes an admittance $Y_p(p) = pC_p + 1/pL_p$, where $C_p = 1/BW\ l_n$ and $L_p = BW\ l_n/\omega_o^2$. A capacitor c_n in the LPP with impedance $z_c(s) = 1/sc_n$ becomes with (71.20) an impedance $Z_s(p) = pL_s + 1/pC_s$, where $L_s = 1/c_nBW$ and $C_s = c_nBW/\omega_o^2$. To transform an LPP network into a bandpass network, capacitors in the LPP network are replaced by a series connection of an inductor with value L_s and a capacitor with value C_s, while inductors in the LPP are replaced by the parallel combination of a capacitor C_p and inductor L_p. This is illustrated in Fig. 71.10(a).

Example 5. Consider the LPP network shown in Fig. 71.3(a). It corresponds to the specifications: $A_p = 2$ dB, $A_s = 45$ dB and $\Omega_s = 1.6$. Transform it into a bandpass network using the following parameters from Example 4: $\omega_o^2 = (2\pi)^2\ 144$, $BW = 2\pi\ 7$ Mrad/s (units for ω_o are μrad/s).

Solution. The circuit of Fig. 71.10(b) is obtained applying the transformations indicated in Fig. 71.10(a).

72.1 Introduction

Using sensitivity one can evaluate the change in a filter performance characteristic (bandpass, *Q*-factor) or in a filter function (input impedance, transfer function) resulting from a change in the nominal value of one or more of the filter components. Hence, sensitivities and based on them, sensitivity measures, can be used to compare different realizations of electric filters that meet the same specifications. Sensitivities can also be used to estimate the spread of the performance characteristic caused by the spread of the element values. In the design of filters one is interested both in choosing realizations that have low sensitivities and in minimizing the sensitivities. This allows use of components with wider tolerances for a given variation or a given spread of the filter characteristic or function.

72.2 Definitions of Sensitivity

Let y be the filter performance characteristic and x be the value of the parameter of a filter element that is causing the characteristic change. The **relative sensitivity** is defined as follows:

$$S_x^y(y,x) = \frac{\partial y}{\partial x}\frac{x}{y} = \frac{\partial y/y}{\partial x/x} = \frac{\partial(\ln y)}{\partial(\ln x)} \tag{72.1}$$

© 2003 by CRC Press LLC

TABLE 72.1 Properties of the Relative Sensitivity

Property Number	Relation	Property Number	Relation
1	$S_x^{ky} = S_{kx}^{y} = S_x^y$	10	$S_x^{y_1/y_2} = S_x^{y_1} - S_x^{y_2}$
2	$S_x^x = S_x^{kx} = S_{kx}^x = 1$	11	$S_{x_1}^{y} = S_{x_2}^{y} S_{x_1}^{x_2}$
3	$S_{1/x}^{y} = S_x^{1/y} = -S_x^y$	12[a]	$S_x^y = S_x^{\lvert y\rvert} + j \arg y S_x^{\arg y}$
4	$S_x^{y_1 y_2} = S_x^{y_1} + S_x^{y_2}$	13[a]	$S_x^{\arg y} = \dfrac{1}{\arg y} \operatorname{Im} S_x^y$
5	$S_x^{\prod_{i=1}^{n} y_i} = \sum_{i=1}^{n} S_x^{y_i}$	14[a]	$S_x^{\lvert y\rvert} = \operatorname{Re} S_x^y$
6	$S_x^{y^n} = n\, S_x^y$	15	$S_x^{y+z} = \dfrac{1}{y+z}\left(y\, S_x^y + z\, S_x^z\right)$
7	$S_x^{x^n} = n\, S_x^{kx^n} = n$	16	$S_x^{\sum_{i=1}^{n} y_i} = \dfrac{\sum_{i=1}^{n} y_i\, S_x^{y_i}}{\sum_{i=1}^{n} y_i}$
8	$S_{x^n}^{y} = \dfrac{1}{n} S_x^y$	17	$S_x^{\ln y} = \dfrac{1}{\ln y} S_x^y$
9	$S_{x^n}^{x} = S_{kx^n}^{x} = \dfrac{1}{n}$		

[a] In this relation, y is a complex quantity and x is a real quantity.

It is usually used to establish the approximate relationship between the relative changes $\delta y = \Delta y/y$ and $\delta x = \Delta x/x$. Here, Δy and Δx are absolute changes. The interpretation of relative changes δy and δx depends on the problem at hand. If these relative changes are small, one writes that[1]

$$\delta y \approx \mathbf{S}_x^y(y,x)\delta x \tag{72.2}$$

The argument in the parentheses of (72.2), when it does not involve any ambiguity, will usually be omitted, i.e., we will write simply $\mathbf{S}_x^y$. Some simple properties of the sensitivity determined by (72.1) can be established by differentiation only. They are summarized in Table 72.1 [1].

One can also define two *semirelative sensitivities*

$$\mathbf{S}_x(y,x) = x\frac{\partial y}{\partial x} = \frac{\partial y}{\partial x/x} = \frac{\partial y}{\partial(\ln x)} \tag{72.3}$$

which is here frequently denoted by $\mathbf{S}_x(y)$ and

$$\mathbf{S}^y(y,x) = \frac{1}{y}\frac{\partial y}{\partial x} = \frac{\partial y/y}{\partial x} = \frac{\partial(\ln y)}{\partial x} \tag{72.4}$$

[1]This relationship assumes that $\mathbf{S}_x^y$ is different from zero. If $\mathbf{S}_x^y = 0$, the relative changes δy and δx may be independent. This happens, for example, in the passband of doubly terminated *LC* networks (see below), where the passband attenuation always increases independently on the sign in the variation of a reactance element.

© 2003 by CRC Press LLC

which is also denoted by $\mathbf{S}^{y}(x)$. Both these sensitivities can be used in a way similar to (72.2) to establish the approximate relationships between one relative and one absolute change. Finally, the *absolute sensitivity* $\mathbf{S}(y, x)$ is simply the partial derivative of y with respect to x, i.e., $\mathbf{S}(y, x) = \partial y/\partial x$ and can be used to establish the relationship between absolute changes. The variable x represents the value for any component of the filter. The set of values for all the components will be denoted as $\mathbf{x} = \{x_i\}$, where $i = 1, 2, \ldots, n$.

72.3 Function Sensitivity to One Variable

Let the chosen quantity y be the filter function $F(s, x)$. When it does not involve any ambiguity this function will be denoted as $F(s)$. The element x is a passive or active element in the circuit realization of the function. The *function sensitivity* is defined as

$$\mathbf{S}_x^{F(s,x)} = \frac{\partial F(s,x)}{\partial x}\frac{x}{F(s,x)} \tag{72.5}$$

Under conditions of sinusoidal steady state, when $s = j\omega$, the function $F(j\omega, x)$ can be represented as

$$F(j\omega,x) = \left|F(j\omega,x)\right| e^{j\arg F(j\omega,x)} = e^{-\alpha(\omega,x)+j\beta(\omega,x)} \tag{72.6}$$

and using the left-hand part of (72.6), one finds that

$$\mathbf{S}_x^{F(j\omega,x)} = \mathrm{Re}\,\mathbf{S}_x^{F(j\omega,x)} + j\,\mathrm{Im}\,\mathbf{S}_x^{F(j\omega,x)} = \mathbf{S}_x^{|F(j\omega,x)|} + j\frac{\partial \arg F(j\omega,x)}{\partial x/x} \tag{72.7}$$

as follows from property 12 of Table 72.1. Thus, the real part of the function sensitivity gives the relative change in the magnitude response, and the imaginary part gives the change in the phase response, both with respect to a normalized element change. If one determines $\delta F = [F(j\omega, x) - F(j\omega, x_0)]/F(j\omega, x_0)$ and $\delta x = (x - x_0)/x_0$, where x_0 is the initial value of the element and the deflection $\Delta x = x - x_0$ is small, then (72.5) is used to write

$$\delta F \approx \mathbf{S}_x^{F(s,x)}\delta x \tag{72.8}$$

And if one determines $\delta|F| = [|F(j\omega, x)| - |F(j\omega, x_0)|]/|F(j\omega, x_0)|$, then using (72.7), one obtains

$$\delta|F| \approx \mathrm{Re}\,\mathbf{S}_x^{F(j\omega,x)}\delta x \tag{72.9}$$

These calculations assume that the sensitivity is also calculated at $x = x_0$.

A frequently used alternate form of (72.7) is obtained by using the attenuation function $\alpha(\omega, x) = \ln(1/|F(j\omega, x)|) = -\ln|F(j\omega, x)|$ and the phase function $\beta(\omega,x) = \arg F(j\omega, x)$ defined by the right-hand part of (72.6) [this interpretation is usually used when $F(s)$ is the filter transfer function $T(s)$]. In terms of these, (72.7) may be rewritten as

$$\mathbf{S}_x^{F(j\omega,x)} = -\frac{\partial\alpha(\omega,x)}{\partial x/x} + j\frac{\partial\beta(\omega,x)}{\partial x/x} = -\mathbf{S}_x\left[\alpha(\omega),x\right] + j\mathbf{S}_x\left[\beta(\omega),x\right] \tag{72.10}$$

From (72.7) and (72.10), one concludes that $\mathbf{S}_x^{|F(j\omega,x)|} = -\mathbf{S}_x[\alpha(\omega, x)]$. Besides, using (72.7) and (72.10), one can write that

$$\Delta\arg F(j\omega,x) = \Delta\beta(\omega,x) \approx \mathrm{Im}\,\mathbf{S}_x^{F(j\omega,x)}\,\delta x = \mathbf{S}_x\left[\beta(\omega,x)\right]\delta x \tag{72.11}$$

where $\Delta \arg F(j\omega, x) = \arg F(j\omega, x) - \arg F(j\omega, x_0)$.

© 2003 by CRC Press LLC

When the filter function is a ratio of two polynomials $N(s)$ and $D(s)$, i.e.,

$$F(s)=\frac{N(s)}{D(s)} \tag{72.12}$$

then, assuming that the coefficients of $N(s)$ and $D(s)$ depend on the element x, and using (72.1), one derives the following form of (72.5):

$$\mathbf{S}_x^{F(s)}=x\left[\frac{\partial N(s)/\partial x}{N(s)}-\frac{\partial D(s)/\partial x}{D(s)}\right] \tag{72.13}$$

which is sometimes more convenient.

72.4 Coefficient Sensitivity

In general, a network function $F(s)$ for any active or passive lumped network is a ratio of polynomials having the form

$$F(s)=\frac{N(s)}{D(s)}=\frac{a_0+a_1s+a_2s^2+\cdots+a_ms^m}{d_0+d_1s+d_2s^2+\cdots+d_ns^n} \tag{72.14}$$

in which the coefficients a_i and d_i are real and can be functions of an arbitrary filter element x. For such an element x one may define the *relative coefficient sensitivities* as follows:

$$\mathbf{S}_x^{a_i}=\frac{\partial a_i}{\partial x}\frac{x}{a_i} \qquad \mathbf{S}_x^{d_i}=\frac{\partial d_i}{\partial x}\frac{x}{d_i} \tag{72.15}$$

or the *semirelative coefficient sensitivities* (they are even more useful):

$$\mathbf{S}_x(a_i)=x\frac{\partial a_i}{\partial x} \qquad \mathbf{S}_x(d_i)=x\frac{\partial d_i}{\partial x} \tag{72.16}$$

The coefficient sensitivities defined in this way are related to the function sensitivity introduced in the previous section. Indeed, using (72.13) and (72.16) one easily obtains that

$$\mathbf{S}_x^{F(s)}=\frac{\sum_{i=0}^{m}\mathbf{S}_x(a_i)s^i}{N(s)}-\frac{\sum_{i=0}^{n}\mathbf{S}_x(d_i)s^i}{D(s)} \tag{72.17}$$

or, in terms of relative sensitivities, that

$$\mathbf{S}_x^{F(s)}=\frac{\sum_{i=0}^{m}\mathbf{S}_x^{a_i}a_is^i}{N(s)}-\frac{\sum_{i=0}^{n}\mathbf{S}_x^{d_i}d_is^i}{D(s)} \tag{72.18}$$

The manner is which the filter function depends on any element x is a bilinear dependence [2]. Thus, $F(s)$ of (72.14) may also be written to the form

$$F(s)=\frac{N(s)}{D(s)}=\frac{N_1(s)+xN_2(s)}{D_1(s)+xD_2(s)} \tag{72.19}$$

© 2003 by CRC Press LLC

where $N_1(s)$, $N_2(s)$, $D_1(s)$, and $D_2(s)$ are polynomials with real coefficients that are not functions of the filter element x. This is true whether x is chosen to be the value of a passive resistor or capacitor, the gain of some amplifier or controlled source, etc. Only for filters with ideal transformers, ideal gyrators and ideal negative impedance converters the filter functions are the biquadratic functions of the ideal element parameters [2].

Because of the bilinear dependence property there are only two ways in which a coefficient, say, a_i may depend on a network element. The first of these has the form $a_i = kx$, in which case $\mathbf{S}_x^{a_i} = 1$, and $\mathbf{S}_x(a_i) = kx$; the second possible dependence for a coefficient a_i (or d_i) is $a_i = k_0 + k_1x$, in which case $\mathbf{S}_x^{a_i} = k_1x/(k_0 + k_1x)$ and $\mathbf{S}_x(a_i) = k_1x$. In this latter situation one has two cases: 1) the parities of the terms are the same, and thus the magnitude of $\mathbf{S}_x^{a_i}$ is less than one; and 2) the terms have opposite parities, in which case the magnitude of $\mathbf{S}_x^{a_i}$ is greater than one. In the last case the relative sensitivity $\mathbf{S}_x^{a_i}$ can have an infinite value, as the result of dividing by zero. In this case a more meaningful measure of the change would be to use the semirelative coefficient sensitivity $\mathbf{S}_x(a_i)$.

72.5 Root Sensitivities

A filter function can also be represented as

$$F(s) = \frac{a_m \prod_{i=1}^{m} (s - z_i)}{d_n \prod_{i=1}^{n} (s - p_i)} \tag{72.20}$$

where z_i are zeros and p_i are poles. If $F(s)$ is also a function of the filter element x, the location of these poles and zeros will depend on this element. This dependence is described by the *semirelative root sensitivities*

$$\mathbf{S}_x(z_i) = x\frac{\partial z_i}{\partial x} \qquad \mathbf{S}_x(p_i) = x\frac{\partial p_i}{\partial x} \tag{72.21}$$

We will give calculation of the pole sensitivities only (they are used more frequently, to verify the stability) calculating the absolute change Δp_i for a given δx, the calculation of the zero sensitivities follows the same pattern. Assume that p_i is a simple pole of $F(s)$ then

$$D(p_i) = D_1(p_i) + xD_2(p_i) = 0 \tag{72.22}$$

When the parameter x becomes $x + \Delta x$, the pole p_i moves to the point $p_i + \Delta p_i$. Substituting these values in (72.22) one obtains that

$$D_1(p_i + \Delta p_i) + (x + \Delta x)D_2(p_i + \Delta p_i) = 0 \tag{72.23}$$

If one uses Taylor's expansions $D_1(p_i + \Delta p_i) = D_1(p_i) + [\partial D_1(s)/\partial s]\big|_{s=p_i} \Delta p_i + \cdots$ and $D_2(p_i + \Delta p_i) = D_2(p_i) + [\partial D_2(s)/\partial s]\big|_{s=p_i} \Delta p_i + \cdots$ and substitutes them in (72.23), keeping the terms of the first order of smallness one obtains that

$$\frac{\Delta p_i}{\Delta x} = -\frac{D_2(p_i)}{D'(p_i)} \tag{72.24}$$

where $D'(p_i) = [\partial D(s)/\partial s]\big|_{s=p_i}$. This result allows calculation of the pole sensitivity, which becomes

© 2003 by CRC Press LLC

$$\mathbf{S}_x(p_i) = x\frac{\partial p_i}{\partial x} = -x\frac{D_2(p_i)}{D'(p_i)} \tag{72.25}$$

One can write that

$$D_1(s) = b_0 + b_1 s + b_2 s^2 + \cdots \quad \text{and} \quad D_2(s) = c_0 + c_1 s + c_2 s^2 + \cdots$$

Then, taking into consideration (72.19), one can write that

$$D(s) = d_0 + d_1 s + d_2 s^2 + \cdots = (b_0 + xc_0) + (b_1 + xc_1)s + (b_2 + xc_2)s^2 + \cdots$$

Differentiating this result, one obtains that

$$D_2(s) = c_0 + c_1 s + c_2 s^2 + \cdots = \partial d_0/\partial x + (\partial d_1/\partial x)s + (\partial d_2/\partial x)s^2 + \cdots = (1/x)\left[\mathbf{S}_x(d_0) + \mathbf{S}_x(d_1)s + \mathbf{S}_x(d_2)s^2 + \cdots\right]$$

From the other side, $D'(s) = \partial D(s)/\partial s = d_1 + 2d_2 s + 3d_3 s^2 + \cdots$. Calculating the two last expressions at $s = p_i$ and substituting them in (72.25), one obtains that

$$\mathbf{S}_x(p_i) = -\frac{\sum_{j=0}^{n} p_i^j \mathbf{S}_x(d_j)}{\sum_{j=0}^{n-1}(j+1)d_{j+1}p_i^j} = -\frac{\sum_{j=0}^{n} d_j p_i^j \mathbf{S}_x^{d_j}}{\sum_{j=0}^{n-1}(j+1)d_{j+1}p_i^j} \tag{72.26}$$

The result (72.26) produces the pole sensitivity without representation of poles via coefficients of $D(s)$ (which is not possible if $n > 4$). It is convenient even for polynomials of low degree [3]. If p_i is a multiple root then the derivative $D'(p_i) = 0$ and $\mathbf{S}_x(p_i) = \infty$. But this does not mean that the variation δx causes infinitely large change of the pole location. This variation splits this multiple root into a group of simple roots. The location of these roots can be calculated in the following way. The roots are always satisfying the equation $D_1(s) + (x + \Delta x)D_2(s) = 0$, i.e., the equation $D(s) + \Delta x D_2(s) = 0$. One can rewrite the last equation as

$$1 + \delta x\left[\frac{xD_2(s)}{D(s)}\right] = 0 \tag{72.27}$$

where $\delta x = \Delta x/x$ as usual. The function $G(s) = [xD_2(s)/D(s)]$ can be represented as a sum of simple ratios. If the roots of $D(s)$ [i.e., poles of $F(s)$] are simple, then

$$G(s) = \sum_{j=1}^{n} \frac{K_{ip}}{s - p_i} + K_{0p} \tag{72.28}$$

where $K_{0p} = G(\infty)$ and $K_{ip} = (s - p_i)\,G(s)|_{s=p_i}$. In the vicinity of $s = p_i$, (72.27) can be substituted by

$$\lim_{s \to p_i}\left[1 + \delta x G(s)\right] = 1 + \delta x \frac{K_{ip}}{s - p_i} \tag{72.29}$$

Equating the right-hand side of (72.29) to zero and substituting $s = p_i + \Delta p_i$ in this equation, one obtains that when $\Delta x \to 0$, the pole sensitivity can be calculated as

© 2003 by CRC Press LLC

$$\mathbf{S}_x(p_i) = \frac{\partial p_i}{\partial x / x} = -K_{ip} \tag{72.30}$$

If a pole of $G(s)$ is not simple, but multiple, with the multiplicity of k, then the limit form of (72.28) will be

$$1 + \delta x \left[\frac{K_{ip}^{(1)}}{s - p_i} + \frac{K_{ip}^{(2)}}{(s - p_i)^2} + \cdots + \frac{K_{ip}^{(k)}}{(s - p_i)^k} \right] = 0 \tag{72.31}$$

If now $s = p_i + \Delta p_i$ is substituted in (72.31) and only the largest term is kept, one finds that

$$\Delta p_i = \left[-\delta x K_{ip}^{(k)} \right]^{1/k} \tag{72.32}$$

Hence, these new simple roots of $D(s)$ are equiangularly spaced on a circle around p_i.

Similar calculations with similar results can be obtained for the zeros z_i of the function $F(s)$. They, together with the calculation for poles, allow one to establish the relationship between relative sensitivity of $F(s)$ and the sensitivities of its zeros and poles. Indeed, taking into consideration (72.19), the result (72.13) can be rewritten as

$$\mathbf{S}_x^{F(s)} = \frac{xN_2(s)}{N(s)} - \frac{xD_2(s)}{D(s)} = H(s) - G(s) \tag{72.33}$$

Expanding both $H(s)$ and $G(s)$ into sums of simple ratios, one obtains

$$\mathbf{S}_x^{F(s)} = \sum_{i=1}^{n} \frac{\mathbf{S}_2(p_i)}{s - p_i} - \sum_{i=1}^{m} \frac{\mathbf{S}_x(z_i)}{s - z_i} + K_{0z} - K_{0p} \tag{72.34}$$

Here, $K_{0z} = H(\infty)$, $K_{0p} = G(\infty)$, and it is assumed that both zeros and poles of $F(s)$ are simple. Finally, a useful modification is obtained for the case when a coefficient d_k in the polynomial $D(s) = d_0 + d_1 s + d_2 s^2 + \cdots$ is considered as a variable parameter. If d_k is substituted by $d_k + \Delta d_k$, the polynomial $D(s)$ becomes $D(s) + \Delta d_k s^k$. For this case the function $G(s) = (\delta d_k s^k)/D(s)$ and one can write that

$$1 + \frac{\Delta d_k s^k}{D(s)} = 1 + \frac{\Delta d_k s^k}{(s - p_i) D'(s)} \tag{72.35}$$

Here $D'(s) = \partial D(s)/\partial s$ and it is assumed that p_i is a simple root of $D(s)$. Hence, in the vicinity of $s = p_i + \Delta p_i$, the value of Δp_i can be obtained from the equation

$$1 + \frac{\Delta d_k p_i^k}{\Delta p_i D'(p_i)} = 0 \tag{72.36}$$

From (72.36), one finds that

$$\frac{\Delta p_i}{\Delta d_k} = -\frac{p_i^k}{D'(p_k)} \tag{72.37}$$

and, if necessary, the *pole-coefficient sensitivity*

$$\mathbf{S}_{d_k}(p_i) = \frac{\partial p_i}{\partial d_k / d_k} = -d_k \frac{p_i^k}{D'(p_i)} \tag{72.38}$$

© 2003 by CRC Press LLC

72.6 Statistical Model for One Variable

Assume that x is the value of a filter element. This x differs from the average value $\bar{x}$ in a way that cannot be controlled by the filter designer. This situation can be modeled by considering x as a random variable. Its statistical distribution depends on the manufacturing process. An approximate calculation is sufficient in most practical cases. If $F(s, x)$ is a filter function that depends on x, then the variation $F(s, x)$ around the average value $\bar{x}$ can be approximated by

$$F(s,x) \approx F(s,\bar{x}) + (x-\bar{x})\left.\frac{\partial F(s,x)}{\partial x}\right|_{x=\bar{x}} \tag{72.39}$$

The statistical interpretation of (72.39) follows. Due to its dependence on the random variable x, $F(s, x)$ becomes a random variable as well. The values $\bar{x}$, $F(s, \bar{x}) = \bar{F}(s)$ and $\partial F(s, x)/\partial x$ calculated at $x = \bar{x}$ are constants. The last constant can be denoted as $\partial F(s, \bar{x})/\partial x$. Instead of x and $F(s, x)$ it is preferable to use their relative deviations from the average values, namely $\delta x = (x - \bar{x})/\bar{x}$ and $\delta F(s) = (F - \bar{F})/\bar{F}$. Then one obtains from (72.39) that

$$\delta F(s) \approx \left[\frac{\bar{x}}{F(s,\bar{x})}\frac{\partial F(s,\bar{x})}{\partial x}\right]\delta x = \mathbf{S}_x^{F(s,\bar{x})}\delta x \tag{72.40}$$

Hence, in the first-order approximation the random variables $\delta F(s)$ and δx are proportional, and the proportionality factor is the same sensitivity of $F(s,x)$ with respect to x calculated at the average point $\bar{x}$. Thus, on the $j\omega$ axis the average and the variance of $\delta F(j\omega)$ and δx are related by

$$\mu_{\delta F} \approx \mathbf{S}_x^{F(j\omega,\bar{x})}\mu_{\delta x} \tag{72.41}$$

and

$$\sigma_{\delta F}^2 = E\left\{\left|\frac{F(j\omega,x) - F(j\omega,\bar{x})}{F(j\omega,\bar{x})}\right|^2\right\} \approx \left|\mathbf{S}_x^{F(j\omega,\bar{x})}\right|^2 \sigma_{\delta x}^2 \tag{72.42}$$

where $E\{\ \}$ means the expected value. Here, $\mu_{\delta x}$ is the average value of δx, $\mu_{\delta F}$ is the average value of δF, and $\sigma_{\delta x}^2$ and $\sigma_{\delta F}^2$ are the dispersions of these values. If the deviation δx is bound by the modulus $M_{\delta x}$, i.e., the probability distribution is concentrated in the interval $[-M_{\delta x}, M_{\delta x}]$, then the deviation δF is bound in the first approximation by

$$|\delta F| \le M_{\delta F} \approx \left|\mathbf{S}_x^{F(j\omega,\bar{x})}\right| M_{\delta x} \tag{72.43}$$

Normally, the probability distribution of x should be centered around the average value $\bar{x}$, so that it can be assumed $\mu_{\delta x} = 0$. This implies that $\mu_{\delta F} = 0$ as well.

It is not difficult to see that (72.8) and (72.40) are different by interpretation of δx and δF (since these were deflections from the nominal point, it was tacitly assumed that we were dealing with one sample of the filter, here they are random) and the point of calculation of sensitivity. The interpretation with a random variable is possible for (72.9) as well. One has to determine $\delta|F| = [|F(j\omega, x)| - |F(j\omega, \bar{x})|]/|F(j\omega, \bar{x})|$, then using (72.9) one can write

$$\mu_{\delta|F|} \approx \mathrm{Re}\ \mathbf{S}_x^{F(j\omega,\bar{x})}\mu_{\delta x} \tag{72.44}$$

and

© 2003 by CRC Press LLC

$$\sigma^2_{\delta|F|} \approx \left(\mathrm{Re}\, S_x^{F(j\omega,\bar{x})}\right)^2 \sigma^2_{\delta x} \tag{72.45}$$

The result (72.11) can also be interpreted for random variables and allow one to calculate the average and the variance of the change in the filter function argument (which is hardly ever done in filter design).

72.7 Multiparameter Sensitivities and Sensitivity Measures

The multiparameter sensitivities (sometimes [4] they are called sensitivity indices) appear as an effort to introduce generalized functions that represent the influence of all filter elements. They can be used for comparison of different designs and should be minimized in the design process. The sensitivity measures appear as numbers (they are functionals of the multiparameter sensitivities) that should be minimized in the design.

First of all, the definition of function sensitivity given in (72.5) is readily extended to determine the effect on the filter function of variations of more than one component. In this case $F(s, x_1, x_2, \ldots, x_n) = F(s,\mathbf{x})$ and one may write that

$$\frac{dF(s,\mathbf{x})}{F(s,\mathbf{x})} = d\left[\ln F(s,\mathbf{x})\right] = \sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(s,\mathbf{x})} \frac{dx_i}{x_i} \tag{72.46}$$

where n is the number of components being considered. Here, $\mathbf{S}_{x_i}^{F(s,\mathbf{x})} = [x_i \partial F(s,\mathbf{x})]/[F(s,\mathbf{x})\partial x_i]$. From this result one directly (substituting $s = j\omega$ and separating real and imaginary parts) obtains that

$$\frac{d|F(j\omega,\mathbf{x})|}{|F(j\omega,\mathbf{x})|} = \sum_{i=1}^{n} \mathrm{Re}\ \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \frac{dx_i}{x_i} \tag{72.47}$$

and

$$d\arg\ F(j\omega,\mathbf{x}) = \sum_{i=1}^{n} \mathrm{Im}\ \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \frac{dx_i}{x_i} \tag{72.48}$$

The results (72.47) and (72.48) are used to evaluate the deviations of the magnitude and phase values of a given filter realization from their nominal values when the circuit elements have prescribed normalized deviations $\delta x_i = (x_i - x_{i0})/x_{i0}$ ($i = 1, 2, \ldots, n$). One can introduce a column vector of normalized deviation $\delta\mathbf{x} = [\delta x_1\ \delta x_2 \ldots \delta x_n]^t$, where t means transpose and a sensitivity row vector

$$\mathbf{S}_{\mathbf{x}}^{F(s,\mathbf{x})} = \left[\mathbf{S}_{x_1}^{F(s,\mathbf{x})}\ \ \mathbf{S}_{x_2}^{F(s,\mathbf{x})}\ \ \cdots\ \ \mathbf{S}_{x_n}^{F(s,\mathbf{x})}\right] \tag{72.49}$$

Then defining $\delta F(s,\mathbf{x}) = [F(s,\mathbf{x}) - F(s,\mathbf{x}_0)]/F(s,\mathbf{x}_0)$ one can use (72.46) to write

$$\delta F(s,\mathbf{x}) \approx \mathbf{S}_{\mathbf{x}}^{F(s,\mathbf{x})} \delta\mathbf{x} \tag{72.50}$$

which is analogous to (72.8). As was mentioned before, the calculation of the filter function magnitude change is traditionally considered of primary importance in filter design. Introducing $\delta|F(j\omega, \mathbf{x})| = [|F(j\omega, \mathbf{x})| - |F(j\omega, \mathbf{x}_0)|]/|F(j\omega, \mathbf{x}_0)|$ and using (72.47), one writes

$$\delta|F(j\omega,\mathbf{x})| \approx \left[\mathrm{Re}\ \mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\right] \delta\mathbf{x} \tag{72.51}$$

where the row vector

© 2003 by CRC Press LLC

$$\left[\operatorname{Re} \mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\right] = \left[\operatorname{Re} \mathbf{S}_{x_1}^{F(j\omega,\mathbf{x})} \operatorname{Re} \mathbf{S}_{x_2}^{F(j\omega,\mathbf{x})} \cdots \operatorname{Re} \mathbf{S}_{x_n}^{F(j\omega,\mathbf{x})}\right] \tag{72.52}$$

is used. This vector is determined by the function $F(s, \mathbf{x})$ and its derivatives calculated at $\mathbf{x} = \mathbf{x}_0$. To characterize and compare the vectors of this type one can introduce different vector measures that are called *sensitivity indices*. The most frequently used ones are the *average sensitivity index*

$$\psi(F) = \sum_{i=1}^{n} \operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \tag{72.53}$$

then the *worst-case sensitivity index*

$$\nu(F) = \sum_{i=1}^{n} \left|\operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right| \tag{72.54}$$

(sometimes it is called worst-case magnitude sensitivity), and, finally, the *quadratic sensitivity index*

$$\rho(F) = \left[\sum_{i=1}^{n} \left(\operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right)^2\right]^{1/2} \tag{72.55}$$

These sensitivity indices can be considered as multiparameter sensitivities.

If we let the individual nominal values of n elements be given as x_{i0}, then we may define a tolerance constant ε_i (positive number) by the requirement that

$$x_{i0}(1-\varepsilon_i) \le x_i \le x_{i0}(1+\varepsilon_i) \tag{72.56}$$

Then we may define a *worst-case measure of sensitivity*

$$M_W = \int_{\omega_1}^{\omega_2} \left(\sum_{i=1}^{n} \left|\operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right| \varepsilon_i\right) d\omega \tag{72.57}$$

The goal of the filter design should be the search for the set of tolerance constants yielding the least expensive in the production filter. This is a difficult problem, and at the design stage it can be modeled by the minimization of the chosen sensitivity measure. In the design based on the worst-case measure of sensitivity the usual approach [2] is to chose the tolerance constants in such a way that the contributions $\left|\operatorname{Re} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right| \varepsilon_i$ are approximately equal, i.e., the elements with lower sensitivities get wider tolerance constants.

For any values of the filter elements x_i satisfying (72.56), the magnitude characteristic will lie within the definite bounds that are apart from the nominal characteristic by the distance less than $\varepsilon_{i\max} \nu(F)$. If the tolerance constants are all equal to ε, then the maximum deviation from the nominal characteristic (when $\mathbf{x} = \mathbf{x}_0$) is thus given as $\varepsilon \nu(F)$. And the worst-case measure of sensitivity becomes, for this case

$$M_W = \varepsilon \int_{\omega_1}^{\omega_2} \nu(F) d\omega \tag{72.58}$$

Considering the imaginary parts of the sensitivity row vector one can introduce corresponding sensitivity indices and similar sensitivity measures for the filter function phase.

The element tolerances obtained using the worst-case sensitivity index and measure are extremely tight and this set of elements is frequently unfeasible. Besides, with given tolerances, the set of elements

© 2003 by CRC Press LLC

producing the worst-case sensitivity is never obtained in practice. A more feasible set of tolerances is obtained when one uses the sum of the squares of the individual functions. One may define a *quadratic measure of sensitivity* as

$$M_Q = \int_{\omega_1}^{\omega_2} \left[\sum_{i=1}^{n} \left(\text{Re } \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right)^2 \varepsilon_i^2 \right] d\omega \tag{72.59}$$

In the design using the sensitivity measure given by (72.59) one also tries to get the tolerances so that the contributions of each term $(\text{Re } \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})})^2 \varepsilon_i^2$ are approximately equal in the considered bandwidth. Again, if the tolerances are equal then this expression is simplified to

$$M_Q = \varepsilon^2 \int_{\omega_1}^{\omega_2} \rho^2(F)\, d\omega \tag{72.60}$$

useful for comparison of different filters.

As one can see, the multivariable sensitivities appear as a result of certain operations with the sensitivity row vector components. Additional multivariable sensitivities could be introduced, for example, the sum of magnitudes of vector components, the sum of their squares, etc. The multivariable sensitivities and the measures considered above represent the most frequently used in filter design in the context of filter characteristic variations.

The case of random variables can also be generalized so that imprecisions of the values of several elements are simultaneously considered. Around the nominal value $\bar{\mathbf{x}} = [\bar{x}_i]$ $(i = 1, 2, \ldots, n)$ the function $F(s, \bar{\mathbf{x}})$ can be approximated as

$$F(s,\mathbf{x}) \approx F(s,\bar{\mathbf{x}}) + \sum_{i=1}^{n} (x - \bar{x}_i) \frac{\partial F(s,\mathbf{x})}{\partial x_i} \tag{72.61}$$

and from this approximation one obtains

$$\delta F(s,\mathbf{x}) \approx \sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \delta x_i \tag{72.62}$$

Here, $\delta F(s,\mathbf{x}) = [F(s,\mathbf{x}) = [F(s, \bar{\mathbf{x}})]/F(s, \bar{\mathbf{x}})$ and $\delta x_i = (x_i - \bar{x}_i)/\bar{x}_i$ $(i = 1, 2, \ldots, n)$. This result can be rewritten as

$$\delta F(s,\mathbf{x}) = \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \delta\mathbf{x} \tag{72.63}$$

and is completely analogous to (72.50). It is different in interpretation only. The components of the column vector $\delta\mathbf{x} = [\delta x_1\ \delta x_2 \ldots \delta x_n]^t$ are the random variables now and the components of the row vector $\mathbf{S}_{\mathbf{x}}^{F(s,\mathbf{x})} = [\mathbf{S}_{x_1}^{F(s,\mathbf{x})}\ \mathbf{S}_{x_2}^{F(s,\mathbf{x})} \cdots \mathbf{S}_{x_n}^{F(s,\mathbf{x})}]$ are calculated at the point of $\mathbf{x} = \bar{\mathbf{x}}$.

This interpretation allows us to obtain from (72.63) that on the $j\omega$ axis

$$\mu_{\delta F} = \sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \mu_i \tag{72.64}$$

Here, μ_i is the average of δx_i. If all μ_i are equal, i.e., $\mu_i = \mu_x$ $(i = 1, 2, \ldots, n)$, one can introduce the average sensitivity index

$$\psi(F) = \sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \tag{72.65}$$

© 2003 by CRC Press LLC

Using (72.65), the average value can be calculated as $\mu_{\delta F} = \mu_x \psi(F)$. If, in addition, the deviation of δx_i is bound by M_i, then

$$M_{\delta F} \le \sum_{i=1}^{n} \left| \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right| M_i \tag{72.66}$$

If the elements of a filter have the same precision, which means that all M_i are equal, it is reasonable to introduce the worst-case sensitivity index

$$\nu(F) = \sum_{i=1}^{n} \left| \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right| \tag{72.67}$$

so that when all M_i are equal to M_x, $M_{\delta F} = M_x \nu(F)$. Finally one can calculate $\sigma_{\delta F}^2 = E\{[\delta F(j\omega, \mathbf{x})]^* \ \delta F(j\omega, \mathbf{x})\}$ (here * means complex conjugate) or

$$\sigma_{\delta F}^2 = E\left\{ \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \delta\mathbf{x} \right)^* \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \delta\mathbf{x} \right) \right\} \tag{72.68}$$

To take into consideration possible correlation between the components δx_i one can do the following. The value of $\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\delta\mathbf{x}$ is a scalar. Then,

$$\left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \delta\mathbf{x} \right) = \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \delta\mathbf{x} \right)^t = \left(\delta\mathbf{x} \right)^t \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \right)^t \tag{72.69}$$

Substituting this result into (72.68), one obtains that

$$\delta_{\delta F}^2 = E\left\{ \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \right)^* \left[\left(\delta\mathbf{x} \right)^* \left(\delta\mathbf{x} \right)^t \right] \left(S_x^{F(j\omega,\mathbf{x})} \right)^t \right\} \tag{72.70}$$

But the components of $\delta\mathbf{x}$ are real, i.e., $(\delta\mathbf{x})^* = \delta\mathbf{x}$ and the result of multiplication in the square brackets of (72.70) is a square $n \times n$ matrix. Then, $E\{(\delta\mathbf{x}(\delta\mathbf{x})^t\}$ is also a square matrix

$$[\mathbf{P}] = \begin{bmatrix} \sigma_{x_1}^2 & \rho_{x_1x_2} & \cdots & \rho_{x_1x_n} \\ \rho_{x_2x_1} & \sigma_{x_2}^2 & \cdots & \rho_{x_2x_n} \\ & & \cdots & \\ \rho_{x_nx_1} & & \cdots & \sigma_{x_n}^2 \end{bmatrix} \tag{72.71}$$

the diagonal elements of which are variances of δx_i and off-diagonal terms are nonnormalized correlation coefficients. Then, (72.70) can be rewritten as

$$\sigma_{\delta F}^2 = \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \right)^* [\mathbf{P}] \left(\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})} \right)^t \tag{72.72}$$

which is sometimes [4] called the propagation-of-variance formula. In the absence of correlation between the variations δx_i, the matrix $[\mathbf{P}]$ has the diagonal terms only and (72.71) becomes

$$\sigma_{\delta F}^2 = \sum_{i=1}^{n} \left| \mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} \right|^2 \sigma_{x_i}^2 \tag{72.73}$$

© 2003 by CRC Press LLC

If all σ_{xi} are equal to σ_x one can introduce a quadratic sensitivity index

$$\rho(F)=\left[\sum_{i=1}^{n}\left|\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right|^2\right]^{1/2} \tag{72.74}$$

and in this case $\sigma_{\delta F}^2=\rho^2(F)\sigma_x^2$ (the value $\rho^2(F)$ is sometimes called **Schoeffler multivariable sensitivity**). One can also introduce two sensitivity measures, namely, the worst-case sensitivity measure

$$M_W=\int_{\omega_1}^{\omega_2}\left(\sum_{i=1}^{n}\left|\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right|\mu_i\right)d\omega \tag{72.75}$$

and the quadratic sensitivity measure

$$M_Q=\int_{\omega_1}^{\omega_2}\left(\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right)^{*}[\mathbf{P}]\left(\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right)^{\mathrm{t}}d\omega \tag{72.76}$$

which, when the correlation between the elements of $\delta\mathbf{x}$ is absent, becomes

$$M_Q=\int_{\omega_1}^{\omega_2}\left[\sum_{i=1}^{n}\left|\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}\right|^2\sigma_i^2\right]d\omega \tag{72.77}$$

Here, for simplicity, the notation $\sigma_i=\sigma_{xi}$ is used.

The sensitivity indices and the sensitivity measures introduced for the case when $\delta\mathbf{x}$ is a random vector are cumulative; they take into consideration the variation of the amplitude and phase of the filter function. For this reason some authors prefer to use the indices as they are defined in (72.65), (72.67), and (72.74) and the measures as they are defined by (72.75) and (72.77) for the deterministic cases as well (the deterministic case does not assume any correlation between the variations δx_i), with the corresponding substitution of μ_i by ε_i and σ_i^2 by ε_i^2. From the other side, one can take (72.51) and use it for the case of random vector $\delta\mathbf{x}$ considering, for example, the variation $\delta|F(j\omega,\mathbf{x})|$ as a random variable and calculating $\mu_{\delta|F|}$ and $\sigma_{\delta|F|}^2$, which will be the characteristics of this variable. In this case, one can use the results (72.75), (72.77), etc., substituting $\mathbf{S}_{x_i}^{F(s,\mathbf{x})}$ by $\mathrm{Re}\,\mathbf{S}_{x_i}^{F(s,\mathbf{x})}$. These possibilities are responsible for many formulations of multiparameter sensitivities that represent different measures of the vector $\mathbf{S}_{x_i}^{F(s,\mathbf{x})}$. In the design based, for example, on (72.75) and (72.77), one determines the required $\sigma_{\delta F}^2$ using the reject probability [2] depending on the ratio of $\varepsilon_{\delta F}/\sigma_{\delta F}$. Here, $\varepsilon_{\delta F}$ is the tolerance of $|\delta F(j\omega,\mathbf{x})|$ and in many cases one takes $\varepsilon_{\delta F}/\sigma_{\delta F}=2.5$, which gives the reject probability of 0.01. Then, one determines the dispersions σ_i^2 so that the contributions of each term in (72.77) are equal. Finally, using the probability function that describes the distribution of δx_i within the tolerance borders one finds these borders (if, for example, the selected element has evenly distributed values $-\varepsilon_i\le\delta x_i\le\varepsilon_i$, then $\varepsilon_i=\sqrt{3}\sigma_i$; for Gaussian distribution one frequently accepts $\varepsilon_i=2.5\sigma_i$).

The preliminary calculation of the coefficient sensitivities is useful for finding the sensitivity measures. If, for example, one calculates a multivariable statistical measure of sensitivity then one can consider that

$$F(j\omega,\mathbf{x})=\frac{a_0+a_1(j\omega)+\ldots+\alpha_m(j\omega)^m}{d_0+d_1(j\omega)+\ldots+d_n(j\omega)^n}=F(j\omega,\mathbf{a},\mathbf{d},\mathbf{x}) \tag{72.78}$$

where $\mathbf{a}=[a_0\ a_1\ \ldots\ a_m]^t$ and $\mathbf{d}=[d_0\ d_1\ \ldots\ d_n]^t$. Then, the component $\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})}$ defined earlier can be rewritten as

© 2003 by CRC Press LLC

$$\mathbf{S}_{x_i}^{F(j\omega,\mathbf{x})} = \frac{x_i}{F(j\omega,\mathbf{x})}\left[\frac{\partial \mathbf{a}^t}{\partial x_i}\nabla_a F(j\omega,\mathbf{x}) + \frac{\partial \mathbf{d}^t}{\partial x_i}\nabla_d F(j\omega,\mathbf{x})\right]$$
$$= \frac{1}{F(j\omega,\mathbf{x})}\left[\sum_{j=0}^{m}\frac{\partial F(j\omega,\mathbf{x})}{\partial a_j}\mathbf{S}_{x_i}(a_j) + \sum_{j=0}^{n}\frac{\partial F(j\omega,\mathbf{x})}{\partial d_j}\mathbf{S}_{x_i}(d_j)\right] \tag{72.79}$$

where

$$\nabla_a F(j\omega,\mathbf{x}) = \left[\partial F(j\omega,\mathbf{x})/\partial a_0\ \partial F(j\omega,\mathbf{x})/\partial a_1 \ldots \partial F(j\omega,\mathbf{x})/\partial a_m\right]^t$$

and

$$\nabla_d F(j\omega,\mathbf{x}) = \left[\partial F(j\omega,\mathbf{x})/\partial d_0\ \partial F(j\omega,\mathbf{x})/\partial d_1 \ldots \partial F(j\omega,\mathbf{x})/\partial d_n\right]^t$$

For a given transfer function, the components of the vectors $\nabla_a F(j\omega,\mathbf{x})$ and $\nabla_d F(j\omega,\mathbf{x})$ are independent of the form of the realization or the values of the elements and can be calculated in advance. If we now define a $k \times (m+1)$ matrix $\mathbf{C}_1$ as

$$\mathbf{C}_1 = \begin{bmatrix} \mathbf{S}_{x_1}(a_0) & \mathbf{S}_{x_1}(a_1) & \cdots & \mathbf{S}_{x_1}(a_m) \\ & & \cdots & \\ \mathbf{S}_{x_k}(a_0) & \mathbf{S}_{x_k}(a_1) & \cdots & \mathbf{S}_{x_k}(a_m) \end{bmatrix} \tag{72.80}$$

and $k \times (n+1)$ matrix $\mathbf{C}_2$ as

$$\mathbf{C}_1 = \begin{bmatrix} \mathbf{S}_{x_1}(d_0) & \mathbf{S}_{x_1}(d_1) & \cdots & \mathbf{S}_{x_1}(d_n) \\ & & \cdots & \\ \mathbf{S}_{x_k}(d_0) & \mathbf{S}_{x_k}(d_1) & \cdots & \mathbf{S}_{x_k}(d_n) \end{bmatrix} \tag{72.81}$$

then one can rewrite

$$\left[\mathbf{S}_{\mathbf{x}}^{F(j\omega,\mathbf{x})}\right]^t = \left[\mathbf{S}_{x_1}^{F(j\omega,\mathbf{x})} \quad \mathbf{S}_{x_2}^{F(j\omega,\mathbf{x})} \quad \cdots \quad \mathbf{S}_{x_k}^{F(j\omega,\mathbf{x})}\right]^t$$
$$= \mathbf{C}_1\frac{\nabla_a F(j\omega,\mathbf{x})}{F(j\omega,\mathbf{x})} + \mathbf{C}_2\frac{\nabla_d F(j\omega,\mathbf{x})}{F(j\omega,\mathbf{x})} \tag{72.82}$$

Then, the multiparameter statistical sensitivity measure can be rewritten as

$$M_Q = \int_{\omega_1}^{\omega_2}\left[\left(\frac{\nabla_a F}{F}\right)^{*t}\mathbf{C}_1^t\mathbf{P}\mathbf{C}_1\left(\frac{\nabla_a F}{F}\right) + \left(\frac{\nabla_d F}{F}\right)^{*t}\mathbf{C}_2^t\mathbf{P}\mathbf{C}_2\left(\frac{\nabla_d F}{F}\right)\right]d\omega$$
$$+ \int_{\omega_1}^{\omega_2} 2\,\mathrm{Re}\left[\left(\frac{\nabla_a F}{F}\right)^{*t}\mathbf{C}_1^t\mathbf{P}\mathbf{C}_2\left(\frac{\nabla_d F}{F}\right)\right]d\omega \tag{72.83}$$

and this definition of statistical multiparameter sensitivity measure may be directly applied to a given network realization. In a similar fashion, the matrices of unnormalized coefficient sensitivities can be used with other multiparameter sensitivity measures.

© 2003 by CRC Press LLC

72.8 Sensitivity Invariants

When one is talking about sensitivity invariants [7] it is assumed that for a filter function $F(s, \mathbf{x})$ there exists the relationship

$$\sum_{i=1}^{n} \mathbf{S}_{x_i}^{F(s,\mathbf{x})} = k \tag{72.84}$$

where $\mathbf{x} = [x_1\ x_2\ \ldots, x_n]^t$ as usual and k is a constant. These relationships are useful to check the sensitivity calculations. In the cases considered below, this constant can have one of three possible values, namely, 1, 0, and –1, and the sensitivity invariants are obtained from the homogeneity of some of the filter functions.

The function $F(s, \mathbf{x})$ is called homogeneous of order k with respect to the vector $\mathbf{x}$ if and only if it satisfies the relationship

$$F(s, \lambda\mathbf{x}) = \lambda^k F(s, \mathbf{x}) \tag{72.85}$$

where λ is an arbitrary scalar. For the homogeneous function $F(s, \mathbf{x})$ the sensitivities are related by (72.84). Indeed, if one takes the logarithm of both sides of (72.85) one obtains

$$\ln F(s, \lambda\mathbf{x}) = k \ln \lambda + \ln F(s, \mathbf{x}) \tag{72.86}$$

Taking the derivative of both sides of (72.86) with respect to λ one obtains that

$$\frac{1}{F(s, \lambda\mathbf{x})}\left[\sum_{i=1}^{n} \frac{\partial F(s, \lambda\mathbf{x})}{\partial(\lambda x_i)} x_i\right] = \frac{k}{\lambda} \tag{72.87}$$

Substituting in (72.87) $\lambda = 1$ gives (72.84).

Let the filter be a passive *RLC* circuit that includes r resistors, l inductors, and c capacitors, so that $r + l + c = n$ and $\mathbf{x} = [R_1, R_2, \ldots, R_r, L_1, L_2, \ldots, L_l, D_1, D_2, \ldots, D_c]$, where $D_i = 1/C_i$. One of the frequently used operations is the impedance scaling. If the scaling operation is applied to a port impedance or a transimpedance of the filter, i.e., $F(s, \mathbf{x}) = Z(s, \mathbf{x})$, then

$$Z(s, \lambda\mathbf{x}) = \lambda Z(s, \mathbf{x}) \tag{72.88}$$

Equation (72.88) is identical to (72.85), with $k = 1$. Then, one can write that

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{Z(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{Z(s,\mathbf{x})} + \sum_{i=1}^{c} \mathbf{S}_{D_i}^{Z(s,\mathbf{x})} = 1 \tag{72.89}$$

Considering that $D_i = 1/C_i$ and $\mathbf{S}_{C_i}^{Z(s,\mathbf{x})} = -\mathbf{S}_{D_i}^{Z(s,\mathbf{x})}$ (see Table 72.1), this result can be rewritten as

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{Z(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{Z(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{Z(s,\mathbf{x})} = 1 \tag{72.90}$$

If the same scaling operation is applied to a port admittance or a transadmittance of the filter, i.e., $F(s, \mathbf{x}) = Y(s, \mathbf{x})$, then

$$Y(s, \lambda\mathbf{x}) = \lambda^{-1} Y(s, \mathbf{x}) \tag{72.91}$$

© 2003 by CRC Press LLC

But (72.91) is identical to (72.85), with $k = -1$. Then

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{Y(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{Y(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{Y(s,\mathbf{x})} = -1 \tag{72.92}$$

Finally, the transfer functions (voltage or current) do not depend on the scaling operation, i.e., if $F(s, \mathbf{x}) = T(s, \mathbf{x})$, hence,

$$T(s, \lambda\mathbf{x}) = T(s, \mathbf{x}) \tag{72.93}$$

which is identical to (72.85), with $k = 0$. Then,

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{T(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{T(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{T(s,\mathbf{x})} = 0 \tag{72.94}$$

Additional sensitivity invariants can be obtained using the relation $\mathbf{S}_{x_i}^{F(s,\,\mathbf{x})} = -\mathbf{S}_{1/x_i}^{F(s,\,\mathbf{x})}$ and using $G_i = 1/R_i$ and $\Gamma_i = 1/L_i$.

Another group of sensitivity invariants is obtained using the frequency scaling operation. The following relationship is held for a filter function:

$$F(s, R_i, \lambda L_i, \lambda C_i) = F(\lambda s, R_i, L_i, C_i) \tag{72.95}$$

Taking the logarithm of both parts, then differentiating both sides with respect to λ and substituting $\lambda = 1$ in both sides gives

$$\sum_{i=1}^{r} \mathbf{S}_{L_i}^{F(s,\mathbf{x})} + \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} = \mathbf{S}_{s}^{F(s,\mathbf{x})} \tag{72.96}$$

Substituting $s = j\omega$ in (72.96) and dividing the real and imaginary parts, one obtains

$$\mathrm{Re} \sum_{i=1}^{l} \mathbf{S}_{L_i}^{F(j\omega,\mathbf{x})} + \mathrm{Re} \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(j\omega,\mathbf{x})} = \omega \frac{\partial \ln |T(\omega)|}{\partial \omega} = -\frac{\partial a(\omega)}{\partial \omega} \tag{72.97}$$

and

$$\mathrm{Im} \sum_{i=1}^{l} \mathbf{S}_{L_i}^{F(j\omega,\mathbf{x})} + \mathrm{Im} \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(j\omega,\mathbf{x})} = \omega \frac{\partial \arg T(\omega)}{\partial \omega} \tag{72.98}$$

The results (72.97) and (72.98) show that in an *RLC* filter, when all inductors and capacitors (but not resistors!) are subjected to the same relative change, then the resulting change in the magnitude characteristic does not depend on the circuit realization and is determined by the slope of the magnitude characteristic at a chosen frequency. A similar statement is valid for the phase characteristic.

The sensitivity invariants for passive *RC* circuits can be obtained from the corresponding invariants for passive *RLC* circuits omitting the terms for sensitivities to the inductor variations. The results can be summarized the following way. For a passive *RC* circuit

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{F(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} = k \tag{72.99}$$

© 2003 by CRC Press LLC

where $k = 1$ if $F(s, \mathbf{x})$ is an input impedance or transimpedance function, then $k = 0$ if $F(s, \mathbf{x})$ is a voltage- or current-transfer function, and $k = -1$ if $F(s, \mathbf{x})$ is an input admittance or transconductance function. Application of the frequency scaling gives the result

$$\sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} = \mathbf{S}_s^{F(s,\mathbf{x})} \tag{72.100}$$

and combination of (72.99) and (72.100) gives

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{F(s,\mathbf{x})} = \mathbf{S}_s^{F(s,\mathbf{x})} + k \tag{72.101}$$

and

$$\sum_{i=1}^{r} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} + \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} = 2\mathbf{S}_s^{F(s,\mathbf{x})} + k \tag{72.102}$$

Considering real and imaginary parts of (72.100)–(72.102), one can obtain the results that determine the limitations imposed on the sensitivity sums by the function $F(j\omega, \mathbf{x})$ when resistors and/or capacitors are subjected to the same relative change.

Finally, if the filter is not passive, then the vector of parameters

$$\mathbf{x} = \left[R_1, R_2, \cdots, R_r, L_1, L_2, \cdots, L_l, C_1, C_2, \cdots, C_c, R_{T1}, R_{T2}, \cdots, R_{Ta}, G_{T1}, G_{T2}, \cdots, G_{Tb}, A_{v1}, A_{v2}, \cdots, A_{vp}, A_{i1}, A_{i2}, \cdots, A_{iq}\right]$$

includes the components of transresistors R_{Tk}, transconductances G_{Tk}, voltage amplifiers A_{vk}, and current amplifiers A_{ik}. Applying the impedance scaling one can obtain the sensitivity invariant

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}^{F(s,\mathbf{x})} + \sum_{i=1}^{l} \mathbf{S}_{L_i}^{F(s,\mathbf{x})} - \sum_{i=1}^{c} \mathbf{S}_{C_i}^{F(s,\mathbf{x})} + \sum_{i=1}^{a} \mathbf{S}_{R_{T_i}}^{F(s,\mathbf{x})} - \sum_{i=1}^{b} \mathbf{S}_{G_{T_i}}^{F(s,\mathbf{x})} = k \tag{72.103}$$

where $k = 1$ if $F(s, \mathbf{x})$ is an impedance function, then $k = 0$ if $F(s, \mathbf{x})$ is a transfer function, and $k = -1$ if $F(s, \mathbf{x})$ is an admittance function. The frequency scaling will give the same result as (72.96).

The pole (or zero) sensitivities are also related by some invariant relationships. Indeed, the impedance scaling provides the result

$$p_k\left(\lambda R_i, \lambda L_i, \frac{C_i}{\lambda}\right) = p_k\left(R_i, L_i, C_i\right) \tag{72.104}$$

Taking the derivative of both sides of (72.104) with respect to λ and substituting $\lambda = 1$, one obtains that for an arbitrary *RLC* circuit

$$\sum_{i=1}^{r} \mathbf{S}_{R_i}\left(p_k\right) + \sum_{i=1}^{l} \mathbf{S}_{L_i}\left(p_k\right) - \sum_{i=1}^{c} \mathbf{S}_{C_i}\left(p_k\right) = 0 \tag{72.105}$$

This is the relationship between semirelative sensitivities. If $p_k \neq 0$ one can divide both sides of (72.105) by p_k and obtains similar invariants for the relative sensitivities. The frequency scaling gives

$$p_k\left(R_i, \frac{L_i}{\lambda}, \frac{C_i}{\lambda}\right) = \lambda p_k\left(R_i, L_i, C_i\right) \tag{72.106}$$

© 2003 by CRC Press LLC

and from (72.106) one obtains, for relative sensitivities only, that

$$\sum_{i=1}^{l} \mathbf{S}_{L_i}^{p_k} + \sum_{i=1}^{c} \mathbf{S}_{C_i}^{p_k} = -1 \tag{72.107}$$

The pole sensitivity invariants for passive *RC* circuits are obtained from (72.106) and (72.107), omitting the terms corresponding to the inductor sensitivities.

72.9 Sensitivity Bounds

For some classes of filters, the worst-case magnitude sensitivity index may be shown to have a lower bound [8]. Such a bound, for example, exists for filters whose passive elements are limited to resistors, capacitors, and ideal transformers, and whose active elements are limited to gyrators characterized by two gyration resistances (realized as a series connection of transresistance amplifiers and considered as different for sensitivity calculations), CCCSs, VCVSs, VCCSs, and CCVSs. Using the sensitivity invariants, it is easy to show that for such a class of networks for any dimensionless transfer function $T(s)$

$$\sum_{i=1}^{n} \mathbf{S}_{x_i}^{T(s)} = 2\mathbf{S}_{s}^{T(s)} \tag{72.108}$$

where the x_i are taken to include only the passive elements of resistors and capacitors and the active elements of CCVS's and gyrators (if the gyrators are realized as parallel connection of transconductance amplifiers the corresponding terms should be taken with the negative sign). Substituting $s = j\omega$ in (72.108) and equating real parts, one obtains that

$$\sum_{i=1}^{n} \mathbf{S}_{x_i}^{|T(j\omega)|} = 2\mathbf{S}_{\omega}^{|T(j\omega)|} \tag{72.109}$$

Applying (72.54) to the above one obtains for the worst-case magnitude sensitivity index

$$\nu(T) = \sum_{i} \left| \mathbf{S}_{x_i}^{|T(j\omega)|} \right| \geq \left| \sum_{i} \mathbf{S}_{x_i}^{|T(j\omega)|} \right| = \left| 2\mathbf{S}_{\omega}^{|T(j\omega)|} \right| \tag{72.110}$$

Taking the first and last members of this expression one may define a lower bound $LB\nu(T)$ of the worst-case magnitude sensitivity index as

$$LB\nu(T) = \left| 2\mathbf{S}_{\omega}^{|T(j\omega)|} \right| \tag{72.111}$$

This lower bound is a function only of the transfer function $T(s)$ and is independent on the particular synthesis technique (as soon as the above mentioned restrictions are satisfied) used to realize this transfer function. A similar lower bound may be derived [taking the imaginary parts of (72.108)] for worst-case phase sensitivity; but it is impossible to find the design path by which one will arrive at the circuit realizing this minimal bound.

72.10 Remarks on the Sensitivity Applications

The components of active *RC* filters have inaccuracies and parasitic components that distort the filter characteristics. The most important imperfections are the following:

© 2003 by CRC Press LLC

1. The values of the resistors and capacitors and the values of transconductances (the gyrators can be considered usually as parallel connection of two transconductance amplifiers) are different from their nominal values. The evaluation of these effects is done using the worst-case or (more frequently) quadratic multiparameter sensitivity index and multiparameter sensitivity measures and the tolerances are chosen so that the contributions of the passive elements' variations in the sensitivity measure are equal.
2. The operational amplifiers have finite gain and this gain is frequency dependent. The effect of finite gain is evaluated using a semirelative sensitivity of the filter function with respect to variation of $1/A$, where A is the operational amplifier gain. This semirelative sensitivity is $-\mathbf{S}^{F(s)}(1/A) = -\partial F(s)/[F(s)\partial(1/A)] = [A^2/F(s)]\,[\partial F(s)/\partial A] = A\mathbf{S}_A^{F(s)}$, which is called the gain–sensitivity product. In many cases, $\mathbf{S}_A^{F(s)} \to 0$ when $A \to \infty$, whereas $\mathbf{S}_{1/A}[F(s)]$ has a limit that is different from zero. The frequency dependence is difficult to take into consideration [1]. Only in case of cascade realization, as shown next, one can evaluate the effect of this frequency dependence using the sensitivity of Q-factor.
3. Temperature dependence and aging of the passive elements and operational amplifiers can be determined. The influence of temperature, aging and other environmental factors on the value of the elements can be determined by a dependence of the probability distributions for these parameters. For example, if θ is temperature, one has to estimate $\mu_x(\theta)$ and $\sigma_x(\theta)$ before calculation of the sensitivity measures. Normally, at the nominal temperature θ_0 the average value $\mu_x(\theta_0) = 0$ and $\sigma_x(\theta_0)$ depends on the nominal precision of the elements. When the temperature changes, $\mu_x(\theta)$ increases or decreases depending on the temperature coefficients of the elements, whereas $\sigma_x(\theta)$ usually increases for any temperature variation.

72.11 Sensitivity Computations Using the Adjoint Network

The determination of the sensitivities defined in the previous sections may pose difficult computational problems. Finding the network function with the elements expressed in literal form is usually tedious and error prone, and the difficulty of such a determination increases rapidly with the number of elements. Calculating the partial derivatives, which is the most important part of the sensitivity computation, provides additional tedium and increases the possibility of error still more. Thus, in general, it is advantageous to use digital computer methods to compute sensitivities. The most obvious method for doing this is to use one of the many available computer-aided design programs (for example, SPICE) to make an analysis of the network with nominal element values, then repeat the analysis after having perturbed the value of one of the elements. This is not a desirable procedure, since it requires a large number of analyses. It can be justified if the network has some *a priori* known critical elements for which the analyses should be done.

The crucial part of sensitivity computation is, as was mentioned above, calculation of network function derivatives with respect to element variations. To simplify this part of the calculation, the concept of adjoint network [9] is used. This method requires only two analyses to provide all the sensitivities of a given network immittance function.

If $\mathbf{N}$ and $\hat{\mathbf{N}}$ are linear time invariant networks, then they are said to be adjoint (to each other) if the following hold. The two networks have the same topology and ordering of branches; thus their incidence matrices [10] are equal, namely $\mathbf{A} = \hat{\mathbf{A}}$. If excitation with the unit current (unit voltage) at an arbitrary port j (port l) of network $\mathbf{N}$ yields a voltage (current) at an arbitrary port k (port m) of $\mathbf{N}$, excitation with the unit current (unit voltage) at port k (port m) of network $\hat{\mathbf{N}}$ will yield the same voltage (current) as the above in port j (port l) of $\hat{\mathbf{N}}$ (see Fig. 72.1).

Figure 72.1 also shows how the adjoint network should be constructed, as follows. (a) All resistance, capacitive, and inductance branches and transformers in $\mathbf{N}$ are associated, respectively, with resistance, capacitance, and inductance branches and transformers in $\hat{\mathbf{N}}$. (b) All gyrators in $\mathbf{N}$ with gyration resistance r become gyrators in $\hat{\mathbf{N}}$ with gyration resistance $-r$. (c) All VCVSs in $\mathbf{N}$ become CCCSs in $\hat{\mathbf{N}}$ with controlling and controlled branches reversing roles, and with the voltage amplification factor A_v becoming the current

© 2003 by CRC Press LLC

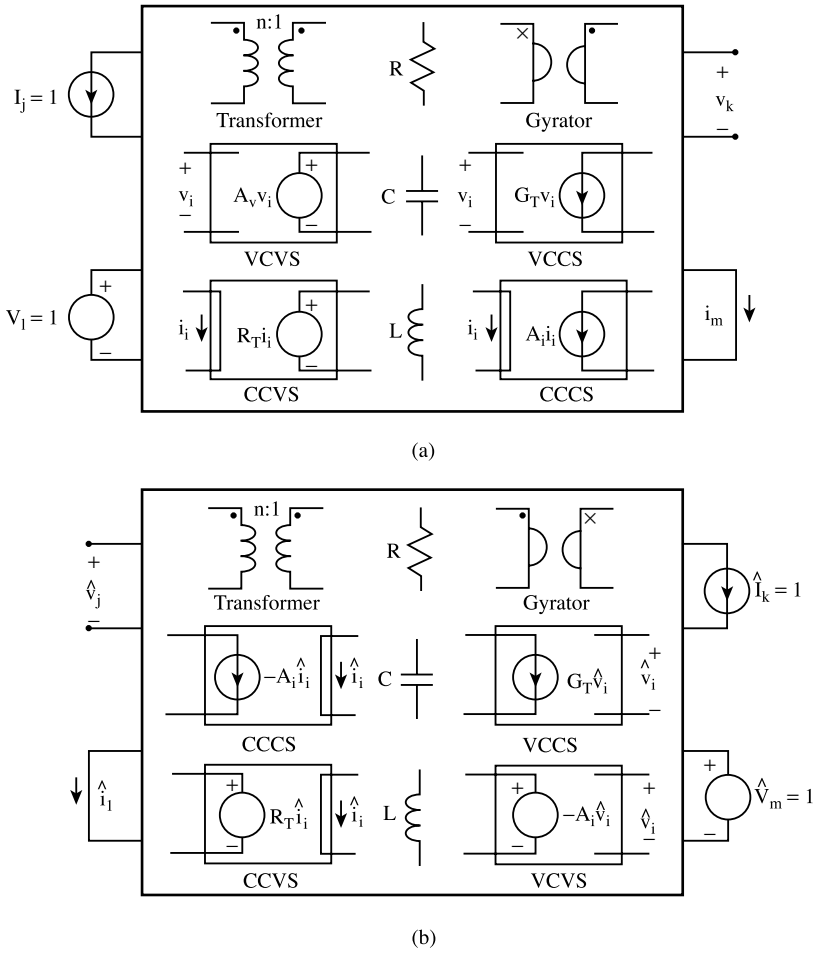

FIGURE 72.1 The components of a network (a) and its adjoint (b).

amplification factor $-A_i$. (d) All CCCSs in **N** become VCVSs in $\hat{\mathbf{N}}$ with controlling and controlled branches reversing roles, and with the current amplification factor A_i becoming the voltage amplification factor $-A_v$. (e) All VCCSs and CCVSs have their controlling and controlled branches in **N** reversed in $\hat{\mathbf{N}}$.

Thus, the Tellegen's theorem [9] applies to the branch voltage and current variables of these two networks. If we let **V** be vector of branch voltages and **I** be the vector of branch currents (using capital letters implies that the quantities are functions of the complex variable s), then

$$\mathbf{V}^t\hat{\mathbf{I}} = \hat{\mathbf{I}}^t\mathbf{V} = \hat{\mathbf{V}}^t\mathbf{I} = \hat{\mathbf{I}}^t\mathbf{V} = \mathbf{0} \tag{72.112}$$

If in both circuits all independent sources have been removed to form n external ports (as illustrated in Fig. 72.2), then one can divide the variables in both circuits in two groups so that

$$\begin{aligned} \mathbf{I}^t &= \left[\mathbf{I}_p^t \mathbf{I}_b^t\right] \quad \mathbf{V}^t = \left[\mathbf{V}_p^t \mathbf{V}_b^t\right] \\ \hat{\mathbf{I}}^t &= \left[\hat{\mathbf{I}}_p^t \hat{\mathbf{I}}_b^t\right] \quad \hat{\mathbf{V}}^t = \left[\hat{\mathbf{V}}_p^t \hat{\mathbf{V}}_b^t\right] \end{aligned} \tag{72.113}$$

© 2003 by CRC Press LLC

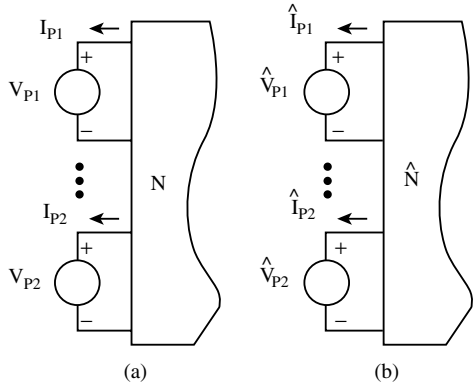

FIGURE 72.2 Separation of port variables in the network (a) and its adjoint (b).

The first are the vectors of port variables $\mathbf{V}_p$ and $\mathbf{I}_p$ in $\mathbf{N}$ and $\hat{\mathbf{V}}_p$ and $\hat{\mathbf{I}}_p$, correspondingly, in $\hat{\mathbf{N}}$. These variables will define n-port open-circuit impedance matrices $\boldsymbol{Z}_{oc}$ and $\hat{\mathbf{Z}}_{oc}$ or n-port short-circuit admittance matrices $\mathbf{Y}_{sc}$ and $\hat{\mathbf{Y}}_{sc}$ via the relationships

$$\begin{aligned} \mathbf{V}_p &= -\mathbf{Z}_{oc}\mathbf{I}_p \qquad \hat{\mathbf{V}}_p = -\hat{\mathbf{Z}}_{oc}\hat{\mathbf{I}}_p \\ \mathbf{I}_p &= -\mathbf{Y}_{sc}\mathbf{V}_p \qquad \hat{\mathbf{I}}_p = -\hat{\mathbf{Y}}_{sc}\mathbf{V}_p \end{aligned} \tag{72.114}$$

Then, the rest of the variables will be nonport variables (including the variables of dependent source branches) $\mathbf{V}_b$ and $\mathbf{I}_b$ for $\mathbf{N}$ and $\hat{\mathbf{V}}_b$ and $\hat{\mathbf{I}}_b$ for $\hat{\mathbf{N}}$. These variables may define branch impedance matrices $\mathbf{Z}_b$ and $\hat{\mathbf{Z}}_b$ and branch admittance matrices $\mathbf{Y}_b$ and $\hat{\mathbf{Y}}_b$ by the relationships

$$\begin{aligned} \mathbf{V}_b &= \mathbf{Z}_b\mathbf{I}_b \qquad \hat{\mathbf{V}}_b = \hat{\mathbf{Z}}_b\hat{\mathbf{I}}_b \\ \mathbf{I}_b &= \mathbf{Y}_b\mathbf{V}_b \qquad \hat{\mathbf{I}}_b = \hat{\mathbf{Y}}_b\hat{\mathbf{V}}_b \end{aligned} \tag{72.115}$$

If the branch impedance and branch admittance matrices do not exist, a hybrid matrix may be used to relate the branch variables. For $\mathbf{N}$, this may be put in the form

$$\begin{bmatrix} \mathbf{V}_{b1} \\ \mathbf{I}_{b2} \end{bmatrix} = \begin{bmatrix} \mathbf{H}_{11} & \mathbf{H}_{12} \\ \mathbf{H}_{21} & \mathbf{H}_{22} \end{bmatrix} \begin{bmatrix} \mathbf{I}_{b1} \\ \mathbf{V}_{b2} \end{bmatrix} \tag{72.116}$$

Similarly, for $\hat{\mathbf{N}}$ one may write

$$\begin{bmatrix} \hat{\mathbf{V}}_{b1} \\ \hat{\mathbf{I}}_{b2} \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{H}}_{11} & \hat{\mathbf{H}}_{12} \\ \hat{\mathbf{H}}_{21} & \hat{\mathbf{H}}_{22} \end{bmatrix} \begin{bmatrix} \hat{\mathbf{I}}_{b1} \\ \hat{\mathbf{V}}_{b2} \end{bmatrix} \tag{72.117}$$

For the adjoint networks, the branch impedance matrices and branch admittance matrices (if they exist) are transposed, namely,

$$\mathbf{Z}_b^t = \hat{\mathbf{Z}}_b \qquad \mathbf{Y}_b^t = \hat{\mathbf{Y}}_b \tag{72.118}$$

and, if a hybrid representation is used, the matrices are connected by the relationship

© 2003 by CRC Press LLC

$$\begin{bmatrix} \mathbf{H}_{11}^t & -\mathbf{H}_{21}^t \\ -\mathbf{H}_{12}^t & \mathbf{H}_{22}^t \end{bmatrix} = \begin{bmatrix} \hat{\mathbf{H}}_{11} & \hat{\mathbf{H}}_{12} \\ \hat{\mathbf{H}}_{21} & \hat{\mathbf{H}}_{22} \end{bmatrix} \tag{72.119}$$

As a result of these relationships, if no controlled sources are present in two networks, they are identical. In the general case it may be shown that

$$\mathbf{Z}_{oc}^t = \hat{\mathbf{Z}}_{oc} \qquad \mathbf{Y}_{sc}^t = \hat{\mathbf{Y}}_{sc} \tag{72.120}$$

The application of adjoint circuits for sensitivity calculations requires that, first of all, using the port variables as independent ones one finds the branch variables, and this is done for both circuits. Assume, for example, that the branch impedance matrices exist. Then, using unity-valued excitation currents as the components of $\mathbf{I}_p$ and $\hat{\mathbf{I}}_p$ one has, first, to find $\mathbf{I}_b$ and $\hat{\mathbf{I}}_b$. Now, in the original network let the elements be perturbed. The resulting vector of currents may thus be written as $\mathbf{I} + \Delta\mathbf{I}$ and the resulting vector of voltages as $\mathbf{V} + \Delta\mathbf{V}$. From Kirchhoff's current law, we have $\mathbf{A}(\mathbf{I} + \Delta\mathbf{I}) = \mathbf{0}$, and since $\mathbf{AI} = \mathbf{0}$ one also has $\mathbf{A}\,\Delta\mathbf{I} = \mathbf{0}$. Thus, $\Delta\mathbf{I} = \Delta\mathbf{I}_p + \Delta\mathbf{I}_b$ may be substituted in any of the relations in (72.112). By similar reasoning one can conclude that it is possible as well to substitute the perturbation vector $\Delta\mathbf{V} = \Delta\mathbf{V}_p + \Delta\mathbf{V}_b$ instead of $\mathbf{V}$ in these relations. Making these substitutions, one obtains

$$\begin{aligned} \hat{\mathbf{V}}_p^t \Delta\mathbf{I}_p + \hat{\mathbf{V}}_b^t \Delta\mathbf{I}_b &= 0 \\ \mathbf{I}_p^t \Delta\mathbf{V}_p + \hat{\mathbf{I}}_b^t \Delta\mathbf{V}_b &= 0 \end{aligned} \tag{72.121}$$

Subtracting these two equations, one has

$$\hat{\mathbf{V}}_p^t \Delta\mathbf{I}_p - \hat{\mathbf{I}}_p^t \Delta\mathbf{V}_p + \hat{\mathbf{V}}_b^t \Delta\mathbf{I}_b - \hat{\mathbf{I}}_p^t \Delta\mathbf{V}_b = 0 \tag{72.122}$$

To a first-order approximation, we have

$$\begin{aligned} \Delta\mathbf{V}_p &= -\Delta\left(\mathbf{Z}_{oc}\mathbf{I}_p\right) \approx -\Delta\mathbf{Z}_{oc}\mathbf{I}_p - \mathbf{Z}_{oc}\Delta\mathbf{I}_p \\ \Delta\mathbf{V}_p &= \Delta\left(\mathbf{Z}_b\mathbf{I}_b\right) \approx \Delta\mathbf{Z}_b\mathbf{I}_b + \mathbf{Z}_b\Delta\mathbf{I}_b \end{aligned} \tag{72.123}$$

Substituting (72.123) in (72.122) and taking into consideration that $\hat{\mathbf{V}}_p^t = -\hat{\mathbf{I}}_p^t \hat{\mathbf{Z}}_{oc}^t = -\hat{\mathbf{I}}_p^t \mathbf{Z}_{oc}$ and that $\hat{\mathbf{V}}_b^t = \hat{\mathbf{I}}_b^t \mathbf{Z}_b$, one can simplify the result (72.122) to

$$\hat{\mathbf{I}}_p^t \Delta\mathbf{Z}_{oc}\mathbf{I}_p = \hat{\mathbf{I}}_b^t \Delta\mathbf{Z}_b\mathbf{I}_b \tag{72.124}$$

Equation (72.124) clearly shows that if all currents in the original network and its adjoint are known, one can easily calculate the absolute sensitivities $\mathbf{S}(\mathbf{Z}_{ij}, \mathbf{Z}_b) \approx \Delta\mathbf{Z}_{ij} / \Delta\mathbf{Z}_b$, which can be used for calculation of the corresponding relative sensitivities. Here, $\mathbf{Z}_{ij}$ is an element of the n-port open circuit impedance matrix. Then, if necessary, these sensitivities can be used for evaluation of the transfer function sensitivity or the sensitivities of other functions derived via the n-port open circuit impedance matrix.

Usually, the transfer function calculation can be easily reduced to the calculation of a particular $\mathbf{Z}_{ij}$. In this case one can choose $\hat{I}_j = 1$, $\hat{I}_k = 0$ (for all $k \neq j$) as an excitation in the original network and $\hat{I}_i$, $\hat{I}_k = 0$ (for all $k \neq i$) as an excitation in the adjoint network. Then, (72.124) becomes

$$\Delta\mathbf{Z}_{ij} = \hat{\mathbf{I}}_b^t \Delta\mathbf{Z}_b\mathbf{I}_b \tag{72.125}$$

where $\mathbf{I}_b$ and $\hat{\mathbf{I}}_b$ are the branch currents in $\mathbf{N}$ and $\hat{\mathbf{N}}$ corresponding to the indicated excitation. The relations for other types of matrices are obtained in the same manner.

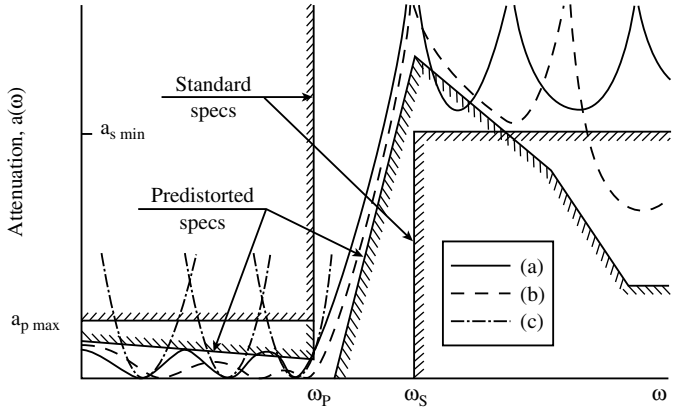

FIGURE 72.3 Attenuation requirements, their predistortion and attenuation of different realizations: (a) attenuation of a standard circuit of higher order; (b) attenuation of the nonstandard circuit; (c) passband attenuation in the stages of cascade realization.

72.12 General Methods of Reducing Sensitivity

It is very desirable from the start of the realization procedure to concentrate on circuits that give lower sensitivity in comparison to other circuits. The practice of active filter realization allows formulation of some general suggestions ensuring that filter realizations will have low sensitivities to component variations.

It is possible to transfer the problem of lower sensitivity at the approximation stage, i.e., before any realization. It is obvious that a low-order transfer function $T(s)$ that just satisfies the specifications will require tighter tolerances in comparison to a higher order transfer function that easily satisfies the specifications. Figure 72.3 shows an example of such an approach for a low-pass filter. Hence, increasing the order of approximation and introducing a redundancy one achieves a set of wider element tolerances.

Usually the most critical region where it is difficult to satisfy the specifications is the edge of the passband. Two approaches can be used to find the function that will have less sensitivity in this frequency region. One way is to introduce a predistortion in the transfer function specifications. This is also shown in Fig. 72.3. The transfer function should satisfy the predistorted (tapered) specifications. It can be obtained directly if the numerical packages solving the approximation problem are available. One can also take a standard table higher order transfer function satisfying the modified specifications and then modify it to more uniformly use the tapered specifications (this allows the increase of the component tolerances even more). Another way [11] is to preserve the initial transfer function specifications and to use transfer functions with a limited value of the maximum Q of the transfer function poles. In [11] one can find such transfer functions corresponding to a Cauer approximation. The nonstandard LC circuits corresponding to these approaches cannot be tabulated and simulated; hence, neither of them is widely used. In addition, they imply the cascaded (building-block) realization that intrinsically has worse sensitivity than the realizations using simulation of doubly terminated lossless matched filters.

72.13 Cascaded Realization of Active Filters

The cascaded (building-block) realization is based on the assumption that the transfer function will have low sensitivity if the realization provides tight control of the transfer function poles and zeros. The relationship between the element value and the transfer function poles and zeros can be established relatively easily if the transfer function is not more complicated than biquadratic (i.e., the ratio of two second-order polynomials). It is difficult (or even impossible) to establish such correspondence if, say, the denominator polynomial degree is higher than two. For a high degree polynomial, a small variation in the polynomial coefficient can result in a large or undesirable migration of the root (it can move to

© 2003 by CRC Press LLC

the right-half plane). This justifies the cascaded approach: one hopes to have a low sensitivity of the transfer function under realization if one chooses a method allowing tight control of the poles' and zeros' locations; hence, cascade realization with $T(s) = T_1(s)T_2(s) \cdots T_i(s) \cdots T_k(s)$. Also, if one chooses for realization of each function $T_i(s)$ the method of lowest sensitivity (discussed below), then it will be possible to obtain the largest element tolerances.

If the realization by cascade connection is chosen it is still a choice of optimum factorization of the transfer function $T(s)$ into low-order factors. This optimum depends on the filter application, the chosen method of the factor realization, and the transfer function itself. It is recommended [1] that, for realization of lower sensitivity, the poles and zeros in the partial functions $T_i(s)$ are located as far apart as possible. This statement is not always true and such a choice of poles and zeros in $T_i(s)$ is in contradiction with the requirement of high dynamic range of the stage. In general, CAD methods should be used.

The methods that are most popular for the realization of the partial transfer functions are mostly limited by the filters providing the output voltage at the output of an operational amplifier. The state–space realizations satisfy this requirement and provide the direct realizations of the polynomial coefficients. It is not occasionally that such an approach is used by a series of manufacturers. This is not the best method from the sensitivity point of view; the methods of realization using gyrators usually give better results [3]. But the cascade realization of gyrator filters require buffers between the blocks, and it is better to use this approach if the filter is not realized in cascade form. Other realization methods [1] are also occasionally used, mostly because of their simplicity.

If the transfer function is realized in a cascade form and $T(s) = T_1(s)\ T_2(s) \cdots T_i(s) \cdots T_k(s)$, the element x is located only in one stage. If this is the stage realizing $T_i(s)$, then

$$\mathbf{S}_x^{T(s)} = \mathbf{S}_x^{T_i(s)} \tag{72.126}$$

Assume that this $T_i(s)$ has the form

$$T_i(s) = K\frac{s^2 + \left(\omega_z/Q_z\right)s + \omega_z^2}{s^2 + \left(\omega_p/Q_p\right)s + \omega_p^2} \tag{72.127}$$

Then, one can write

$$\mathbf{S}_x^{T_i(s)} = \mathbf{S}_K^{T_i(s)}\mathbf{S}_x^{\mathrm{K}} + \mathbf{S}_{\omega_z}^{T_i(s)}\mathbf{S}_x^{\omega_z} + \mathbf{S}_{1/Q_z}^{T_i(s)}\mathbf{S}_x^{1/Q_z} + \mathbf{S}_{\omega_p}^{T_i(s)}\mathbf{S}_x^{\omega_p} + \mathbf{S}_{1/Q_p}^{T_i(s)}\mathbf{S}_x^{1/Q_p} \tag{72.128}$$

The second multiplier in each term of this sum depends on the stage realization method. In the first term $\mathbf{S}_K^{T_i(s)} = 1$, the first multipliers in other terms depend on the Q-factors of zeros and poles. It is enough to consider the influence of the terms related to the poles. One can notice that $\mathbf{S}_{1/Q_p}^{T_i(s)}\ \mathbf{S}_x^{1/Q_p} = \mathbf{S}^{T_i(s)}\ [T_i(s), 1/Q_p]\ \mathbf{S}_x(1/Q_p, x)$, then, calculating $\mathbf{S}^{T_i(s)}\ [T_i(s), 1/Q_p]$ (the calculation of the semirelative sensitivity is done for convenience of graphic representation) and $\mathbf{S}_{\omega_p}^{T_i(s)}$ one obtains

$$\mathbf{S}^{T_i(s)}\left[T_i(s), 1/Q_p\right] = \frac{1}{T_i(s)}\frac{\partial T_i(s)}{\partial\left(1/Q_p\right)} = -\frac{1}{\left(s/\omega_p\right) + \left(\omega_p/s\right) + \left(1/Q_p\right)} \tag{72.129}$$

and

$$\mathbf{S}_{\omega_p}^{T_i(s)} = \frac{\omega_p}{T_i(s)}\frac{\partial T_i(s)}{\partial \omega_p} = -\frac{\left(1/Q_p\right) + 2\left(\omega_p/s\right)}{\left(s/\omega_p\right) + \left(\omega_p/s\right) + \left(1/Q_p\right)} \tag{72.130}$$

Introducing the normalized frequency $\Omega = (\omega/\omega_p - \omega_p/\omega)$, one can find that

© 2003 by CRC Press LLC

$$\text{Re}\,\mathbf{S}^{T_i(s)}\left[T_i(s),1/Q_p\right]=-\frac{1/Q_p}{\Omega^2+\left(1/Q_p\right)^2} \tag{72.131}$$

$$\text{Im}\,\mathbf{S}^{T_i(s)}\left[T_i(s),1/Q_p\right]=\frac{\Omega}{\Omega^2+\left(1/Q_p\right)^2} \tag{72.132}$$

$$\text{Re}\;\mathbf{S}_{\omega_p}^{T_i(s)}=\frac{\Omega\sqrt{\Omega^2+4}-\Omega^2-\left(1/Q_p\right)^2}{\Omega^2+\left(1/Q_p\right)^2} \tag{72.133}$$

$$\text{Im}\;\mathbf{S}_{\omega_p}^{T_i(s)}=\frac{\left(1/Q_p\right)\sqrt{\Omega^2+4}}{\Omega^2+\left(1/Q_p\right)^2} \tag{72.134}$$

Figure 72.4 shows the graphs of these four functions. They allow the following conclusions [4]. The functions reach high values in the vicinity of $\Omega = 0$, i.e., when $\omega \approx \omega_p$. This means that in the filter passband, especially if the poles and zeros are sufficiently divided (which is the condition of optimal cascading) one can neglect the contribution of zeros in modification of the transfer function $T_i(s)$. When Q_p becomes higher this vicinity of $\omega \approx \omega_p$ with a rapid change of the sensitivity functions becomes relatively smaller in the case of Re $\mathbf{S}^{T_i(s)}[T_i(s), 1/Q_p]$ [Fig. 72.4(a)] and Im $\mathbf{S}_{\omega_p}^{T_i(s)}$ [Fig. 72.4(d)] and not so small in the case of Im $\mathbf{S}^{T_i(s)}[T_i(s), 1/Q_p]$ [Fig. 72.4(b)] and Re $\mathbf{S}_{\omega_p}^{T_i(s)}$ [Fig. 72.4(c)]. Normally, the second multipliers in the terms of the sum (72.128) are all real; this means that the function Re $\mathbf{S}_{\omega_p}^{T_i(s)}$ is the most important one in estimation of the sensitivity to variations of passive elements. In many realization methods [1], [3] one obtains that $\omega_p \propto (R_1R_2C_1C_2)^{-1/2}$, which implies that $\mathbf{S}_{R_1}^{\omega_p}=\mathbf{S}_{R2}^{\omega_p}=\mathbf{S}_{C_1}^{\omega_p}=\mathbf{S}_{C2}^{\omega_p}=-1/2$. Thus, finally, the function Re $\mathbf{S}_{\omega_p}^{T_i(s)}$ (which can be called the main passive sensitivity term) will determine the maximum realizable Q_p for given tolerances of passive elements (or for the elements that are simulated as passive elements).

If a stage is realized using, for example a state–space approach, it includes operational amplifiers. The stage is usually designed assuming ideal operational amplifiers, then the realization errors are analyzed considering that the operational amplifiers can be described by a model

$$A(s)=\frac{A_0}{1+\left(s/\omega_0\right)}=\frac{\text{GBW}}{s+\omega_0} \tag{72.135}$$

where A_0 is the dc gain, ω_0 is the amplifier bandwidth, and GBW = $A_0\omega_0$ is the gain–bandwidth product. If the stage transfer function is derived anew, with amplifiers described by the model (72.135), then $T_i(s)$ will no longer be a biquadratic. It will be a ratio of two higher degree polynomials, and the error analysis becomes very complicated [1]. To do an approximate analysis one can pretend that the amplifier gain is simply a real constant A. Then, the transfer function $T_i(s)$ will preserve its biquadratic appearance, and the term $1/Q_p$ will be possible to represent as

$$\frac{1}{Q_p}=\frac{1}{Q}+\frac{k}{A} \tag{72.136}$$

The first term in (72.136) is determined by the ratio of passive elements, the second term (k is the design constant) can be considered as an *absolute* change $\Delta(1/Q_p)$, which on the $j\omega$ axis becomes

$$\Delta\left(\frac{1}{Q_p}\right)\approx\frac{k}{A(j\omega)}=\frac{1}{A_0}+j\frac{k\omega}{\text{GBW}}\approx j\frac{k\omega}{\text{GBW}} \tag{72.137}$$

© 2003 by CRC Press LLC

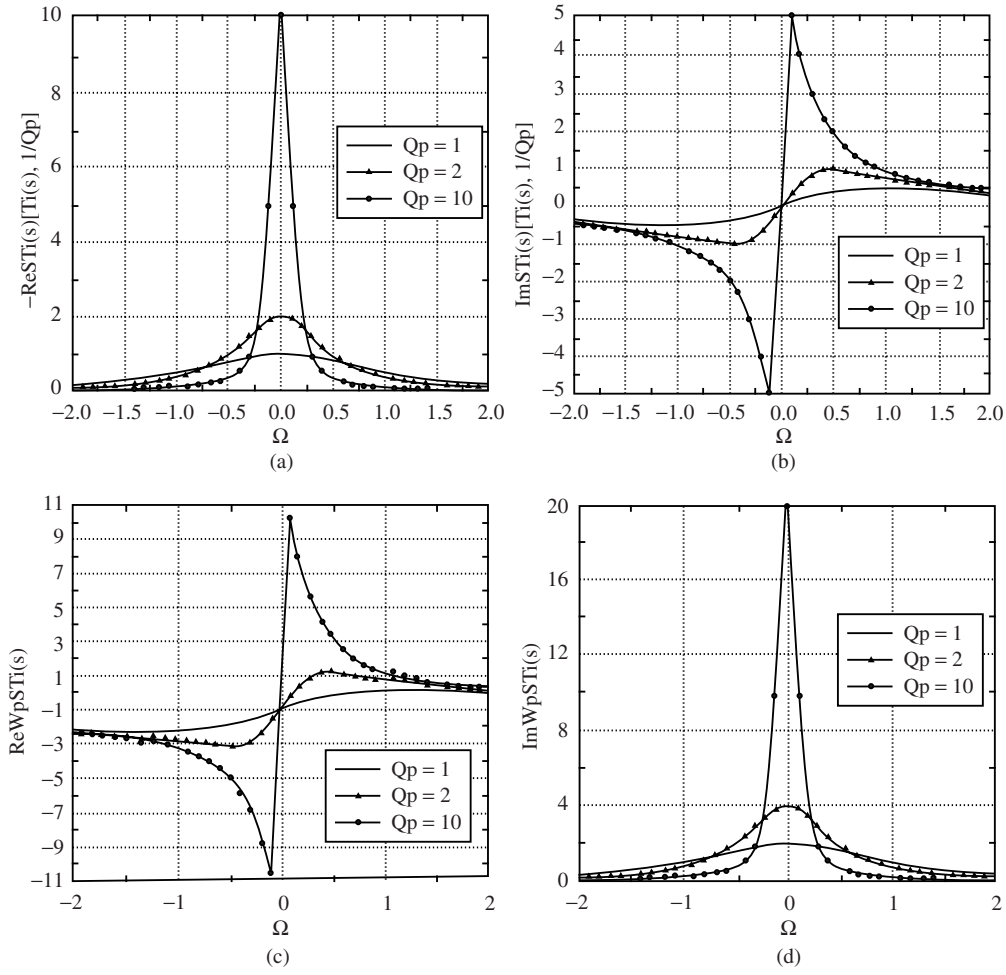

FIGURE 72.4 Stage sensitivities: real (a) and imaginary (b) parts of the *Q*-factor sensitivity; real (c) and imaginary (d) parts of the pole frequency sensitivity.

Then, in calculation of $\delta|T_i|$ = Re $\mathbf{S}_K^{T_i(s)}$ the function Im $\mathbf{S}_{\omega_p}^{T_i(s)}$ becomes important (it can be called the main active sensitivity term) and the product [Im $\mathbf{S}_{\omega_p}^{T_i(s)}$ $(k\omega/\text{GBW})$] allows evaluation of the limitations on the *Q*-factor caused by the stage operational amplifiers.

The relationships given next are useful for any arbitrary realization, but pertain more to the cascade realization, where one can better control the pole's location when the circuit parameters are changing. If the filter transfer function is represented as

$$T(s) = \frac{a_m \prod_{i=1}^{m} (s - z_i)}{d_n \prod_{i=1}^{n} (s - p_i)} \tag{72.138}$$

then taking the logarithm of (72.138) and its derivative gives

$$\frac{dT(s)}{T(s)} = \frac{d(a_m/d_n)}{a_m/d_n} - \sum_{i=1}^{m} \frac{dz_i}{s - z_i} + \sum_{i=1}^{n} \frac{dp_i}{s - p_i} \tag{72.139}$$

© 2003 by CRC Press LLC

Multiplying both sides of (72.139) by x and expressing the differentials via partial derivatives one obtains

$$\mathbf{S}_x^{T(s)} = \mathbf{S}_x^{a_m/d_n} - \sum_{i=1}^{m} \frac{\mathbf{S}_x(z_i)}{s - z_i} + \sum_{i=1}^{n} \frac{\mathbf{S}_x(p_i)}{s - p_i} \tag{72.140}$$

In the vicinity of the pole $p_i = -\sigma_i + j\omega_i$, the sensitivity is determined by the term $\mathbf{S}_x(p_i)/(s - p_i)$. Besides $\mathbf{S}_x(p_i) = -\mathbf{S}_x(\sigma_i) + j\mathbf{S}_x(\omega_i)$ and on the $j\omega$ axis in this region one has

$$\frac{\mathbf{S}_x(p_i)}{j\omega - p_i} = -\frac{\mathbf{S}_x(\sigma_i)\sigma_i + \mathbf{S}_x(\omega_i)(\omega - \omega_i)}{\sigma_i^2 + (\omega - \omega_i)^2} + j\frac{\mathbf{S}_x(\omega_i)\sigma_i + \mathbf{S}_x(\sigma_i)(\omega - \omega_i)}{\sigma_i^2 + (\omega - \omega_i)^2} \tag{72.141}$$

Hence, when $\omega \approx \omega_i$

$$\mathbf{S}_x^{|T(j\omega)|} \approx \frac{-\mathbf{S}_x(\sigma_i)\sigma_i + \mathbf{S}_x(\omega_i)(\omega - \omega_i)}{\sigma_i^2 + (\omega - \omega_i)^2} \tag{72.142}$$

and

$$\mathbf{S}_x[\arg T(j\omega)] \approx \frac{\mathbf{S}_x(\omega_i)\sigma_i + \mathbf{S}_x(\sigma_i)(\omega - \omega_i)}{\sigma_i^2 + (\omega - \omega_i)^2} \tag{72.143}$$

Usually (72.142) and (72.143) are considered at the point $\omega = \omega_i$, where $\mathbf{S}_x^{|T(j\omega)|} = -\mathbf{S}_x(\sigma_i)/\sigma_i$ and $\mathbf{S}_x[\arg T(j\omega)] = \mathbf{S}_x(\omega_i)/\sigma_i$. The frequent conclusion that follows is that the pole's movement toward the $j\omega$ axis is more dangerous (it introduces transfer function magnitude change) than the movement parallel to the $j\omega$ axis. But it is not difficult to see that in the immediate vicinity of this point, at $\omega = \omega_i \pm \sigma_i$, one has $\mathbf{S}_x^{|T(j\omega)|} = [-\mathbf{S}_x(\sigma_i) \pm \mathbf{S}_x(\omega_i)]/(2\sigma_i)$ and $\mathbf{S}_x[\arg T(j\omega)] = [\mathbf{S}_x(\omega_i) \pm \mathbf{S}_x(\sigma_i)]/(2\sigma_i)$; i.e., one has to reduce both components of the pole movement. If care is taken to get $\mathbf{S}_x(\sigma_i) = 0$, then, indeed, $\mathbf{S}_x^{|T(j\omega)|} = 0$ at $\omega = \omega_i$, but at $\omega = \omega_i + \sigma_i$ (closer to the edge of the passband) $\mathbf{S}_x^{|T(j\omega)|} = [\mathbf{S}_x(\omega_i)]/\sigma_i$ and this can result in an essential $\delta|T(j\omega)|$.

Finally, some additional relationships between different sensitivities can be obtained from the definition of $Q_p = \omega_p/(2\sigma_i) = [\sqrt{(\sigma_i^2 + \omega_i^2)}]/(2\sigma_i) \approx \omega_i/(2\sigma_i)$. One can find that

$$\mathbf{S}_x(\omega_p) = \frac{\mathbf{S}_x(\sigma_i)}{2Q_p} + \sqrt{1 - (1/4Q^2)}\,\mathbf{S}_x(\omega_i) \tag{72.144}$$

and

$$\mathbf{S}_x(Q_p) = \frac{\sqrt{4Q_p^2 - 1}\,\mathbf{S}_x(\omega_i) - (4Q_p^2 - 1)\,\mathbf{S}_x(\sigma_i)}{\omega_p} \tag{72.145}$$

for semirelative sensitivities. From this basic definition of the Q-factor, one can also derive the relationships

$$\mathbf{S}_x^{\omega_i} = \frac{\mathbf{S}_x^{\sigma_i}}{4Q_p^2} + \sqrt{1 - (1/4Q^2)}\,\mathbf{S}_x^{\omega_i} \tag{72.146}$$

and

$$\mathbf{S}_x^{Q_p} \approx \mathbf{S}_x^{\omega_i} - \mathbf{S}_x^{\sigma_i} \tag{72.147}$$

involving relative sensitivities. Another group of results can be obtained considering relative sensitivity of the pole $p_i = -\sigma_i + j\omega_i$. For example, one can find that

© 2003 by CRC Press LLC

$$\mathbf{S}_x^{Q_p} = -\sqrt{4Q_p^2 - 1}\,\mathrm{Im}\;\mathbf{S}_x^{p_i} = \frac{x}{\omega_p^2}\left(\frac{\omega_i}{\sigma_i}\right)\left(\sigma_i\frac{\partial\omega_i}{\partial x} - \omega_i\frac{\partial\sigma_i}{\partial x}\right) \tag{72.148}$$

If $\partial\omega_i/\partial x = 0$ and $\partial\sigma_i/\partial x =$ constant, then

$$\mathbf{S}_x^{Q_p} \approx kQ_p \tag{72.149}$$

which shows that in this case $\mathbf{S}_x^{Q_p}$ increases proportionally to the Q-factor independently on the cause of this high sensitivity.

72.14 Simulation of Doubly Terminated Matched Lossless Filters

By cascading the first- and second-order filter sections (occasionally a third-order section is realized in odd-order filters instead of one cascade connection of a first- and second-order section) any high-order transfer function $T(s)$ can be realized. In practice, however, the resulting circuit is difficult to fabricate for high-order and/or highly selective filters. The transfer function of such filters usually contains a pair of complex-conjugate poles very close to the $j\omega$ axis. The sensitivity of this section that realizes high-Q poles is high and the element tolerances for this section can be very tight. The section can be unacceptable for fabrication.

For filters that have such high-Q transfer function poles, other design techniques are often used. The most successful and widely used of these alternative strategies are based on simulating the low-sensitivity transfer function of a doubly terminated lossless (reactance) two-port.

Assume that the two-port shown in Fig. 72.5 is lossless and the transfer function $T(s) = V_2(s)/E(s)$ is realized. Considering power relations one can show [12] that for steady-state sinusoidal operation the equation

$$\left|\rho(j\omega)\right|^2 + \frac{4R_1}{R_2}\left|T(j\omega)\right|^2 = 1 \tag{72.150}$$

is valid for this circuit. Here, $\rho(j\omega) = [R_1 - Z(j\omega)]/[R_1 + Z(j\omega)]$ is the reflection coefficient and $Z(j\omega)$ is the input impedance of the loaded two-port. In many cases the filter requirements are formulated for the transducer function

$$H(s) = \sqrt{\frac{R_2}{4R_1}}\frac{E(s)}{V_2(s)} = \sqrt{\frac{R_2}{4R_1}}\frac{1}{T(s)} \tag{72.151}$$

For this function,

$$\ln H(j\omega) = \alpha(\omega) + j\varphi(\omega) = -\ln\left|T(j\omega)\right| + \ln\left[\sqrt{(R_2/4R_1)}\right] - j\arg T(j\omega) \tag{72.152}$$

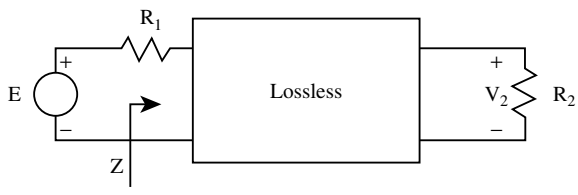

FIGURE 72.5 Lossless two-port with reactance loadings.

© 2003 by CRC Press LLC

Here, $\alpha(\omega)$ is attenuation (it is different from the previously used only by the value of $\ln[\sqrt{(R_2/4R_1)}]$) and $\varphi(\omega) = -\beta(\omega) = -\arg T(j\omega)$ is phase. The impedance $Z(j\omega)$ satisfies the condition Re $Z(j\omega) \geq 0$ (as for any passive circuit input impedance), which means that $|\rho(j\omega)|^2 \leq 1$. Then, as it follows from (72.150) $|H(j\omega|^2 \geq 1$ and $\alpha(\omega) \geq 0$.

When a filter is designed using $\alpha(\omega)$, the attenuation should be small in the filter passband; moreover, the attenuation is optimized so that it is zero in one or more passband points (Fig. 72.3 shows, for example, the attenuation characteristics with three zeros in the passband). Then the attenuation partial derivative with respect to the value of each of the two-port elements is equal to zero at the attenuation zeros. Indeed, let x_i be any element of the two-port and $\partial\alpha/\partial x_i$ be the partial derivative of $\alpha(\omega, x_i)$ with respect to that element. Suppose that x_i does not have its nominal value and differs from it by a small Δx_i variation. Expanding $\alpha(\omega, x_i)$ in the Taylor series one obtains that

$$\alpha(\omega, x_i + \Delta x_i) \cong \alpha(\omega, x_i) + \Delta x_i \frac{\partial\alpha(\omega, x_i)}{\partial x_i} \tag{72.153}$$

If ω_k is an attenuation zero, then $\alpha(\omega_k, x_i) = 0$; but, as was mentioned before, $\alpha(\omega) \geq 0$, and from (72.153), one obtains that at the point $\omega = \omega_k$ one has

$$\Delta x_i \frac{\partial\alpha(\omega_k, x_i)}{\partial x_i} \geq 0 \tag{72.154}$$

Now, the variation Δx_i was of unspecified sign. Therefore, (72.154) can only be satisfied with the equality sign, which means that $\partial\alpha(\omega_k, x_i)/\partial x_i = 0$.

This result is called the **Fettweis–Orchard theorem** [4] and it explains why the preference is always given to the filter realized as a nondissipative two-port between resistive terminations or to the simulation of such a filter if the filter should be realized as an active circuit. First, considering the real parts of (72.152), one obtains that

$$x_i \frac{\partial\alpha(\omega)}{\partial x_i} = \mathbf{S}_{x_i}[\alpha(\omega)] = -\frac{x_i}{|T(j\omega)|}\frac{\partial|T(j\omega)|}{\partial x_i} = -\mathbf{S}_{x_i}^{|T(j\omega)|} \tag{72.155}$$

when x_i is any element inside the two-port. Hence, the points where $\alpha(\omega_k) = 0$ and, simultaneously, $\partial\alpha(\omega_k)/\partial x_i = 0$ are the points of zero sensitivity not only for attenuation but for transfer function magnitude as well.[22] Moreover, if α is small, $\partial\alpha/\partial x_i$ will also remain small [13], which means that the sensitivities are small in the whole passband. If $x_i = R_1$ or $x_i = R_2$, one obtains from (72.152) that

$$R_1 \frac{\partial\alpha(\omega, R_1)}{\partial R_1} = -\mathbf{S}_{R_1}^{|T(j\omega)|} - \frac{1}{2} \tag{72.156}$$

and

$$R_2 \frac{\partial\alpha(\omega, R_2)}{\partial R_2} = -\mathbf{S}_{R_2}^{|T(j\omega)|} + \frac{1}{2} \tag{72.157}$$

The derivatives $\partial\alpha/\partial R_i$ ($i = 1, 2$) are also zero at the points where $\alpha = 0$ and they are small when α remains small [13]. This means that in the passband $\mathbf{S}_{R_1}^{|T(j\omega)|} \approx -1/2$ and $\mathbf{S}_{R_2}^{|T(j\omega)|} \approx 1/2$. Thus, $|T(j\omega)|$ will

[2]As a result of (72.155) and this discussion, one cannot use at these points the relationship $d|T(j\omega)| \approx \mathbf{S}_{x_i}^{|t(j\omega)|}\ \delta x_i$; the relative change $\delta|T(j\omega)|$ is always negative and different from zero with δx_i of unspecified sign.

© 2003 by CRC Press LLC

share the zero sensitivity of α with respect to all the elements inside the two-port, but due to the terms $\pm 1/2$ in (72.156) and (72.157) a change either in R_1 or R_2 will produce a frequency-independent shift (which can usually be tolerated) in $|T(j\omega)|$ in addition to the small effects proportional to $\partial\alpha/\partial R_i$. This is the basis of the low sensitivity of conventional *LC*-ladder filters and of those active, switched-capacitor or digital filters that are based on the *LC* filter model. This is valid with the condition that the transfer functions of the active filter and *LC* prototype are the same and the parameters of the two filters enter their respective transfer functions the same way.

The Fettweis–Orchard theorem explains why the filtering characteristics sought are those with the maximum number of attenuation zeros [for a given order of the transfer function $T(s)$]. It also helps to understand why it is difficult to design a filter that simultaneously meets the requirements of α and $\varphi(\omega)$ [or to $|T(j\omega)|$ and $\beta(\omega)$]: the degrees of freedom used for optimizing $\varphi(\omega)$ will not be available to attain the maximum number of attenuation zeros. It also explains why a cascade realization is more sensitive than the realization based on the *LC* lossless model. Indeed, assume that, say, one of the characteristics of Fig. 72.3 is realized by three cascaded sections (with the attenuation of each section shown by the dash-and-dotted line) with each actual section realized in doubly terminated matched lossless form. Each such section of the cascaded filter will be matched at one frequency and the sensitivities to the elements that are in unmatched sections will be different from zero. In addition, the attenuation ripple in each section is usually much larger than the total ripple, and the derivative $\partial\alpha/\partial x_i$, which is, in the first approximation, proportional to the atttenuation ripple, will not be small. Indeed, practice shows [4] that there is, in fact, a substantial increase in sensitivity in the factored realization.

72.15 Sensitivity of Active *RC* Filters

The required component tolerances are very important factors determining the cost of filters. They are especially important with integrated realizations (where the tolerances are usually higher than in discrete technology). Also, the active filter realizations commonly require tighter tolerances than *LC* realizations. Yet two classes of active *RC* filters have tolerances comparable with those of passive *LC* filters. These are analog-computer and gyrator filters that simulate doubly terminated passive *LC* filters. The tolerance comparison [4] shows the tolerance advantages (sometimes by an order of magnitude) of the doubly terminated lossless structure as compared to any cascade realization. These are the only methods that are now used [14] for high-order high-Q sharp cutoff filters with tight tolerances. For less demanding requirements cascaded realizations could be used. The main advantages that are put forth in this case are the ease of design and simplicity of tuning. But even here the tolerance comparison [4] shows that the stages have better tolerances if they are realized using gyrators and computer simulation methods.

72.16 Errors in Sensitivity Comparisons

In conclusion, we briefly outline some common errors in sensitivity comparison. More detailed treatment can be found in [4].

1. ***Calculating the Wrong Sensitivities.*** The calculated sensitivities should have as close a relation to the filter specification as possible. In general, for a filter specified in the frequency domain the sensitivities of amplitude and phase should be calculated along the $j\omega$ axis. Sensitivities of poles, zeros, Q's, resonant frequencies, etc., should be carefully interpreted in the context of their connection with amplitude and phase sensitivities.
2. ***Sensitivities of Optimized Designs.*** The optimization should use a criterion as closely related as possible to filter specifications. The use of a criterion that is not closely related to the filter specifications (for example, pole sensitivity) can lead to valid conclusions if the filters being compared differ by an order of magnitude in sensitivity [4]. A sensitivity comparison is valid only if all the circuits have been optimized using the criterion on which they will be compared. The

© 2003 by CRC Press LLC

optimized circuit should not be compared with a nonoptimized one. Another error is to optimize a circuit using a very narrow criterion relying on one parameter and forgetting about variations of other parameters or to optimize one part of the transfer function (usually the denominator) and forgetting about the modifying effect of the numerator.

3. ***Comparing the Incomparable.*** A frequent error occurs when comparing sensitivities with respect to different types of elements. In general, different types of elements can be realized with different tolerances, and the comparison is valid only if sensitivities are weighted proportionally. Besides, there are basic differences in variability between circuit parameters with physical dimensions and those without. The latter are often determined in the circuit as the ratio of dimensional quantities (as a result, the tolerance of the ratio will be about double the tolerances of the two-dimensional quantities determining them). In integrated technologies the dimensioned quantities usually have worse tolerances but better matching and tracking ability, especially with temperature. Hence, any conclusion involving sensitivities to different types of components, in addition, is technologically dependent.
4. ***Correlations between Component Values.*** The correlations between components are neglected when they are essential (this is usually done for simplification of the statistical analysis). From the other side, an unwarranted correlation is introduced when it does not exist. This is a frequent case where the realization involves cancellation of terms that are equal only when the elements have their nominal values (for example, a cancellation of a pole of one section of a filter by a zero of another section, cancellation of a positive conductance by a negative conductance).
5. ***Incomplete Analysis.*** Very often only sensitivities to variations of a single component (usually an amplifier gain) are considered. This is satisfactory only if it is the most critical component which is seldom the case. Another form of incomplete analysis is to calculate only one coordinate of a complex sensitivity measure ($\mathbf{S}_x^Q$ is calculated while $\mathbf{S}_x^{\omega_0}$ is ignored). Also, frequency dependent sensitivities are calculated and compared at one discrete frequency instead of being calculated in frequency intervals.
6. ***First-Order Differential Sensitivities Are the Most Commonly Calculated.*** But the fact that $\partial y/\partial x = 0$ implies that the variation of y with x is quadratic at the point considered. A consequence of this is that zero sensitivities do not imply infinitely wide tolerances for the components in question. Similarly, infinite sensitivities do not imply infinitely narrow tolerances. Infinite values arise if the nominal value of y is zero, and the finite variations of x will almost always give finite variations of y.

Passive Immittances and Positive-Real Functions[1]

Wai-Kai Chen
University of Illinois, Chicago

In this section on passive filters, we deal with the design of one-port networks composed exclusively of passive elements such as resistors *R*, inductors *L*, capacitors *C*, and coupled inductors *M*. The one-ports are specified by their driving-point *immittances*, *impedances*, or *admittances*. Our basic problem is that given an immittance function, is it possible to find a one-port composed only of *R*, *L*, *C*, and *M* elements called the *RLCM one-port network* that realizes the given immittance function? This is known as the **realizability problem**, and its complete solution was first given by Brune [3].

Consider a linear RLCM one-port network of Fig. 73.1 excited by a voltage source $V_1(s)$. For our purposes, we assume that there are b branches and the branch corresponding to the voltage source $V_1(s)$ is numbered branch 1 and all other branches are numbered from 2 to b. The Laplace transformed Kirchhoff current law equation can be written as

$$\mathbf{A}\mathbf{I}(s) = \mathbf{0} \tag{73.1}$$

where $\mathbf{A}$ is the basis incidence matrix and $\mathbf{I}(s)$ is the branch-current vector of the network. If $\mathbf{V}_n(s)$ is the nodal voltage vector, then the branch-voltage vector $\mathbf{V}(s)$ can be expressed in terms of $\mathbf{V}_n(s)$ by

$$\mathbf{V}(s) = \mathbf{A}'\mathbf{V}_n(s) \tag{73.2}$$

where the prime denotes the matrix transpose. Taking the complex conjugate of (73.1) in conjunction with (73.2) gives

$$\mathbf{V}'(s)\bar{\mathbf{I}}(s) = \mathbf{V}_n'(s)\mathbf{A}\bar{\mathbf{I}}(s) = \mathbf{V}_n'(s)\,\mathbf{0} = 0 \tag{73.3}$$

or

$$\sum_{k=1}^{b} V_k(s)\bar{I}_k(s) = 0 \tag{73.4}$$

where $V_k(s)$ and $I_k(s)$ are the branch voltages and the branch currents, respectively.

[1]References for this chapter can be found on page 2421.

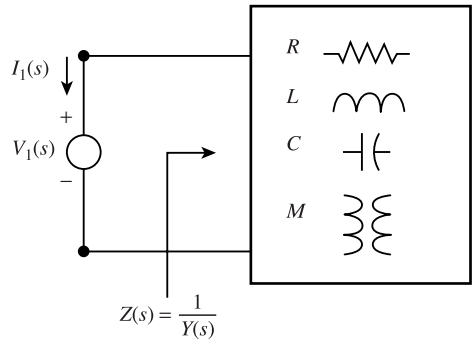

FIGURE 73.1 A general linear *RLCM* one-port network.

From Fig. 73.1, the driving-point impedance of the one-port is defined to be the ratio of $V_1(s)$ to $-I_1(s)$, or

$$Z(s) \equiv \frac{V_1(s)}{-I_1(s)} = \frac{V_1(s)\bar{I}_1(s)}{-I_1(s)\bar{I}_1(s)} = -\frac{V_1(s)\bar{I}_1(s)}{|I_1(s)|^2} \tag{73.5}$$

Equation (73.4) can be rewritten as

$$-V_1(s)\bar{I}_1(s) = \sum_{k=2}^{b} V_k(s)\bar{I}_k(s) \tag{73.6}$$

Substituting this in (73.5) yields

$$Z(s) = \frac{1}{|I_1(s)|^2} \sum_{k=2}^{b} V_k(s)\bar{I}_k(s) \tag{73.7}$$

Likewise, the dual relation of the input admittance

$$Y(s) \equiv \frac{-I_1(s)}{V_1(s)} = \frac{1}{|V_1(s)|^2} \sum_{k=2}^{b} \bar{V}_k(s) I_k(s) \tag{73.8}$$

holds.

We know consider individual types of elements inside the one-port. For a resistive branch k of resistance R_k, we have

$$V_k(s) = R_k I_k(s) \tag{73.9}$$

For a capacitive branch of capacitance C,

$$V_k(s) = \frac{1}{sC_k} I_k(s) \tag{73.10}$$

Finally, for an inductive branch of self-inductance L_k and mutual inductances M_{kj},

$$V_k(s) = sL_k I_k(s) + \sum_{\text{all } j,\, j \neq k} sM_{kj} I_j(s) \tag{73.11}$$

© 2003 by CRC Press LLC

Substituting these in (73.7) and grouping the summation as sums of all resistors R, all capacitors C, and all inductors LM, we obtain

$$\begin{aligned} Z(s) &= \frac{1}{\left|I_1(s)\right|^2}\left[\sum_R R_k\left|I_k(s)\right|^2 + \sum_C \frac{1}{sC_k}\left|I_k(s)\right|^2 + \sum_{LM}\left(sL_k\left|I_k(s)\right|^2 + \sum_{\text{all } j,\, j\neq k} sM_{kj}I_j(s)\bar{I}_k(s)\right)\right] \\ &= \frac{1}{\left|I_1(s)\right|^2}\left[F_0(s) + \frac{1}{s}V_0(s) + sM_0(s)\right] \end{aligned} \tag{73.12}$$

where

$$F_0(s) \equiv \sum_R R_k\left|I_k(s)\right|^2 \geq 0 \tag{73.13a}$$

$$V_0(s) \equiv \sum_C \frac{1}{C_k}\left|I_k(s)\right|^2 \geq 0 \tag{73.13b}$$

$$M_0(s) \equiv \sum_{LM}\left(L_k\left|I_k(s)\right|^2 + \sum_{\text{all } j,\, j\neq k} M_{kj}I_j(s)\bar{I}_k(s)\right) \tag{73.13c}$$

These quantities are closely related to the average power and stored energies of the one-port under steady-state sinusoidal conditions. The average power dissipated in the resistors is

$$P_{\text{ave}} = \frac{1}{2}\sum_R R_k\left|I_k(j\omega)\right|^2 = \frac{1}{2}F_0(j\omega) \tag{73.14}$$

showing that $F_0(j\omega)$ represents twice the average power dissipated in the resistors of the one-port. The average electric energy stored in the capacitors is

$$E_C = \frac{1}{4\omega^2}\sum_C \frac{1}{C_k}\left|I_k(j\omega)\right|^2 = \frac{1}{4\omega^2}V_0(j\omega) \tag{73.15}$$

Thus, $V_o(j\omega)$ denotes $4\omega^2$ times the average electric energy stored in the capacitors. Similarly, the average magnetic energy stored in the inductors is

$$E_M = \frac{1}{4}\sum_{LM}\left[L_k\left|I_k(j\omega)\right|^2 + \sum_{\text{all } q,q\neq k} M_{kq}I_q(j\omega)\bar{I}_k(j\omega)\right] = \frac{1}{4}M_0(j\omega) \tag{73.16}$$

indicating that $M_0(j\omega)$ represents four times the average magnetic energy stored in the inductors.

Therefore, all the three quantities $F_0(j\omega)$, $V_0(j\omega)$, and $M_0(j\omega)$ are real and nonnegative, and (73.12) can be rewritten as

$$Z(s) = \frac{1}{\left|I_1(s)\right|^2}\left(F_0 + \frac{1}{s}V_0 + sM_0\right) \tag{73.17}$$

Likewise, the dual result for $Y(s)$ is found to be

$$Y(s) = \frac{1}{\left|V_1(s)\right|^2}\left(F_0 + \frac{1}{\bar{s}}V_0 + \bar{s}M_0\right) \tag{73.18}$$

© 2003 by CRC Press LLC

Now, we set $s = \sigma + j\omega$ and compute the real part and imaginary part of $Z(s)$ and obtain

$$\text{Re } Z(s) = \frac{1}{|I_1(s)|^2}\left(F_0 + \frac{\sigma}{\sigma^2 + \omega^2}V_0 + \sigma M_0\right) \tag{73.19}$$

$$\text{Im } Z(s) = \frac{\omega}{|I_1(s)|^2}\left(M_0 - \frac{1}{\sigma^2 + \omega^2}V_0\right) \tag{73.20}$$

where **Re** stands for "real part of" and **Im** for "imaginary part of." These equations are valid irrespective of the value of s, except at the zeros of $I_1(s)$. They are extremely important in that many analytic properties of passive impedances can be obtained from them. The following is one of such consequences:

Theorem 1: *If $Z(s)$ is the driving-point impedance of a linear, passive, lumped, reciprocal, and time-invariant one-port network N, then*

1. *Whenever* $\sigma \geq 0$, Re $Z(s) \geq 0$.
2. *If N contains no resistors, then*

$$\sigma > 0 \text{ implies Re } Z(s) > 0$$
$$\sigma = 0 \text{ implies Re } Z(s) = 0$$
$$\sigma < 0 \text{ implies Re } Z(s) < 0$$

3. *If N contains no capacitors, then*

$$\omega > 0 \text{ implies Im } Z(s) > 0$$
$$\omega = 0 \text{ implies Im } Z(s) = 0$$
$$\omega < 0 \text{ implies Im } Z(s) < 0$$

4. *If N contains no self- and mutual inductors, then*

$$\omega > 0 \text{ implies Im } Z(s) < 0$$
$$\omega = 0 \text{ implies Im } Z(s) = 0$$
$$\omega < 0 \text{ implies Im } Z(s) > 0$$

Similar results can be stated for the admittance function $Y(s)$ simply by replacing $Z(s)$, Re $Z(s)$, *and* Im $Z(s)$ *by $Y(s)$,* Re $Y(s)$, *and* $-$Im $Y(s)$, *respectively.*

The theorem states that the driving-point impedance $Z(s)$ of a passive LMC, RLM, or RC one-port network maps different regions of the complex-frequency s-plane into various regions of the Z-plane. Now, we assert that the driving-point immittance of a passive one-port is a positive-real function, and every positive-real function can be realized as the input immittance of an RLCM one-port network.

Definition 1. *Positive-real function. A positive-real function $F(s)$,* abbreviated as a **PR function**, is an analytic function of the complex variable $s = \sigma + j\omega$ satisfying the following three conditions:

1. $F(s)$ is analytic in the open RHS (*right-half* of the s-plane), i.e., $\sigma > 0$.
2. $F(\bar{s}) = \bar{F}(s)$ for all s in the open RHS.
3. Re $F(s) \geq 0$ whenever Re $s \geq 0$.

The concept of a positive-real function, as well as many of its properties, is credited to Otto Brune [3]. Our objective is to show that positive realness is a necessary and sufficient condition for a passive one-port immittance. The above definition holds for both rational and transcendental functions. A **rational**

© 2003 by CRC Press LLC

function is defined as a ratio of two polynomials. Network functions associated with any linear lumped system, with which we deal exclusively in this section, are rational. In the case of rational functions, not all three conditions in the definition are independent. For example, the analyticity requirement is implied by the other two. The second condition is equivalent to stating the $F(s)$ is real when s is real, and for a rational $F(s)$ it is always satisfied if all the coefficients of the polynomial are real.

Some important properties of a positive-real function can be stated as follows:

1. If $F_1(s)$ and $F_2(s)$ are positive real, so is $F_1[F_2(s)]$.
2. If $F(s)$ is positive real, so are $1/F(s)$ and $F(1/s)$.
3. A positive-real function is devoid of poles and zeros in the open RHS.
4. If a positive-real function has any poles or zeros on the $j\omega$-axis (0 and ∞ included), such poles and zeros must be simple. At a simple pole on the $j\omega$-axis, the residue is real positive.

Property 1 states that a positive-real function of a positive-real function is itself positive real, and property 2 shows that the reciprocal of a positive-real function is positive real. The real significance of the positive-real functions is its use in the characterization of the passive one-port immittances. This characterization is one of the most penetrating results in network theory, and is stated as

Theorem 2: *A real rational function is the driving-point immittance of a linear, passive, lumped, reciprocal, and time-invariant one-port network if and only if it is positive real.*

The necessity of the theorem follows directly from (73.19). The sufficiency was first established by Brune in 1930 by showing that any given positive-real rational function can be realized as the input immittance of a passive one-port network using only the passive elements such as resistors, capacitors, and self- and mutual inductors. A formal constructive proof will be presented in the following section.

Example 1. Consider the passive one-port of Fig. 73.2, the driving-point impedance of which is found to be

$$Z(s) = \frac{3s^2 + s + 2}{2s^2 + s + 3} \tag{73.21}$$

To verify that the function $Z(s)$ is positive real, we compute its real part by substituting $s = \sigma + j\omega$ and obtain

$$\begin{aligned} \operatorname{Re} Z(s) &= \operatorname{Re} Z(\sigma + j\omega) = \operatorname{Re} \frac{3(\sigma + j\omega)^2 + (\sigma + j\omega) + 2}{2(\sigma + j\omega)^2 + (\sigma + j\omega) + 3} \\ &= \frac{6(\omega^2 - 1)^2 + (12\omega^2\sigma + 5\omega^2 + 6\sigma^3 + 5\sigma^2 + 14\sigma + 5)\sigma}{(2\sigma^2 - 2\omega^2 + \sigma + 3)^2 + \omega^2(4\sigma + 1)^2} \geq 0, \quad \sigma \geq 0 \end{aligned} \tag{73.22}$$

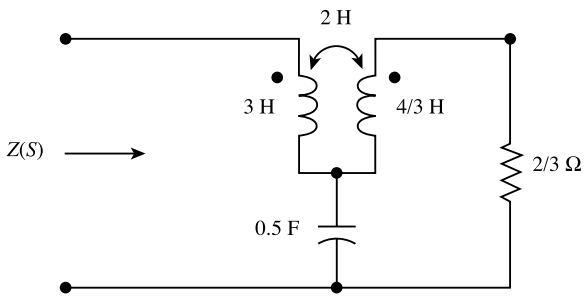

FIGURE 73.2 A passive one-port network.

© 2003 by CRC Press LLC

This, in conjunction with the facts that $Z(s)$ is analytic in the open RHS and that all the coefficients of $Z(s)$ are real, shows that $Z(s)$ is positive real.

Observe that if the function $Z(s)$ is of high order, the task of ascertaining its positive realness is difficult if condition 3 of Definition 1 is employed for checking. Hence, it is desirable to have alternate but much simpler conditions for testing. For this reason, we introduce the following equivalent conditions that are relatively easy to apply:

Theorem 3: *A rational function $F(s)$ is positive real if and only if the following conditions are satisfied:*

1. *$F(s)$ is real when s is real.*
2. *$F(s)$ has no poles in the open RHS.*
3. *Poles of $F(s)$ on the $j\omega$-axis, if they exist, are simple, and residues evaluated at these poles are real and positive.*
4. *Re $F(j\omega) \geq 0$ for all ω, except at the poles.*

PROOF: From the definition of a PR function, we see immediately that all the conditions are necessary. To prove sufficiency, we expand $F(s)$ in a partial fraction as

$$\begin{aligned} F(s) &= \left[k_\infty s + \frac{k_0}{s} + \sum_x \left(\frac{k_x}{s + j\omega_x} + \frac{k_x}{s - j\omega_x} \right) \right] + F_1(s) \\ &= \left(k_\infty s + \frac{k_0}{s} + \sum_x \frac{2k_x s}{s^2 + \omega_x^2} \right) + F_1(s) \end{aligned} \tag{73.23}$$

where k_∞, k_0, and k_x are residues evaluated at the $j\omega$-axis poles $j\infty$, 0, and $\pm j\omega_x$, respectively, and are real and positive. $F_1(s)$ is the function formed by the terms corresponding to the open LHS (*l*eft-*h*alf of the s-plane) poles of $F(s)$, and therefore is analytic in the RHS and the entire $j\omega$-axis including the point at infinity. For such a function, the minimum value of the real part throughout the region where the function is analytic lies on the boundary, namely, the $j\omega$-axis. (See, for example, Churchill [8)]. This shows that the minimum value of Re $F_1(s)$ for all Re $s \geq 0$ occurs on the $j\omega$-axis; but, according to (73.23), this value is nonnegative:

$$\text{Re}\, F_1(j\omega) = \text{Re}\, F(j\omega) \geq 0 \tag{73.24}$$

Thus, the real part of $F_1(s)$ is nonnegative everywhere in the closed RHS or

$$\text{Re}\, F_1(s) \geq 0 \quad \text{for} \quad \text{Re}\, s \geq 0 \tag{73.25}$$

This, together with the fact that $F_1(s)$ is real whenever s is real, shows that $F_1(s)$ is positive real.

Since each term inside the parentheses of (73.23) is positive real, and since the sum of two or more positive-real functions is positive real, $F(s)$ is positive real. This completes the proof of the theorem.

In testing for positive realness, we may eliminate some functions from consideration by inspection because they violate certain simple necessary conditions. For example, a function cannot be PR if it has a pole or zero in the open RHS. Another simple test is that the highest powers of s in numerator and denominator not differ by more than unity, because a PR function can have at most a simple pole or zero at the origin or infinity, both of which lie on the $j\omega$-axis.

A **Hurwitz polynomial** is a polynomial devoid of zeros in the open RHS. Thus, it may have zeros on the $j\omega$-axis. To distinguish such a polynomial from the one that has zeros neither in the open

© 2003 by CRC Press LLC

RHS nor on the $j\omega$-axis, the latter is referred to as a **strictly Hurwitz polynomial**. For computational purposes, Theorem 3 can be reformulated and put in a much more convenient form.

Theorem 4: *A rational function represented in the form*

$$F(s) = \frac{P(s)}{Q(s)} = \frac{m_1(s) + n_1(s)}{m_2(s) + n_2(s)} \tag{73.26}$$

where $m_1(s)$, $m_2(s)$, and $n_1(s)$, $n_2(s)$ are the even and odd parts of the polynomials $P(s)$ and $Q(s)$, respectively, is positive real if and only if the following conditions are satisfied:

1. *$F(s)$ is real when s is real.*
2. *$P(s) + Q(s)$ is strictly Hurwitz.*
3. *$m_1(j\omega)m_2(j\omega) - n_1(j\omega)n_2(j\omega) \geq 0$ for all ω.*

A real polynomial is strictly Hurwitz if and only if the continued-fraction expansion of the ratio of the even part to the odd part or the odd part to the even part of the polynomial yields only real and positive coefficients, and does not terminate prematurely. For $P(s) + Q(s)$ to be strictly Hurwitz, it is necessary and sufficient that the continued-fraction expansion

$$\left[\frac{m_1(s) + m_2(s)}{n_1(s) + n_2(s)}\right]^{\pm 1} = \alpha_1 s + \cfrac{1}{\alpha_2 s + \cfrac{1}{\ddots + \cfrac{1}{\alpha_k s}}} \tag{73.27}$$

yields only real and positive α's, and does not terminate prematurely, i.e., k must equal the degree $m_1(s) + m_2(s)$ or $n_1(s) + n_2(s)$, whichever is larger. It can be shown that the third condition of the theorem is satisfied if and only if its left-hand-side polynomial does not have real positive roots of odd multiplicity. This may be determined by factoring it or by the use of the Sturm's theorem, which can be found in most texts on elementary theory of equations. We illustrate the above procedure by the following examples.

Example 2. Test the following function to see if it is PR:

$$F(s) = \frac{2s^4 + 4s^3 + 5s^2 + 5s + 2}{s^3 + s^2 + s + 1} \tag{73.28}$$

For illustrative purposes, we follow the three steps outlined in the theorem, as follows:

$$F(s) = \frac{2s^4 + 4s^3 + 5s^2 + 5s + 2}{s^3 + s^2 + s + 1} = \frac{P(s)}{Q(s)} = \frac{m_1(s) + n_1(s)}{m_2(s) + n_2(s)} \tag{73.29}$$

where

$$m_1(s) = 2s^4 + 5s^2 + 2, \qquad n_1(s) = 4s^3 + 5s \tag{73.30a}$$

$$m_2(s) = s^2 + 1, \qquad n_2(s) = s^3 + s \tag{73.30b}$$

© 2003 by CRC Press LLC

Condition 1 is clearly satisfied. To test condition 2, we perform the Hurwitz test, which gives

$$\frac{m_1(s)+m_2(s)}{n_1(s)+n_2(s)}=\frac{2s^4+6s^2+3}{5s^3+6s}=\frac{2}{5}s+\cfrac{1}{\cfrac{25}{18}s+\cfrac{1}{\cfrac{324}{165}s+\cfrac{1}{\cfrac{33}{54}s}}} \tag{73.31}$$

Since all the coefficients are real and positive and since the continued-fraction expansion does not terminate prematurely, the polynomial $P(s)+Q(s)$ is strictly Hurwitz. Thus, condition 2 is satisfied.

To test condition 3, we compute

$$\begin{aligned} m_1(j\omega)m_2(j\omega)-n_1(j\omega)\,n_2(j\omega) &= 2\omega^6-2\omega^4-2\omega^2+2 \\ &= 2\left(\omega^2+1\right)\left(\omega^2-1\right)^2\geq 0 \end{aligned} \tag{73.32}$$

which is nonnegative for all ω, or, equivalently, which does not possess any real positive roots of odd multiplicity. Therefore $F(s)$ is positive real.

Passive Cascade Synthesis[1]

Wai-Kai Chen
University of Illinois, Chicago

74.1 Introduction
74.2 Type-E Section
74.3 The Richards Section
74.4 The Darlington Type-D Section

74.1 Introduction

In this chapter, we demonstrate that any rational positive-real function can be realized as the input immittance of a passive one-port network terminated in a resistor, thereby also proving the sufficiency of Theorem 2, Chapter 73.

Consider the even part

$$\text{Ev } Z(s) = r(s) = \frac{1}{2}\left[Z(s) + Z(-s)\right] \tag{74.1}$$

of a given rational positive-real impedance $Z(s)$. As in (73.26), we first separate the numerator and denominator polynomials of $Z(s)$ into even and odd parts, and write

$$Z(s) = \frac{m_1 + n_1}{m_2 + n_2} \tag{74.2}$$

Then, we have

$$r(s) = \frac{m_1 m_2 - n_1 n_2}{m_2^2 + n_2^2} \tag{74.3}$$

showing that if s_0 is a zero or pole of $r(s)$, so is $-s_0$. Thus, the zeros and poles of $r(s)$ possess quadrantal symmetry with respect to both the real and imaginary axes. They may appear in pairs on the real axis, in pairs on the $j\omega$-axis, or in the form of sets of quadruplets in the complex-frequency plane. Furthermore, for a positive-real $Z(s)$, the $j\omega$-axis zeros of $r(j\omega)$ are required to be of even multiplicity in order that Re $Z(j\omega) = r(j\omega)$ never be negative.

Suppose that we can extract from $Z(s)$ a set of open-circuit impedance parameters $z_{ij}(s)$ characterizing a component two-port network, as depicted in Fig. 74.1, which produces one pair of real axis zeros, one pair of $j\omega$-axis zeros, or one set of quadruplet of zeros of $r(s)$, and leaves a rational positive-real

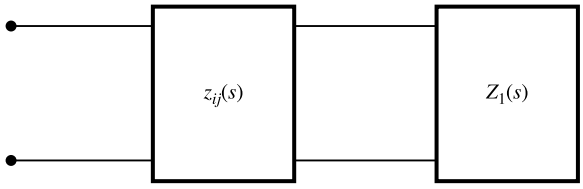

FIGURE 74.1 A two-port network terminated in $Z_1(s)$.

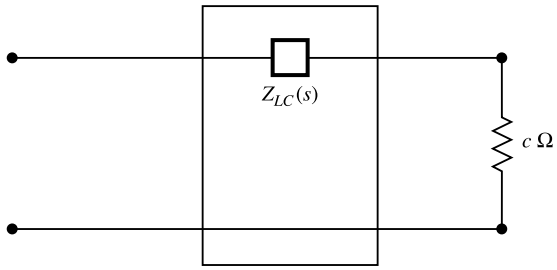

FIGURE 74.2 A two-port network terminated in a resistor.

impedance $Z_1(s)$ of lower degree, the even part of which $r_1(s)$ is devoid of these zeros but contains all other zeros of $r(s)$. After a finite q steps, we arrive at a rational positive-real impedance $Z_q(s)$, the even part $r_q(s)$ of which is devoid of zeros in the entire complex-frequency plane, meaning that its even part must be a nonnegative constant c:

$$r_q(s) = \frac{1}{2}\left[Z_q(s) + Z_q(-s)\right] = c \tag{74.4}$$

Therefore, $Z_q(s)$ is expressible as the sum of a reactance function[2] $Z_{\text{LC}}(s)$ and a resistance c:

$$Z_q(s) = Z_{\text{LC}}(s) + c \tag{74.5}$$

which can be realized as the input impedance of a lossless two-port network terminated in a c-ohm resistor, as shown in Fig. 74.2.

To motivate our discussion, we first present a theorem credited to Richards [11, 12], which is intimately tied up with the famous Bott-Duffin technique [2].

Theorem 1: *Let $Z(s)$ be a positive-real function that is neither of the form Ls nor $1/Cs$. Let k be an arbitrary positive-real constant. Then, the* **Richards function**

$$W(s) = \frac{kZ(s) - sZ(k)}{kZ(k) - sZ(s)} \tag{74.6}$$

is also positive real.

The **degree** of a rational function is defined as the sum of the degrees of its relatively prime numerator and denominator polynomials. Thus, the Richards function $W(s)$ is also rational, the degree of which is not greater than that of $Z(s)$. It was first pointed out by Richards that if k can be chosen so that the even part of $Z(s)$ vanishes at k, then the degree of $W(s)$ is at least two less than that of $Z(s)$. Let

[2]A formal definition will be given in Chapter 75 of this volume.

© 2003 by CRC Press LLC

$$s_0 = \sigma_0 + j\omega_0 \tag{74.7}$$

be a point in the closed RHS. Then, according to the preceding theorem, the function

$$\hat{W}_1(s) = \frac{s_0 Z(s) - sZ(s_0)}{s_0 Z(s_0) - sZ(s)} \tag{74.8}$$

is positive real if s_0 is positive real; and the function

$$W_1(s) = Z(s_0)\hat{W}_1(\bar{s}_0)\frac{\bar{s}_0 \hat{W}_1(s) - s\hat{W}_1(\bar{s}_0)}{\bar{s}_0 \hat{W}_1(\bar{s}_0) - s\hat{W}_1(s)} \tag{74.9}$$

is positive real if s_0 is a positive-real constant and $\hat{W}_1(s)$ is a positive-real function. Substituting (74.8) in (74.9) yields

$$W_1(s) = \frac{D_1(s)Z(s) - B_1(s)}{-C_1(s)Z(s) + A_1(s)} \tag{74.10}$$

where

$$A_1(s) = q_4 s^2 + |s_0|^2 \tag{74.11a}$$

$$B_1(s) = q_2 s \tag{74.11b}$$

$$C_1(s) = q_3 s \tag{74.11c}$$

$$D_1(s) = q_1 s^2 + |s_0|^2 \tag{74.11d}$$

$$q_1 = \frac{R_0/\sigma_0 - X_0/\omega_0}{R_0/\sigma_0 + X_0/\omega_0} \tag{74.12a}$$

$$q_2 = \frac{2|Z_0|^2}{R_0/\sigma_0 + X_0/\omega_0} \tag{74.12b}$$

$$q_3 = \frac{2}{R_0/\sigma_0 - X_0/\omega_0} \tag{74.12c}$$

$$q_4 = \frac{R_0/\sigma_0 + X_0/\omega_0}{R_0/\sigma_0 - X_0/\omega_0} = \frac{1}{q_1} \tag{74.12d}$$

in which

$$Z(s_0) = R_0 + jX_0 \equiv Z_0 \tag{74.13}$$

In the case $\omega_0 = 0$, then X_0/ω_0 must be replaced by $Z'(\sigma_0)$:

$$\frac{X_0}{\omega_0} \to Z'(\sigma_0) = \left.\frac{dZ(s)}{ds}\right|_{s=\sigma_0} \tag{74.14a}$$

© 2003 by CRC Press LLC

For $\sigma = 0$ and $R_0 = 0$, R_0/σ_0 is replaced by $X'(\omega_0)$:

$$\frac{R_0}{\sigma_0} \to X'(\omega_0) = \left.\frac{dZ(s)}{ds}\right|_{s = j\omega_0} \tag{74.14b}$$

Definition 1. *Index set.* For a given positive-real function $Z(s)$, let s_0 be any point in the open RHS or any finite nonzero point on the $j\omega$-axis where $Z(s)$ is analytic. Then, the set of four real numbers q_1, q_2, q_3, and q_4, as defined in (74.12)–(74.14), is called the **index set** assigned to the point s_0 by the positive-real function $Z(s)$.

We illustrate this concept by the following example.

Example 1. Determine the index set assigned to the point $s_0 = 0.4551 + j1.099$ by the positive-real function

$$Z(s) = \frac{s^2 + s + 1}{s^2 + s + 2} \tag{74.15}$$

From definition and (74.15), we have

$$s_0 = 0.4551 + j1.099 = \sigma_0 + j\omega_0 \tag{74.16a}$$

$$\begin{aligned} Z(s_0) &= Z(0.4551 + j1.099) = 0.7770 + j0.3218 = 0.8410e^{j22.5^\circ} \\ &= R_0 + jX_0 \equiv Z_0 \end{aligned} \tag{74.16b}$$

$$|Z_0|^2 = 0.7073 \tag{74.17}$$

obtaining from (74.12)

$$q_1 = 0.707, \quad q_2 = 0.707, \quad q_3 = 1.414, \quad q_4 = 1.414 \tag{74.18}$$

With these preliminaries, we now state the following theorem, which forms the cornerstone of the method of cascade synthesis of a rational positive-real impedance according to the Darlington theory [7].

Theorem 2: *Let $Z(s)$ be a positive-real function, which is neither of the form Ls nor $1/Cs$, L and C being real nonnegative constants. Let $s_0 = \sigma_0 + j\omega_0$ be a finite nonzero point in the closed RHS where $Z(s)$ is analytic, then the function*

$$W_1(s) = \frac{D_1(s)Z(s) - B_1(s)}{-C_1(s)Z(s) + A_1(s)} \tag{74.19}$$

is positive real; where A_1, B_1, C_1, and D_1 are defined in (74.11) and $\{q_1, q_2, q_3, q_4\}$ is the index set assigned to the point s_0 by $Z(s)$. Furthermore, $W_1(s)$ possesses the following attributes:

(i) *If $Z(s)$ is rational, $W_1(s)$ is rational, the degree of which is not greater than that of $Z(s)$, or*

$$\text{degree } W_1(s) \le \text{degree } Z(s) \tag{74.20}$$

(ii) *If $Z(s)$ rational and if s_0 is a zero of its even part $r(s)$, then*

© 2003 by CRC Press LLC

$$\text{degree } W_1(s) \le \text{degree } Z(s) - 4, \qquad \omega_0 \neq 0 \tag{74.21a}$$

$$\text{degree } W_1(s) \le \text{degree } Z(s) - 2, \qquad \omega_0 = 0 \tag{74.21b}$$

(iii) *If $s_0 = \sigma_0 > 0$ is a real zero of $r(s)$ of at least multiplicity 2 and if $Z(s)$ is rational, then*

$$\text{degree } W_1(s) \le \text{degree } Z(s) - 4 \tag{74.22}$$

We remark that since $Z(s)$ is positive real, all the points in the open RHS are admissible. Any point on the $j\omega$-axis, exclusive of the origin and infinity, where $Z(s)$ is analytic is admissible as s_0.

We are now in a position to show that any positive-real function can be realized as the input impedance of a lossless one-port network terminated in a resistor. Our starting point is (74.19), which after solving $Z(s)$ in terms of $W_1(s)$ yields

$$Z(s) = \frac{A_1(s)W_1(s) + B_1(s)}{C_1(s)W_1(s) + D_1(s)} \tag{74.23}$$

It can be shown that $Z(s)$ can be realized as the input impedance of a two-port network N_1, which is characterized by its transmission matrix

$$\mathbf{T}_1(s) = \begin{bmatrix} A_1(s) & B_1(s) \\ C_1(s) & D_1(s) \end{bmatrix} \tag{74.24}$$

terminated in $W_1(s)$, as depicted in Fig. 74.3. To see this, we first compute the corresponding impedance matrix $\mathbf{Z}_1(s)$ of N_1 from $\mathbf{T}_1(s)$ and obtain

$$\mathbf{Z}_1(s) = \begin{bmatrix} z_{11}(s) & z_{12}(s) \\ z_{21}(s) & z_{22}(s) \end{bmatrix} = \frac{1}{C_1(s)} \begin{bmatrix} A_1(s) & A_1(s)D_1(s) - B_1(s)C_1(s) \\ 1 & D_1(s) \end{bmatrix} \tag{74.25}$$

The input impedance $Z_{11}(s)$ of N_1 with the output port terminating in $W_1(s)$ is found to be

$$Z_{11}(s) = z_{11}(s) - \frac{z_{12}(s)z_{21}(s)}{z_{22}(s) + W_1(s)} = \frac{A_1(s)W_1(s) + B_1(s)}{C_1(s)W_1(s) + D_1(s)} = Z(s) \tag{74.26}$$

The determinant of the transmission matrix $\mathbf{T}_1(s)$ is computed as

$$\det \mathbf{T}_1(s) = A_1(s)D_1(s) - B_1(s)C_1(s) = s^4 + 2\left(\omega_0^2 - \sigma_0^2\right)s^2 + |s_0|^4 \tag{74.27}$$

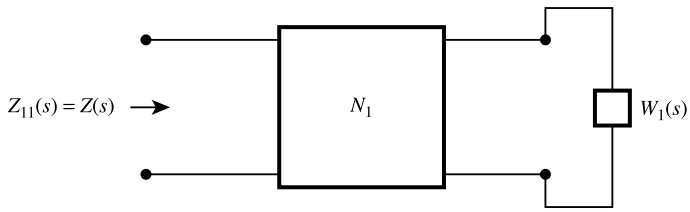

FIGURE 74.3 A two-port network N_1 terminated in the impedance $W_1(s)$.

© 2003 by CRC Press LLC

Observe that det $\mathbf{T}_1(s)$ depends only upon the point s_0 and not on $Z(s)$, and that the input impedance $Z_{11}(s)$ remains unaltered if each element of $\mathbf{T}_1(s)$ is multiplied or divided by a nonzero finite quality. To complete the realization, we must now demonstrate that the two-port network N_1 is physically realizable.

74.2 Type-E Section

Consider the lossless nonreciprocal two-port network of Fig. 74.4 known as the **type-E section**. Our objective is to show that this two-port realizes N_1. To this end, we first compute its impedance matrix $\mathbf{Z}_E(s)$ as

$$\mathbf{Z}_E(s) = \begin{bmatrix} L_1(s) + 1/Cs & Ms + 1/Cs + \zeta \\ Ms + 1/Cs - \zeta & L_2 s + 1/Cs \end{bmatrix} \tag{74.28}$$

where $M^2 = L_1 L_2$, the determinant of which is given by

$$\det \mathbf{Z}_E(s) = \frac{L_1 + L_2 - 2M + \zeta^2 C}{C} \tag{74.29}$$

a constant independent of s due to perfect coupling. From the impedance matrix $\mathbf{Z}_E(s)$, its corresponding transmission matrix $\mathbf{T}_E(s)$ is found to be

$$\mathbf{T}_E(s) = \frac{1}{MCs^2 - \zeta Cs + 1} \begin{bmatrix} L_1 Cs^2 + 1 & \left(L_1 + L_2 - 2M + \zeta^2 C\right)s \\ Cs & L_2 Cs^2 + 1 \end{bmatrix} \tag{74.30}$$

To show that the type-E section realizes N_1, we divide each element of $\mathbf{T}_1(s)$ of (74.24) by $|s_0|^2$ ($MCs^2 - \zeta Cs + 1$). This manipulation will not affect the input impedance $Z(s)$ but it will result in a transmission matrix having the form of $\mathbf{T}_E(s)$. Comparing this new matrix with (74.30) in conjunction with (74.11) yields the following identifications:

$$L_1 C = \frac{q_4}{|s_0|^2} \tag{74.31a}$$

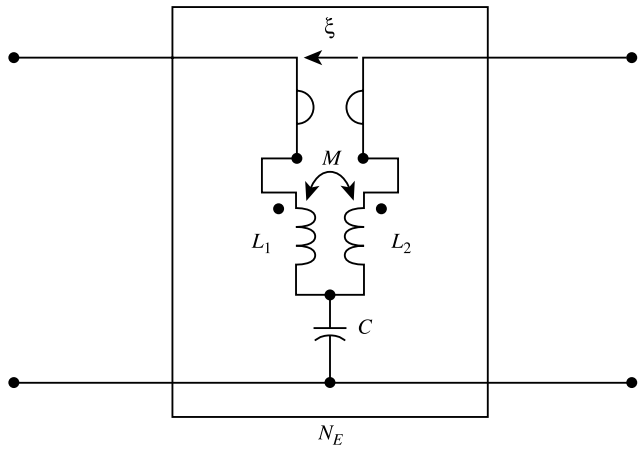

FIGURE 74.4 The type-E section.

© 2003 by CRC Press LLC

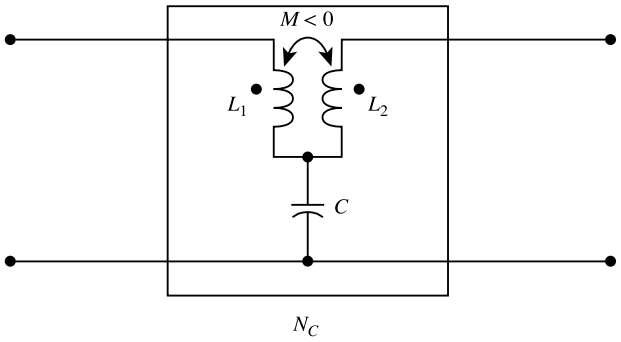

FIGURE 74.5 The Darlington type-C section.

$$L_1 + L_2 - 2M + \zeta^2 C = \frac{q_2}{|s_0|^2} \tag{74.31b}$$

$$C = \frac{q_3}{|s_0|^2} \tag{74.31c}$$

$$L_2 C = \frac{q_1}{|s_0|^2} \tag{74.31d}$$

Solving these for the element values of the type-E section, we obtain

$$L_1 = \frac{q_4}{q_3} = \frac{1}{q_1 q_3}, \qquad L_2 = \frac{q_1}{q_3} \tag{74.32a}$$

$$C = \frac{q_3}{|s_0|^2}, \qquad M = \frac{1}{q_3}, \qquad \zeta = \pm \frac{2\sigma_0}{q_3} \tag{74.32b}$$

Since the elements of the index set assigned to the point s_0 by $Z(s)$ are positive and finited for all admissible points s_0 in the closed RHS except at those admissible points $s_0 = j\omega_0$ on the $j\omega$-axis where $R_0 \neq 0$, all the elements in (74.32) are physical. But at those admissible points $s_0 = j\omega_0$ where $R_0 \neq 0$, R_0/σ_0 becomes infinity and $q_1 = q_4 = 1$ and $q_2 = q_3 = 0$. Under this situation, $W_1(s) = Z(s)$ and the corresponding two-port network N_1 degenerates into a pair of wires.

Appealing to Theorem 2 shows that if s_0 is chosen to be a complex open RHS zero of the even part $r(s)$ of $Z(s)$, the type-E section is capable of extracting a set of quadrantal zeros of $r(s)$ and leads to at least a four-degree reduction. For zeros of $r(s)$ on the $j\omega$-axis or the σ-axis, the type-E section degenerates into other types of sections, as follows:

CASE 1. $s_0 = \sigma_0 > 0$. Then, we have $\zeta = 0$ and

$$L_1 = \frac{q_4}{q_3} = \frac{1}{q_1 q_3}, \qquad L_2 = \frac{q_1}{q_3}, \qquad C = \frac{q_3}{\sigma_0^2}, \qquad M = -\frac{1}{q_3} < 0 \tag{74.33}$$

The type-E section degenerates to the **Darlington type-C section**, as shown in Fig. 74.5.

CASE 2. $s_0 = j\omega_0$ and $R_0 = 0$. In this case, we replace R_0/σ_0 by $X'(\omega_0)$ and the gyrator in the type-E section can be avoided because $\zeta = 0$. The type-E section degenerates into the **Brune section** of Fig. 74.6, the element values of which are given by

© 2003 by CRC Press LLC

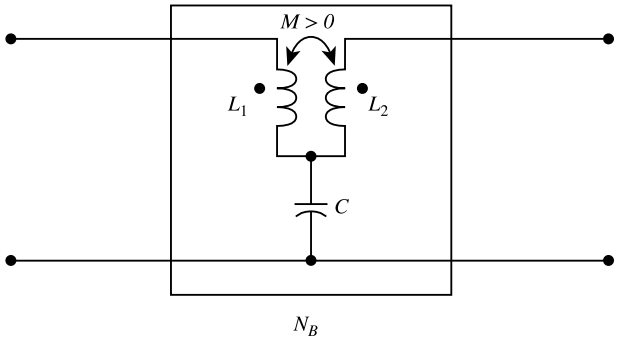

FIGURE 74.6 The Brune section.

$$L_1 = \frac{q_4}{q_3} = \frac{1}{q_1 q_3} = \frac{\omega_0 X'(\omega_0) + X_0}{2\omega_0} \tag{74.34a}$$

$$L_2 = \frac{q_1}{q_3} = \frac{\left[\omega_0 X'(\omega_0) - X_0\right]^2}{2\omega_0\left[\omega_0 X'(\omega_0) + X_0\right]} \tag{74.34b}$$

$$C = \frac{q_3}{|s_0|^2} = \frac{2}{\omega_0\left[\omega_0 X'(\omega_0) - X_0\right]} \tag{74.34c}$$

$$M = \frac{1}{q_3} = \frac{\omega_0 X'(\omega_0) - X_0}{2\omega_0} > 0 \tag{74.34d}$$

In particular, if $X_0 = 0$ or $Z(j\omega_0) = 0$, the Brune section degenerates into the two-port network of Fig. 74.7 with element values

$$L = \frac{1}{2} X'(\omega_0), \qquad C = \frac{2}{\omega_0^2 X'(\omega_0)} \tag{74.35}$$

As ω_0 approaches zeros, this degenerate Brune section goes into the **type-A section** of Fig. 74.8 with

$$L = \frac{1}{2} Z'(0) \tag{74.36}$$

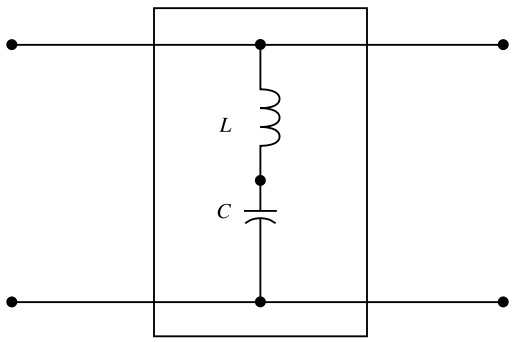

FIGURE 74.7 A degenerate Brune section.

© 2003 by CRC Press LLC

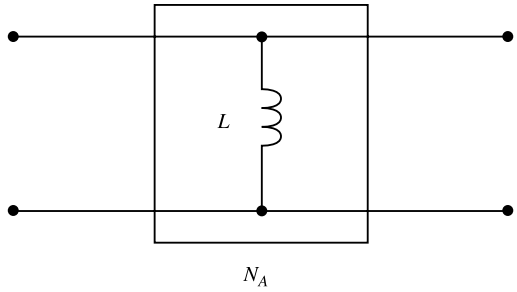

FIGURE 74.8 The type-A section.

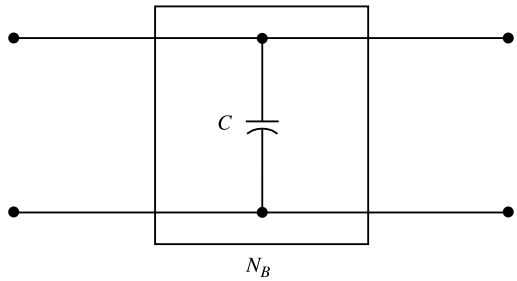

FIGURE 74.9 The type-B section.

When ω_0 approaches infinity, the degenerate Brune section collapses into the **type-B section** of Fig. 74.9 with

$$\frac{2}{C} = \lim_{s\to\infty} sZ(s) \tag{74.37}$$

CASE 3. $s_0 = j\omega_0$ and $R_0 \neq 0$. In this case, R_0/σ_0 is infinity and

$$q_1 = q_4 = 1, \qquad q_2 = q_3 = 0 \tag{74.38}$$

The type-E section degenerates into a pair of wires.

Therefore, the Brune section is capable of extracting any $j\omega$-axis zero of the even part of a positive-real impedance, and leads to at least a four-degree reduction if $j\omega_0$ is nonzero and finite, a two-degree reduction otherwise. The latter corresponds to the type-A or type-B section.

Example 2. Consider the positive-real impedance

$$Z(s) = \frac{8s^2 + 9s + 10}{2s^2 + 4s + 4} \tag{74.39}$$

The zeros of its even part $r(s)$ are found from the polynomial

$$m_1 m_2 - n_1 n_2 = 16\left(s^4 + s^2 + 2.5\right) \tag{74.40}$$

obtaining

$$s_0 = \sigma_0 + j\omega_0 = 0.735 + j1.020 \tag{74.41a}$$

$$Z(s_0) \equiv R_0 + jX_0 = 2.633 + j0.4279 = 2.667e^{j9.23^\circ} \equiv Z_0 \tag{74.41b}$$

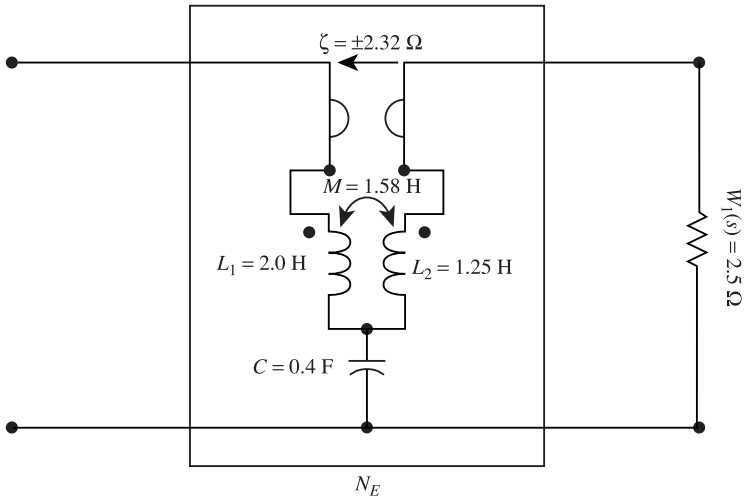

FIGURE 74.10 A realization of the impedance function of (74.39).

The elements of the index set assigned to s_0 by $Z(s)$ are computed as

$$q_1 = 0.7904, \quad q_2 = 3.556, \quad q_3 = 0.6323, \quad q_4 = 1.265 \tag{74.42}$$

Substituting these in (74.32) yields the element values of the type-E section as shown in Fig. 74.10.

$$L_1 = 2\ \text{H}, \quad L_2 = 1.25\ \text{H}, \quad C = 0.40\ \text{F} \tag{74.43a}$$

$$M = 1.58\ \text{H}, \quad \zeta = \pm 2.32\ \Omega \tag{74.43b}$$

The terminating impedance $W_1(s)$ is a resistance of value

$$W_1(s) = Z(0) = 2.5\ \Omega \tag{74.44}$$

as shown in Fig. 74.10.

74.3 The Richards Section

In this part, we show that any positive real zero $s_0 = \sigma_0$ of the even part $r(s)$ of a positive-real impedance $Z(s)$, in addition to being realized by the reciprocal Darlington type-C section, can also be realized by a nonreciprocal section called the **Richards section** of Fig. 74.11.

Let $Z(s)$ be a rational positive-real function. Then according to Theorem 1, for any positive real σ_0, the function

$$W_1(s) = Z(\sigma_0)\frac{\sigma_0 Z(s) - sZ(\sigma_0)}{\sigma_0 Z(\sigma_0) - sZ(s)} \tag{74.45}$$

is also rational and positive real, the degree of which is not greater than that of $Z(s)$. As pointed out by Richards [11], if σ_0 is a zero of $r(s)$, then

$$\text{degree}\, W_1(s) \le \text{degree}\, Z(s) - 2 \tag{74.46}$$

© 2003 by CRC Press LLC

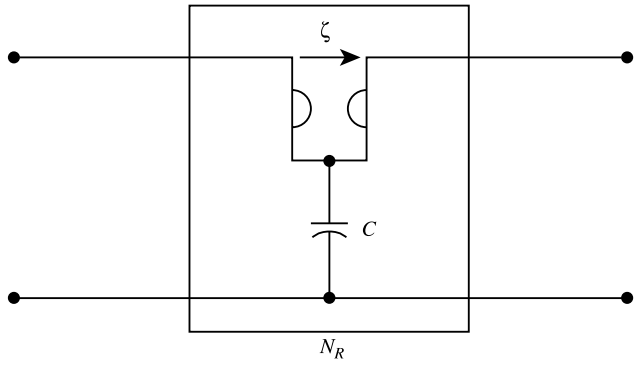

FIGURE 74.11 The Richards section.

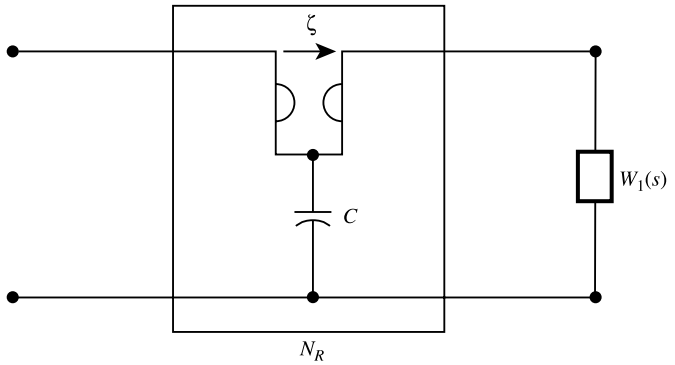

FIGURE 74.12 A realization of $Z(s)$ by Richards section.

Inverting (74.45) for $Z(s)$ yields

$$Z(s) = \frac{\sigma_0 W_1(s) + sZ(\sigma_0)}{sW_1(s)/Z(\sigma_0) + \sigma_0} \tag{74.47}$$

This impedance can be realized by the Richards section terminated in the impedance $W_1(s)$ as indicated in Fig. 74.12 with the element values

$$C = \frac{1}{\sigma_0 Z(\sigma_0)}, \qquad \zeta = \pm Z(\sigma_0) \tag{74.48}$$

74.4 The Darlington Type-D Section

In the foregoing, we have demonstrated that the lossless two-port network N_1 can be realized by the lossless nonreciprocal type-E section, which degenerates into the classical type-A, type-B, type-C, and the Brune sections when the even part zero s_0 of the positive-real impedance is restricted to the $j\omega$-axis or the positive σ-axis. In the present section, we show that N_1 can also be realized by a lossless reciprocal two-port network by the application of Theorem 1 twice.

Let s_0 be a zero of the even part $r(s)$ of a rational positive-real impedance $Z(s)$. By Theorem 2, the function $W_1(s)$ of (74.19) is also rational positive real, and its degree is at least four or two less that that of $Z(s)$, depending on whether $\omega_0 \neq 0$ or $\omega_0 = 0$. Now, apply Theorem 2 to $W_1(s)$ at the same point s_0. Then, the function

© 2003 by CRC Press LLC

$$W_2(s) = \frac{D_2(s)W_1(s) - B_2(S)}{-C_2(s)W_1(s) + A_2(s)} \tag{74.49}$$

is rational positive real, the degree of which cannot exceed that of $W_1(s)$, being at least two or four degrees less than that of $Z(s)$, where

$$A_2(s) = p_4 s^2 + |s_0|^2 \tag{74.50a}$$

$$B_2(s) = p_2 s \tag{74.50b}$$

$$C_2(s) = p_3 s \tag{74.50c}$$

$$D_2(s) = p_1 s^2 + |s_0|^2 \tag{74.50d}$$

and $\{p_1, p_2, p_3, p_4\}$ is the index set assigned to the point s_0 by the positive-real function $W_1(s)$. Solving for $W_1(s)$ in (74.49) gives

$$W_1(s) = \frac{A_2(s)W_2(s) + B_2(s)}{C_2(s)W_2(s) + D_2(s)} \tag{74.51}$$

which can be realized as the input impedance of a two-port network N_2 characterized by the transmission matrix

$$\mathbf{T}_2(s) = \begin{bmatrix} A_2(s) & B_2(s) \\ C_2(s) & D_2(s) \end{bmatrix} \tag{74.52}$$

terminated in $W_2(s)$, as depicted in Fig. 74.13.

Consider the cascade connection of the two-port N_1 of Fig. 74.3 and N_2 of Fig. 74.13 terminated in $W_2(s)$, as shown in Fig. 74.14. The transmission matrix $\mathbf{T}(s)$ of the overall two-port network N is simply the product of the transmission matrices of the individual two-ports:

$$\mathbf{T}(s) = \mathbf{T}_1(s)\mathbf{T}_2(s) \tag{74.53}$$

the determinant of which is found to be

$$\det \mathbf{T}(s) = [\det \mathbf{T}_1(s)][\det \mathbf{T}_2(s)] = \left[s^4 + 2(\omega_0^2 - \sigma_0^2)s^2 + |s_0|^4\right]^2 \tag{74.54}$$

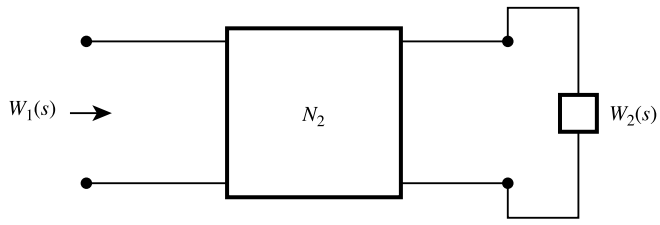

FIGURE 74.13 A realization of the impedance function $W_1(s)$.

© 2003 by CRC Press LLC

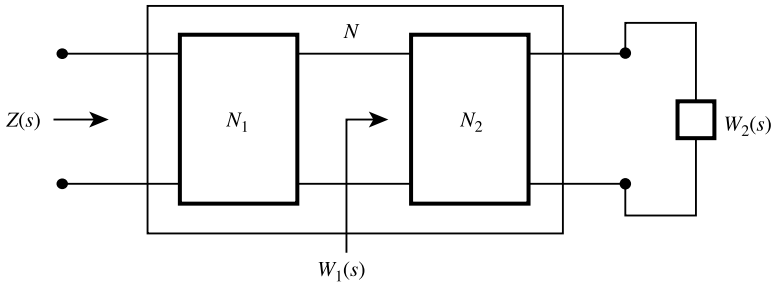

FIGURE 74.14 The cascade connection of two-port networks N_1 and N_2.

Thus, when N is terminated in $W_2(s)$, the input impedance of Fig. 74.14 is $Z(s)$. This impedance remains unaltered if each element of $\mathbf{T}_1(s)$ is divided by a nonzero finite quantity. For our purposes, we stipulate that the two-port N_1 be characterized by the transmission matrix

$$\hat{\mathbf{T}}_1(s) = \frac{1}{\Delta(s)}\mathbf{T}_1(s) \tag{74.55}$$

where

$$\Delta(s) = s^4 + 2\left(\omega_0^2 - \sigma_0^2\right)s^2 + |s_0|^4 \tag{74.56}$$

Using this matrix $\hat{\mathbf{T}}_1(s)$ for N_1, the transmission matrix $\hat{\mathbf{T}}(s)$ of the overall two-port network N becomes

$$\begin{aligned}\hat{\mathbf{T}}(s) &= \frac{1}{\Delta(s)}\mathbf{T}_1(s)\mathbf{T}_2(s) \equiv \frac{1}{\Delta(s)}\begin{bmatrix} A(s) & B(s) \\ C(s) & D(s)\end{bmatrix} \\ &= \frac{1}{\Delta(s)}\begin{bmatrix} p_4q_4s^4 + |s_0|^4 & \left(p_2q_4 + p_1q_2\right)s^3 \\ \quad + \left[\left(p_4 + q_4\right)|s_0|^2 + p_3q_2\right]s^2 & \quad + \left(p_2 + q_2\right)|s_0|^2 s \\ \left(p_4q_3 + p_3q_1\right)s^3 & p_1q_1s^4 + |s_0|^4 + \left[\left(p_1 + q_1\right)|s_0|^2\right. \\ \quad + \left(p_3 + q_3\right)|s_0|^2 s & \quad \left. + p_2q_3\right]s^2\end{bmatrix}\end{aligned} \tag{74.57}$$

The corresponding impedance matrix $\mathbf{Z}(s)$ of the overall two-port network is found to be

$$\mathbf{Z}(s) = \frac{1}{C(s)}\begin{bmatrix} A(s) & \Delta(s) \\ \Delta(s) & D(s)\end{bmatrix} \tag{74.58}$$

showing that N is reciprocal because $\mathbf{Z}(s)$ is symmetric.

Now consider the reciprocal lossless **Darlington type-D section** N_D of Fig. 74.15 with two perfectly coupled transformers

$$L_1L_2 = M_1^2, \quad L_3L_4 = M_2^2 \tag{74.59}$$

© 2003 by CRC Press LLC

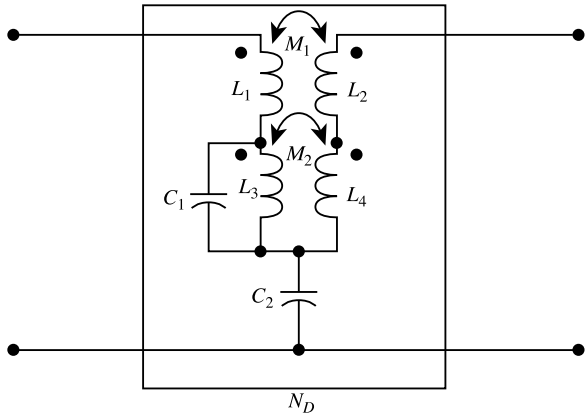

FIGURE 74.15 The Darlington type-D section N_D.

The impedance matrix $\mathbf{Z}_D(s)$ of N_D is found to be

$$\mathbf{Z}_D(s) = \begin{bmatrix} L_1 s + \dfrac{1}{C_2 s} + \dfrac{s/C_1}{s^2 + \omega_a^2} & M_1 s + \dfrac{1}{C_2 s} + \dfrac{\omega_a^2 M_2 s}{s^2 + \omega_a^2} \\ M_1 s + \dfrac{1}{C_2 s} + \dfrac{\omega_a^2 M_2 s}{s^2 + \omega_a^2} & L_2 s + \dfrac{1}{C_2 s} + \dfrac{\omega_a^2 L_4 s}{s^2 + \omega_a^2} \end{bmatrix} \tag{74.60}$$

where $\omega_a^2 = 1/C_1 L_3$.

Setting $\mathbf{Z}_D(s) = \mathbf{Z}(s)$ in conjunction with (74.57) and after considerable algebraic manipulations, we can make the following identifications:

$$L_1 = \frac{p_4 q_4}{p_4 q_3 + p_3 q_1} \tag{74.61a}$$

$$L_2 = \frac{p_1 q_1}{p_4 q_3 + p_3 q_1} = \frac{M_1^2}{L_1} \tag{74.61b}$$

$$M_1 = \frac{1}{p_4 q_3 + p_3 q_1} = \sqrt{L_1 L_2} \tag{74.61c}$$

$$C_2 = \frac{p_3 + q_3}{|s_0|^2} \tag{74.61d}$$

$$\omega_a^2 = \omega_1^2 = \frac{|s_0|^2 (p_3 + q_3)}{p_4 q_3 + p_3 q_1} \tag{74.61e}$$

$$\begin{aligned} M_2 &= -\frac{\omega_1^4 - 2(\omega_0^2 - \sigma_0^2)\omega_1^2 + |s_0|^4}{\omega_1^4 (p_4 q_3 + p_3 q_1)} \\ &= -\frac{p_3^2 q_3^2 \left|\overline{W_1}(s_0) + Z(s_0) q_1\right|^2}{|s_0|^2 (p_4 q_3 + p_3 q_1)(p_3 + q_3)^2} \le 0 \end{aligned} \tag{74.61f}$$

© 2003 by CRC Press LLC

$$L_4 = \frac{\left[\left(p_1 + q_1\right)\left|s_0\right|^2 + p_2 q_3\right]\omega_1^2 - p_1 q_1 \omega_1^4 - \left|s_0\right|^4}{\omega_1^4\left(p_4 q_3 + p_3 q_1\right)} = -\frac{q_3 M_2}{p_3} \tag{74.61g}$$

$$L_3 = \frac{M_2^2}{L_4} = -\frac{p_3 M_2}{q_3} \tag{74.61h}$$

$$C_1 = \frac{1}{\omega_1^2 L_3} = -\frac{q_3}{\omega_1^2 p_3 M_2} \tag{74.61i}$$

Thus, all the element values except M_2 are nonnegative, and the lossless reciprocal Darlington type-D section is equivalent to the two type-E sections in cascade.

Example 3. Consider the positive-real impedance

$$Z(s) = \frac{6s^2 + 5s + 6}{2s^2 + 4s + 4} \tag{74.62}$$

the even part of which has a zero at

$$s_0 = \sigma_0 + j\omega_0 = 0.61139 + j1.02005 \tag{74.63}$$

The elements of the index set assigned to s_0 by $Z(s)$ are given by

$$q_1 = 0.70711, \quad q_2 = 1.76784, \quad q_3 = 0.94283, \quad q_4 = 1.41421 \tag{74.64}$$

The terminating impedance $W_1(s)$ is determined to be

$$W_1(s) = W_1(0) = Z(0) = 1.5\ \Omega \tag{74.65}$$

The elements of the index set assigned to the point s_0 by $W_1(s)$ are found to be

$$p_1 = 1, \quad p_2 = 1.83417, \quad p_3 = 0.81519, \quad p_4 = 1 \tag{74.66}$$

Substituting these in (74.61) yields the desired element values of the type-D section, as follows:

$$L_1 = \frac{p_4 q_4}{p_4 q_3 + p_3 q_1} = 0.93086\ \text{H} \tag{74.67a}$$

$$L_2 = \frac{p_1 q_1}{p_4 q_3 + p_3 q_1} = 0.46543\ \text{H} \tag{74.67b}$$

$$M_1 = \frac{1}{p_3 q_3 + p_3 q_1} = 0.65822\ \text{H} \tag{74.67c}$$

$$C_2 = \frac{p_3 + q_3}{\left|s_0\right|^2} = 1.24303\ \text{F} \tag{74.67d}$$

$$\omega_1^2 = \frac{\left|s_0^2\right|\left(p_3 + q_3\right)}{p_4 q_3 + p_3 q_1} = 1.63656 \tag{74.67e}$$

Synthesis of LCM and RC One-Port Networks[1]

Wai-Kai Chen
University of Illinois, Chicago

75.1 Introduction
75.2 LCM One-Port Networks
75.3 RC One-Port Networks

75.1 Introduction

In Chapter 74, we showed that any positive-real function can be realized as the input immittance of a passive one-port network, which is describable as a lossless two-port network terminated in a resistor. Therefore, insofar as the input immittance is concerned, any passive network is equivalent to one containing at most one resistor. In this section, we consider the synthesis of a one-port network composed only of self and mutual inductors and capacitors called the **LCM one-port**, or a one-port composed only of resistors and capacitors called the **RC one-port**.

75.2 LCM One-Port Networks

Consider the input impedance $Z(s)$ of an LCM one-port network written in the form

$$Z(s) = \frac{m_1 + n_1}{m_2 + n_2} \tag{75.1}$$

the even part of which is given by

$$r(s) = \frac{m_1 m_2 - n_1 n_2}{m_2^2 - n_2^2} \tag{75.2}$$

Since the one-port is lossless, we have

$$r(j\omega) = \text{Re}\, Z(j\omega) = 0 \text{ for all } \omega \tag{75.3}$$

To make Re $Z(j\omega) = 0$, there are three nontrivial ways: (i) $m_1 = 0$ and $n_2 = 0$, (ii) $m_2 = 0$ and $n_1 = 0$, (iii) $m_1 m_2 - n_1 n_2 = 0$. The first possibility leads $Z(s)$ to n_1/m_2, the second to m_1/n_2. For the third possibility, we require that $m_1 m_2 = n_1 n_2$ or

$$(m_1 + n_1) m_2 = (m_2 + n_2) n_1 \tag{75.4}$$

[1]References for this Chapter can be found on page 2421.

© 2003 by CRC Press LLC

which is equivalent to

$$Z(s) = \frac{m_1 + n_1}{m_2 + n_2} = \frac{n_1}{m_2} \tag{75.5}$$

Therefore, the driving-point immittance of a lossless network is always the quotient of even to odd or odd to even polynomials. Its zeros and poles must occur in quadrantal symmetry, being symmetric with respect to both axes. As a result, they are simple and purely imaginary from stability considerations, or $Z(s)$ can be explicitly written as

$$Z(s) = H \frac{\left(s^2 + \omega_{z1}^2\right)\left(s^2 + \omega_{z2}^2\right)\left(s^2 + \omega_{z3}^2\right)\ldots}{s\left(s^2 + \omega_{p1}^2\right)\left(s^2 + \omega_{p2}^2\right)\ldots} \tag{75.6}$$

where $\omega_{z1} \geq 0$. This equation can be expanded in partial fraction as

$$Z(s) = Hs + \frac{K_0}{s} + \sum_{i=1}^{n} \frac{2K_i s}{s^2 + \omega_i^2} \tag{75.7}$$

where $\omega_{pi} = \omega_i$, and the residues H, K_0 and K_i are all real and positive.

Substituting $s = j\omega$ and writing $Z(j\omega) = \text{Re}\, Z(j\omega) + j\, \text{Im}\, Z(j\omega)$ results in an odd function known as the **reactance function** $X(\omega)$:

$$X(\omega) = \text{Im}\, Z(j\omega) = H\omega - \frac{K_0}{\omega} + \sum_{i=1}^{n} \frac{2K_i\omega}{-\omega^2 + \omega_i^2} \tag{75.8}$$

Taking the derivatives on both sides yields

$$\frac{dX(\omega)}{d\omega} = H + \frac{K_0}{\omega^2} + \sum_{i=1}^{n} \frac{2K_i\left(\omega^2 + \omega_i^2\right)}{\left(-\omega^2 + \omega_i^2\right)^2} \tag{75.9}$$

Since every factor in this equation is positive for all positive and negative values of ω, we conclude that

$$\frac{dX(\omega)}{d\omega} > 0 \text{ for } -\infty < \omega < \infty \tag{75.10}$$

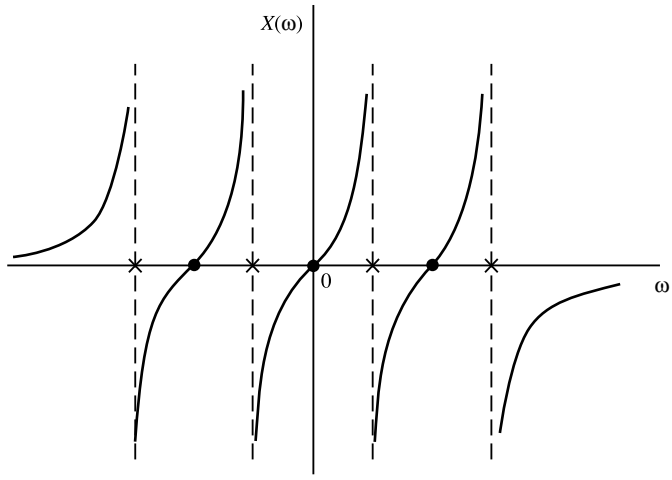
It states that the slope of the reactance function versus frequency curve is always positive, as depicted in Fig. 75.1. Consequently, the poles and zeros of $Z(s)$ alternate along the $j\omega$-axis. This is known as the **separation property** for reactance function credited to Foster [9]. Because of this, the pole and zero frequencies of (75.6) are related by

$$0 \leq \omega_{z1} < \omega_{p1} < \omega_{z2} < \omega_{p2} < \cdots \tag{75.11}$$

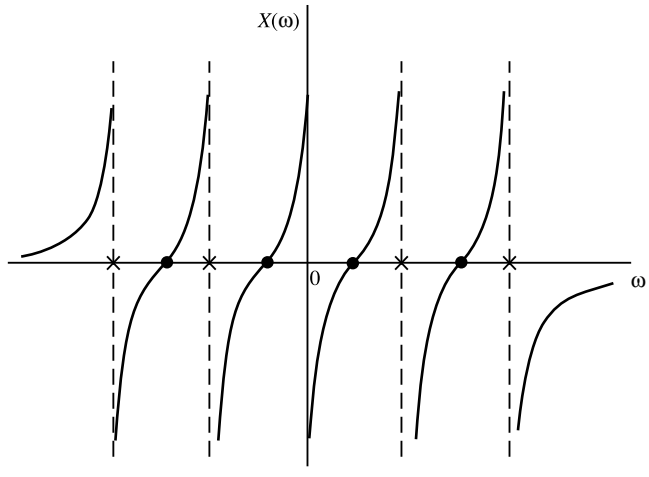
We now consider the realization of $Z(s)$. If each term on the right-hand side of (75.7) can be identified as the input impedance of the LC one-port, the series connection of these one-ports would yield the desired realization. The first term is the impedance of an inductor of inductance H, and the second term corresponds to a capacitor of capacitance $1/K_0$. Each of the remaining term can be realized as a parallel combination of an inductor of inductance $2K_i/\omega_i^2$ and a capacitor of capacitance $1/2K_i$. The resulting realization is shown in Fig. 75.2 known as the **first Foster canonical form**. Likewise, if we consider the admittance function $Y(s) = 1/Z(s)$ and expanded it in partial fraction, we obtain

$$Y(s) = \tilde{H}s + \frac{\tilde{K}_0}{s} + \sum_{i=1}^{n} \frac{2\tilde{K}_i s}{s^2 + \omega_i^2} \tag{75.12}$$

© 2003 by CRC Press LLC



(a)



(b)

FIGURE 75.1 The plots of reactance function $X(\omega)$ versus ω.

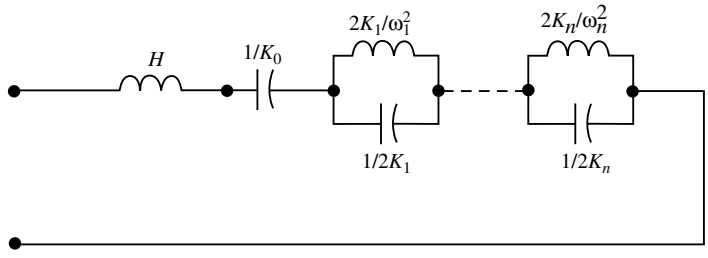


FIGURE 75.2 The first Foster canonical form.

which can be realized by the one-port of Fig. 75.3 known as the **second Foster canonical form**. The term **canonical form** refers to a network containing the minimum number of elements to meet given specifications.

We summarize the preceding results by stating the following theorem:

© 2003 by CRC Press LLC

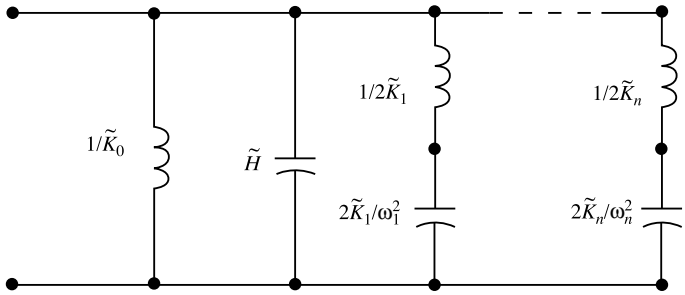

FIGURE 75.3 The second Foster canonical form.

Theorem 1: *A real rational function is the input immittance function of an LCM one-port network if and only if all of its zeros and poles are simple, lie on the jω-axis, and alternate with each other.*

In addition to the two Foster canonical forms, there is another synthesis procedure, that gives rise to one-ports known as the **Cauer canonical form** [4]. Let us expand, $Z(s)$ in a continued fraction

$$Z(s)=\frac{m(s)}{n(s)}=L_1 s+\cfrac{1}{C_2 s+\cfrac{1}{L_3 s+\cfrac{1}{C_4 s+\cfrac{1}{\ddots}}}} \tag{75.13}$$

where $m(s)$ is assumed to be of higher degree than $n(s)$. Otherwise, we expand $Y(s) = 1/Z(s)$ instead of $Z(s)$. Equation (75.13) can be realized as the input impedance of the LC ladder network of Fig. 75.4 and is known as the **first Cauer canonical form**.

Suppose now that we rearrange the numerator and denominator polynomials $m(s)$ and $n(s)$ in ascending order of s, and expand the resulting function in a continued fraction. Such an expansion yields

$$\begin{aligned} Z(s)=\frac{m(s)}{n(s)}&=\frac{a_0+a_2 s^2+\cdots+a_{k-2}s^{k-2}+a_k s^k}{b_1 s+b_3 s^3+\cdots+b_{k-1}s^{k-1}} \\ &=\frac{1}{C_1 s}+\cfrac{1}{\cfrac{1}{L_2 s}+\cfrac{1}{\cfrac{1}{C_3 s}+\cfrac{1}{\cfrac{1}{L_4 s}+\cfrac{1}{\ddots}}}} \end{aligned} \tag{75.14}$$

which can be realized by the LC ladder of Fig. 75.5 known as the **second Cauer canonical form**.

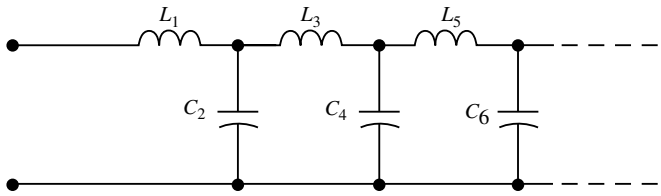

FIGURE 75.4 The first Cauer canonical form.

© 2003 by CRC Press LLC

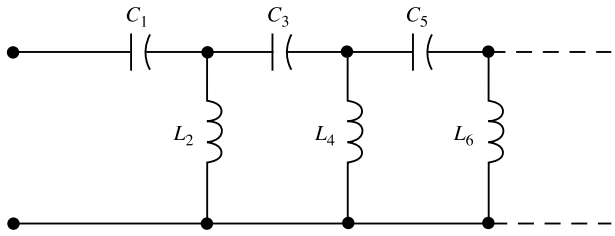

FIGURE 75.5 The second Cauer canonical form.

Example 1. Consider the reactance function

$$Z(s) = \frac{s(s^2+4)(s^2+36)}{(s^2+1)(s^2+25)(s^2+81)} \tag{75.15}$$

For the first Foster canonical form, we expand $Z(s)$ in a partial fraction

$$Z(s) = \frac{7s/128}{s^2+1} + \frac{11s/64}{s^2+25} + \frac{99s/128}{s^2+81} \tag{75.16}$$

and obtain the one-port network of Fig. 75.6.

For the second Foster canonical form, we expand $Y(s) = 1/Z(s)$ in a partial fraction

$$Y(s) = s + \frac{225/16}{s} + \frac{4851s/128}{s^2+4} + \frac{1925s/128}{s^2+36} \tag{75.17}$$

and obtain the one-port network of Fig. 75.7.

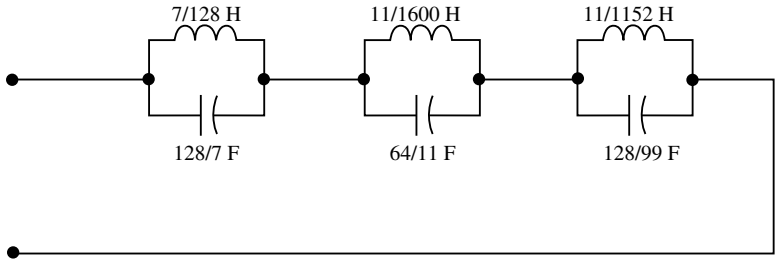

FIGURE 75.6 The first Foster canonical form.

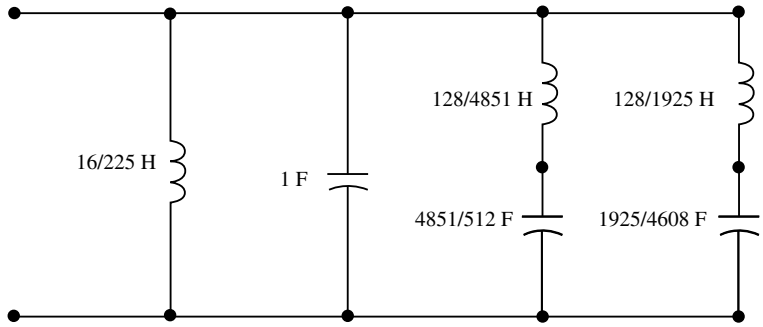

FIGURE 75.7 The second Foster canonical form.

© 2003 by CRC Press LLC

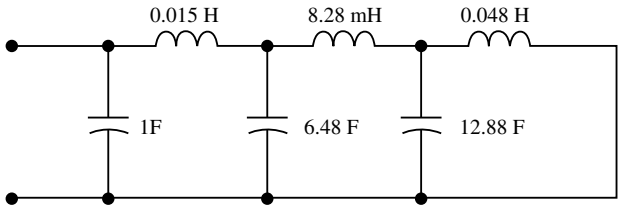

FIGURE 75.8 The first Cauer canonical form.

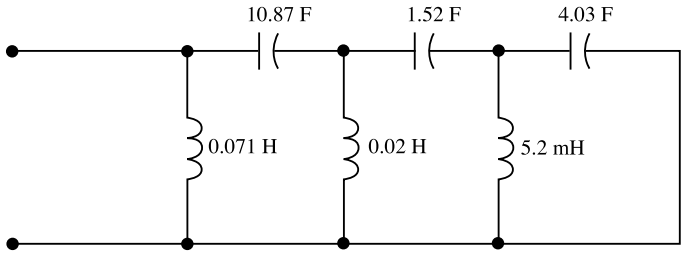

FIGURE 75.9 The second Cauer canonical form.

For the Cauer canonical form, we expand the function in a continued fraction

$$Z(s)=\cfrac{1}{s+\cfrac{1}{0.015s+\cfrac{1}{6.48s+\cfrac{1}{8.28\times10^{-3}s+\cfrac{1}{12.88s+\cfrac{1}{0.048s}}}}}} \tag{75.18}$$

and obtain the one-port network of Fig. 75.8.

For the second Cauer canonical form, we rearrange the polynomials in ascending order of s, then expand the resulting function in a continued fraction, and obtain

$$Z(s)=\cfrac{1}{\cfrac{14.06}{s}+\cfrac{1}{\cfrac{0.092}{s}+\cfrac{1}{\cfrac{49.84}{s}+\cfrac{1}{\cfrac{0.66}{s}+\cfrac{1}{\cfrac{192.26}{s}+\cfrac{1}{\cfrac{0.248}{s}}}}}}} \tag{75.19}$$

The desired LC ladder is shown in Fig. 75.9.

75.3 RC One-Port Networks

In this part, we exploit the properties of impedance functions of the RC one-ports from the known properties of the LCM one-ports of the preceding section.

© 2003 by CRC Press LLC

From a given RC one-port N_{RC}, we construct an LC one-port N_{LC} by replacing each resistor of resistance R_i by an inductor of inductance $L_i = R_i$. Suppose that we use loop analysis for both N_{RC} and N_{LC}, and choose the same set of loop currents. In addition, assume that the voltage source at the input port is traversed only by loop current ①. Then the input impedance $Z_{LC}(s)$ of N_{LC} is determined by the equation

$$Z_{LC}(s) = \frac{\tilde{\Delta}(s)}{\tilde{\Delta}_{11}(s)} \tag{75.20}$$

Where $\tilde{\Delta}$ is the loop determinant and $\tilde{\Delta}_{11}$ is the cofactor corresponding to loop current ① in N_{LC}. Similarly, the input impedance $Z_{RC}(s)$ of N_{RC} can be written as

$$Z_{RC}(s) = \frac{\Delta(s)}{\Delta_{11}(s)} \tag{75.21}$$

where Δ is the loop determinant and Δ_{11} is the cofactor corresponding to loop current ① in N_{RC}. It is not difficult to see that these loop determinants and cofactors are related by

$$\Delta(s) = \left.\frac{\tilde{\Delta}(p)}{p^r}\right|_{p^2=s} \tag{75.22a}$$

$$\Delta_{11}(s) = \left.\frac{\tilde{\Delta}_{11}(p)}{p^{r-1}}\right|_{p^2=s} \tag{75.22b}$$

where r is the order of the loop determinants $\tilde{\Delta}$ and Δ. Combining (75.20)–(75.22) yields

$$Z_{RC}(s) = \left[\frac{1}{p} Z_{LC}(p)\right]_{p^2=s} \tag{75.23}$$

This relation allows us to deduce the properties of RC networks from those of the LC networks. Substituting (75.6) and (75.7) in (75.23), we obtain the general forms of the RC impedance function as

$$Z_{RC}(s) = H\,\frac{(s+\sigma_{z1})(s+\sigma_{z2})(s+\sigma_{z3})\ldots}{s(s+\sigma_{p1})(s+\sigma_{p2})\ldots} = H + \frac{K_0}{s} + \sum_{i=1}^{n} \frac{\hat{K}_i}{s+\sigma_i} \tag{75.24}$$

where $\sigma_{zj} = \omega_{zj}^2$, $\sigma_{pi} = \omega_{pi}^2$, $\sigma_i = \omega_i^2$, and $\hat{K}_i = 2K_i$, and from (75.11)

$$0 \le \sigma_{z1} < \sigma_{p1} < \sigma_{z2} < \sigma_{p2} < \ldots \tag{75.25}$$

Thus, the zeros and poles of an RC impedance alternate along the nonpositive real axis. This property turns out also to be sufficient to characterize the RC impedances.

Theorem 2: *A real rational function is the driving-point impedance of an RC one-port network if and only if all the poles and zeros are simple, lie on the nonpositive real axis, and alternate with each other, the first critical frequency (pole or zero) being a pole.*

The slope of $Z_{RC}(\sigma)$ is found from (75.24) to be

$$\frac{dZ_{RC}(\sigma)}{d\sigma} = -\frac{K_0}{\sigma^2} - \sum_{i=1}^{n} \frac{\hat{K}_i}{(\sigma+\sigma_i)^2} \tag{75.26}$$

© 2003 by CRC Press LLC

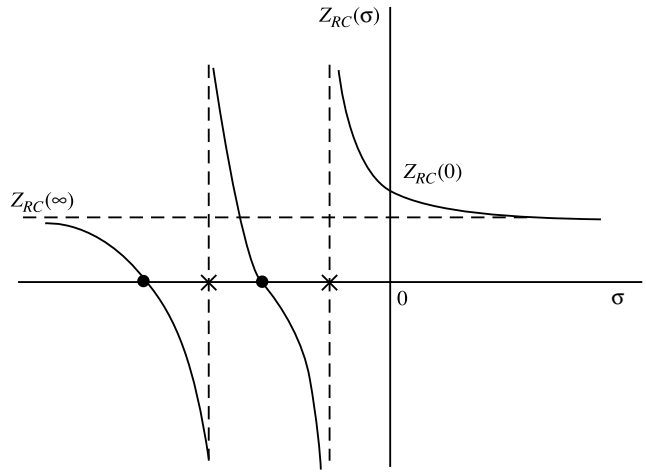

FIGURE 75.10 A plot of $Z_{RC}(\sigma)$ as a function of σ.

which is negative for all values of σ, since K_0 and $\hat{K}_i$ are positive. Thus, we have

$$\frac{dZ_{RC}(\sigma)}{d\sigma} < 0 \tag{75.27}$$

A plot of Z_{RC} (σ) as a function of σ is shown in Fig. 75.10. Since no poles and zeros exist along the positive real axis, we have

$$Z_{RC}(\infty) \le Z_{RC}(0) \tag{75.28}$$

We now proceed to the realization of the RC one-port networks. Suppose that we are given $Z_{RC}(\sigma)$ as in (75.24). By analogy to the LC case, this impedance can be realized by the one-port network of Fig. 75.11 called the **first Foster canonical form** for the RC impedance.

To obtain the **second Foster canonical form**, we expand $Y_{RC}(s)/s$ in a partial fraction, where $Y_{RC}(s) = 1/Z_{RC}(s)$, and then multiply the resulting equation by s. The reason is that a direct partial-fraction expansion of $Y_{RC}(s)$ will result in negative residues. Proceeding in this way, we obtain

$$Y_{RC}(s) = K_0 + K_\infty s + \sum_{i=1}^{n} \frac{K_i s}{s + \sigma_i} \tag{75.29}$$

yielding the one-port network of Fig. 75.12.

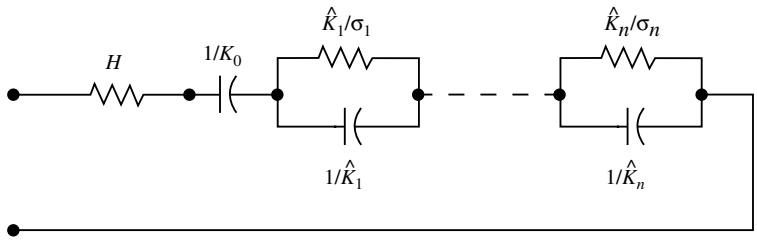

FIGURE 75.11 The first Foster canonical form.

© 2003 by CRC Press LLC

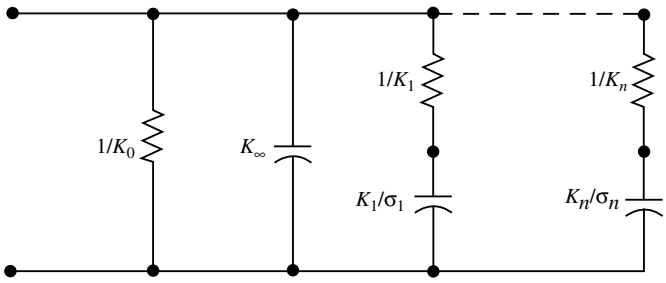

FIGURE 75.12 The second Foster canonical form.

As before, in addition to the two Foster forms, RC ladder realizations are also possible. Following the LC case, we perform a continued-fraction expansion of $Z_{RC}(s)$ and obtain

$$Z_{RC}(s) = R_1 + \cfrac{1}{C_2 s + \cfrac{1}{R_3 + \cfrac{1}{C_4 s + \cfrac{1}{\ddots}}}} \tag{75.30}$$

This expansion can be realized by the ladder network of Fig. 75.13 known as the **first Cauer canonical form** for RC impedance. If we rearrange the terms of $Z_{RC}(s)$ so that the numerator and denominator polynomials appear in ascending order of s, the resulting continued-fraction expansion takes the general form

$$Z_{RC}(s) = \cfrac{1}{C_1 s} + \cfrac{1}{\cfrac{1}{R_2} + \cfrac{1}{\cfrac{1}{C_3 s} + \cfrac{1}{\cfrac{1}{R_4} + \cfrac{1}{\cfrac{1}{C_5 s} + \cfrac{1}{\ddots}}}}} \tag{75.31}$$

yielding the **second Cauer canonical form** of Fig. 75.14.

Example 2. Consider the impedance function

$$Z(s) = \frac{s^2 + 12s + 35}{s^2 + 10s + 24} \tag{75.32}$$

To obtain the first Foster canonical form, we expand $Z(s)$ in partial fraction as

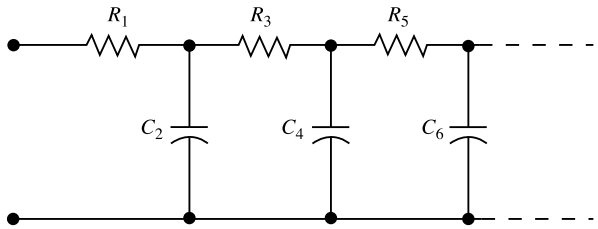

FIGURE 75.13 The first Cauer canonical form.

© 2003 by CRC Press LLC

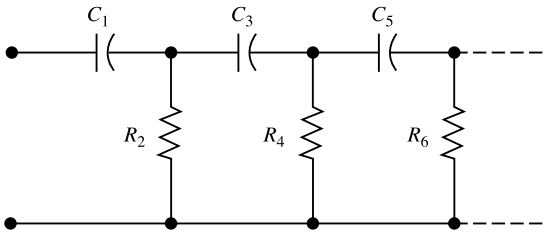

FIGURE 75.14 The second Cauer canonical form.

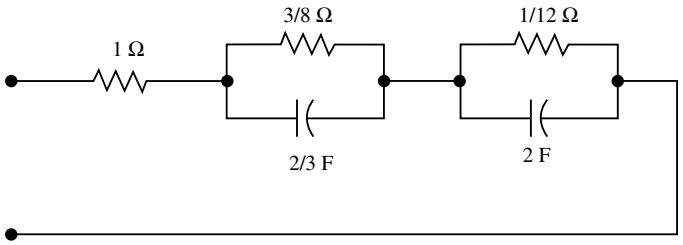

FIGURE 75.15 The first Foster canonical form.

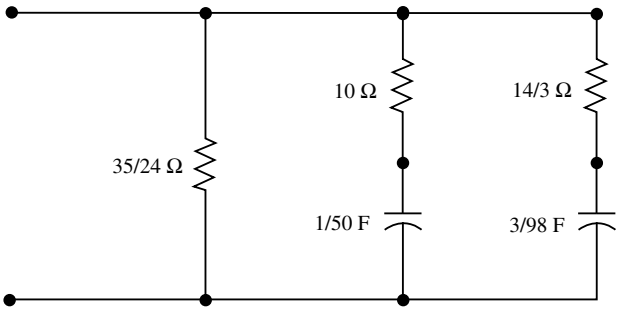

FIGURE 75.16 The second Foster canonical form.

$$Z(s) = 1 + \frac{3/2}{s+4} + \frac{1/2}{s+6} \tag{75.33}$$

and obtain the one-port of Fig. 75.15.

For the second Foster canonical form, the proper function to expand is $Y(s)/s$, yielding

$$Y(s) = \frac{24}{35} + \frac{s/10}{s+5} + \frac{3s/14}{s+7} \tag{75.34}$$

The corresponding realization is shown in Fig. 75.16.

For the first Cauer canonical form, we expand $Z(s)$ in a continued fraction as

$$Z(s) = 1 + \cfrac{1}{\cfrac{s}{2} + \cfrac{1}{\cfrac{4}{9} + \cfrac{1}{\cfrac{27s}{2} + \cfrac{1}{\cfrac{1}{72}}}}} \tag{75.35}$$

© 2003 by CRC Press LLC

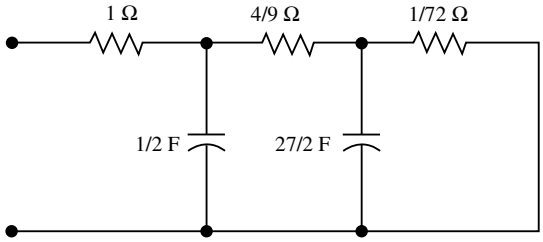

FIGURE 75.17 The first Cauer canonical form.

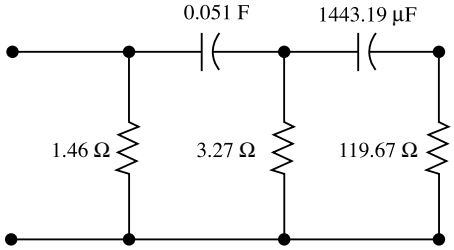

FIGURE 75.18 The second Cauer canonical form.

which can be realized by the ladder of Fig. 75.17. To obtain the second Cauer canonical form, we rearrange the numerator and denominator polynomials in ascending order of s, and then expand in a continued fraction

$$Z(s) = \frac{35+12s+s^2}{24+10s+s^2} = \cfrac{1}{0.69+\cfrac{1}{\cfrac{19.76}{s}+\cfrac{1}{0.306+\cfrac{1}{\cfrac{692.91}{s}+\cfrac{1}{8.36\times10^{-3}}}}}} \tag{75.36}$$

yielding the ladder of Fig. 75.18.

Two-Part Synthesis by Ladder Development[1]

Wai-Kai Chen
University of Illinois, Chicago

76.1 Introduction
76.2 The LC Ladder
76.3 The RC Ladder
76.4 The Parallel or Series Ladders

76.1 Introduction

In two-port synthesis, specifications are often given in terms of the transfer functions such as the transfer voltage ratio, transfer current ratio, transfer impedance, or transfer admittance. The actual realization, however, is accomplished by means of the *y*- or *z*-parameters. Figure 76.1 shows a two-port network driven by a voltage source with output terminating in an impedance $Z_2(s)$. It is straightforward to show that the transfer voltage ratio function $G_{12}(s)$ can be expressed in terms of its *y*-parameters $y_{ij}(s)$ or *z*-parameters $z_{ij}(s)$ by the equation

$$G_{12}(s) = \frac{V_2}{V_1} = \frac{-y_{21}}{y_{22} + Y_2} \tag{76.1}$$

where $Y_2(s) = 1/Z_2(s)$. When the output is open-circuited, (76.1) becomes

$$G_{12}(s) = \frac{V_2}{V_1} = \frac{-y_{21}}{y_{22}} = \frac{z_{21}}{z_{11}} \tag{76.2}$$

Likewise, the transfer current ratio $\alpha_{12}(s)$ can be expressed as

$$\alpha_{12}(s) = -\frac{I_2}{I_1} = \frac{z_{21}}{z_{22} + Z_2} \tag{76.3}$$

The **zeros of transmission** of a two-port network are defined as the frequencies at which the two-port results in zero output for a finite input. They play an important role in ladder development. There are many ways of producing zeros of transmission. One possibility to prevent the input signal from reaching the output is by shorting together all transmission paths or by opening all transmission paths by means of a series or parallel resonance. Another possibility is that signals transmitted by different paths cancel at the output.

[1]References for this Chapter can be found on page 2421.

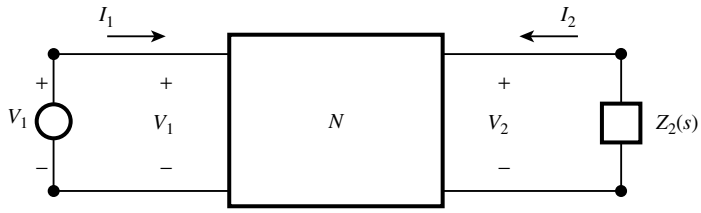

FIGURE 76.1 A terminated two-port network.

Observe from (76.1) and (76.2) that zero output, $V_2 = 0$, implies a zero for each of these functions. Therefore, zeros of transmission are zeros of $-y_{21}$ or z_{21} provided y_{21} and y_{22} or z_{21} and z_{11} have the same poles. For the ladder network, the transmission can be interrupted only by the short circuit in a shunt arm or an open circuit in a series arm. The short circuit of a shunt arm corresponds to the pole frequencies of its admittances, whereas the open circuit of a series arm corresponds to the pole frequencies of its impedances. Therefore, the zeros of transmission of a ladder network can be identified directly with the zeros of the impedances of the shunt arms and the poles of the impedances of the series arms. For the LC ladder, all zeros of transmission lie on the $j\omega$-axis, and for the RC ladder they are on the nonpositive real axis of the complex-frequency s-plane.

76.2 The LC Ladder

For LC ladders, the conditions imposed on $-y_{21}$ and y_{22} or z_{21} and z_{22} are that the driving-point functions y_{22} and z_{22} be positive real with poles and zeros interlaced on the $j\omega$-axis. The transfer functions $-y_{21}$ and z_{21}, assuming to have the same poles as y_{22} or z_{22}, must have all of its zeros on the $j\omega$-axis. However, these zeros need not be interlaced with the poles and they may not be simple. Our strategy in realization is that of carrying out the driving-point synthesis of y_{22} or z_{22}, using Cauer ladder development method, in such a way that the zeros of transmission are realized at the same time. The procedure consists of two steps: a zero-shifting step and a zero-producing step, as described below.

Zero Shifting by Partial Removal. Consider an impedance of (75.6), the partial-fraction expansion of which is given in (75.7). The first term on the right-hand side of (75.7) is due to the contribution of the pole at the infinity. If this term Hs is subtracted from $Z(s)$, the resulting function $Z(s) - Hs$ is devoid of the pole at the infinity. We say that the pole at infinity has been removed completely. Instead of complete removal of this pole, suppose that we subtract a fraction of the terms Hs from $Z(s)$ by introducing a constant k_p such that

$$Z_1(s) = Z(s) - k_p Hs, \qquad k_p < 1 \tag{76.4}$$

We say that the pole at infinity has been **partially removed** or **weakened**. The function $Z_1(s)$ that results from the partial removal of the pole at infinity still possesses the pole at infinity. Since all the zeros of $Z_1(s)$ are again located on the $j\omega$-axis, these zeros are found by substituting $s = j\omega$ in (76.4),

$$X_1(\omega) = X(\omega) - k_p H\omega \tag{76.5}$$

where $Z_1(j\omega) = jX_1(\omega)$. The zeros of $X_1(\omega)$ are values of ω satisfying the equation

$$X(\omega) = k_p H\omega \tag{76.6}$$

© 2003 by CRC Press LLC

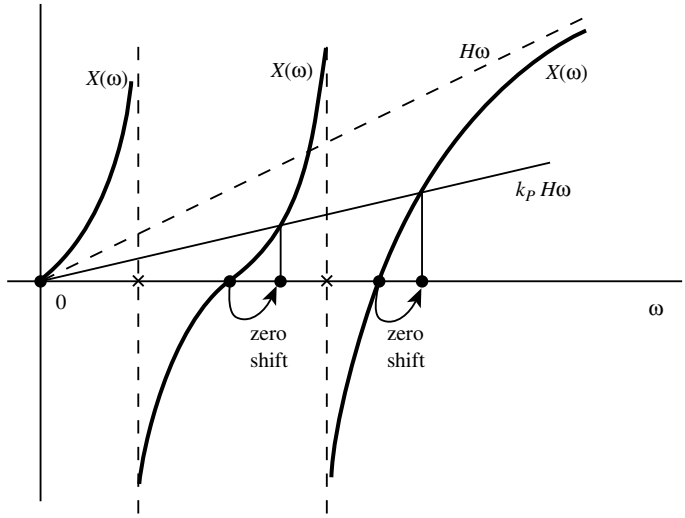

FIGURE 76.2 Zero shifting by weakening the pole at the infinity.

Solutions to this equation are found graphically from the intersections of the curves $X(\omega)$ and $k_pH\omega$, as depicted in Fig. 76.2. Observe that all the zeros in the resulting function are shifted toward the pole being weakened. The amount of shift of the zeros from their original positions depends on the value of k_p and the proximity of a zero to the pole being weakened.

We next consider the term K_0/s in (75.7) due to the pole at the origin. The partial removal of this pole is equivalent to the operation

$$Z_2(s) = Z(s) - k_p \frac{K_0}{s} \tag{76.7}$$

As before, the zeros of $Z_2(s)$ are defined by the intersections of the curves $X(\omega)$ and $-k_pK_0/\omega$ with ω,

$$X(\omega) = -k_p \frac{K_0}{\omega} \tag{76.8}$$

as illustrated in Fig. 76.3. Observe again that the zeros are shifted toward the pole being weakened, which is at the origin.

Finally, for the finite nonzero poles, the corresponding factors take the general form $2K_is/(s^2 + \omega_i^2)$. The partial removal of this pair of complex conjugate poles results in the new function

$$Z_3(s) = Z(s) - k_p \frac{2K_i s}{s^2 + \omega_i^2},\ k_p < 1 \tag{76.9}$$

The zeros of this function are defined by the intersections of the plots of $X(\omega)$ and $-k_p2K_i\omega/(\omega^2 - \omega_i^2)$ with ω,

$$X(\omega) = -k_p \frac{2K_i\omega}{\omega^2 - \omega_i^2},\ k_p < 1 \tag{76.10}$$

as illustrated in Fig. 76.4.

Our conclusion is that the partial removal of a pole shifts the zeros toward that pole. The amount of shift depends on the value of k_p and the proximity of a zero to that pole, but in no case can a zero be shifted beyond an adjacent pole.

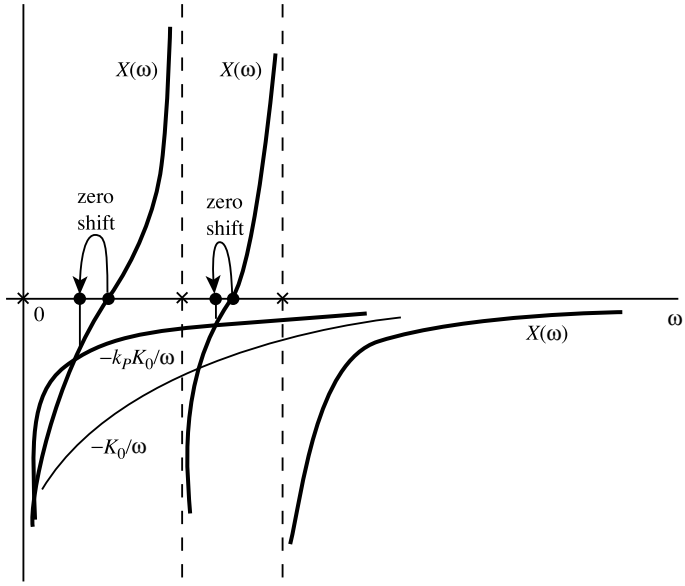

FIGURE 76.3 Zero shifting by weakening the pole at the origin.

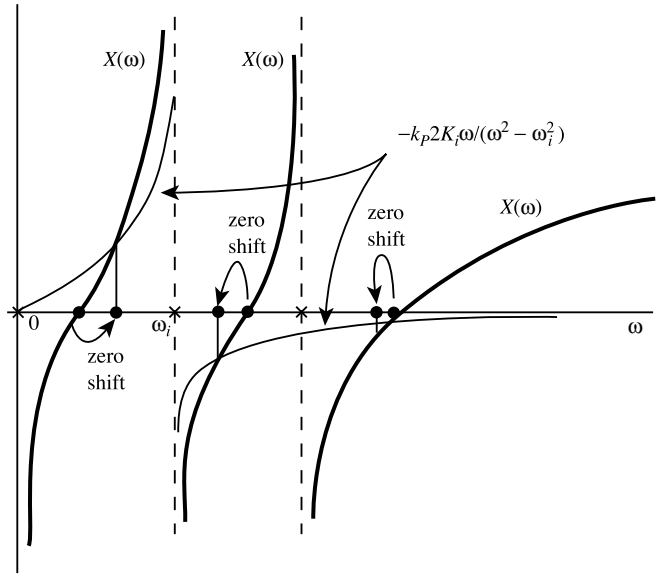

FIGURE 76.4 Zero shifting by weakening a finite nonzero pole.

Zero Producing by Complete Pole Removal. After a zero of transmission has been shifted to a desired location by the partial removal of an appropriate pole, the realization of this zero of transmission is accomplished by the complete removal of the pole of the reciprocal function corresponding to the shifted zero. For the LC ladder two-ports, a series combination of an inductor L and a capacitor C produces a zero at its resonant frequency $\omega = 1/\sqrt{LC}$, and this network is used in the shunt arm in the ladder to produce the desired zero of transmission. Likewise, the parallel connection of L and C yields an infinite impedance at its resonant frequency, and is used in the series arm of the ladder. They are shown in Fig. 76.5.

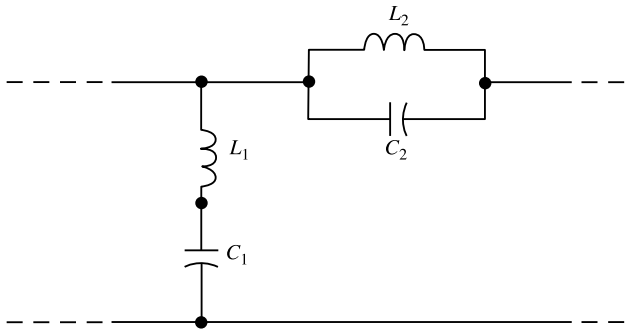

FIGURE 76.5 Zero producing sections in a ladder network.

Example 1. We wish to design a lossless two-port network terminated in a 100-Ω resistor to meet the specifications for the transfer voltage-ratio function

$$G_{12}(s) = \frac{V_2}{V_1} = K\frac{s^2+4}{s^3+4s^2+9s+4} \tag{76.11}$$

within a multiplicative constant.

Since magnitude scaling does not affect the voltage transfer ratio, without loss of generality, we first assume that the terminating resistor is 1 Ω. Equation (76.11) can be rewritten as

$$G_{12}(s) = K\frac{\dfrac{s^2+4}{s(s^2+9)}}{\dfrac{4(s^2+1)}{s(s^2+9)}+1} = \frac{-y_{21}}{y_{22}+Y_2} = \frac{-y_{21}}{y_{22}+1} \tag{76.12}$$

We can make the following identifications:

$$-y_{21}(s) = K\frac{s^2+4}{s(s^2+9)},\quad y_{22}(s) = 4\frac{s^2+1}{s(s^2+9)} \tag{76.13}$$

Both functions have the same poles at $s = 0$ and $s = \pm j3$ and the zeros of transmission of the ladder are located at $s = \pm j2$ and s = ∞. These poles and zeros are shown in Fig. 76.6. To realize the zero of transmission at s = ∞, we remove the pole of $z_1(s) = 1/y_{22}(s)$ at s = ∞.

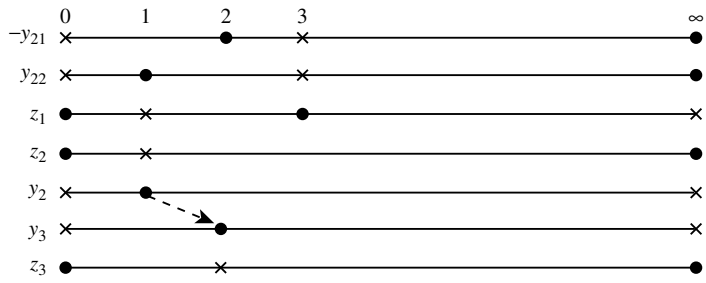

FIGURE 76.6 The poles and zeros of LC immittances.

© 2003 by CRC Press LLC

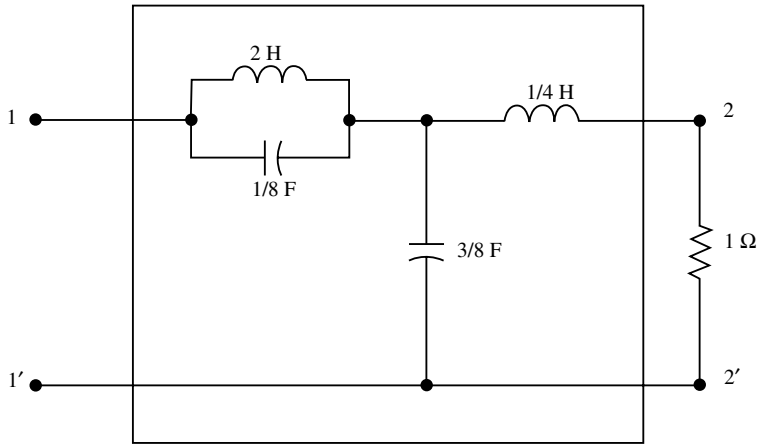

FIGURE 76.7 An LC ladder realization of the transfer voltage ratio (76.11).

$$z_1(s) = \frac{1}{y_{22}(s)} = \frac{s(s^2+9)}{4(s^2+1)} = \frac{2s}{s^2+1} + \frac{s}{4} \tag{76.14}$$

After subtracting the term $s/4$ corresponding to an inductor of inductance 1/4 H shown in Fig. 76.7 from $z_1(s)$, the remaining impedance $z_2(s)$ is found to be

$$z_2(s) = \frac{2s}{s^2+1} \tag{76.15}$$

To realize the zero of transmission at $s = \pm j2$, we partially weaken the pole of the admittance

$$y_2(s) \equiv \frac{1}{z_2(s)} = \frac{s^2+1}{2s} \tag{76.16}$$

at s = ∞ in order to shift the zero at $s = \pm j$ to $s = \pm j2$, or

$$y_3(\pm j2) = y_2(s) - k_p \frac{1}{2} s \Big|_{s=\pm j2} = \frac{-4+1}{\pm j2 \times 2} \mp k_p \frac{1}{2} j2 = 0 \tag{76.17}$$

yielding $k_p = 3/4$. The new function becomes

$$y_3(s) = \frac{s^2+1}{2s} - \frac{3}{8}s = \frac{s^2+4}{8s} \tag{76.18}$$

after the removal of a shunt capacitor of capacitance 3/8 F, as shown in Fig. 76.7. The factor $(s^2 + 4)$ in the numerator was anticipated because our objective was to produce a zero in the driving-point admittance $y_3(s)$ at $s = \pm j2$. To realize this zero, we consider the reciprocal function $z_3(s) = 1/y_3(s)$ by complete removal of its pole at $s = \pm j2$. This yields a parallel connection of $L = 2$ H and $C = 1/8$ F shown in Fig. 76.7. The final realization is obtained by magnitude-scaling by a factor of 100. The realized constant K is found from the network to be $K = 1$.

© 2003 by CRC Press LLC

76.3 The RC Ladder

We now consider the realization of RC ladder with prescribed $-y_{21}(s)$ and $y_{22}(s)$ or $z_{21}(s)$ and $z_{22}(s)$. Following the LC case, the zero shifting for the RC driving-point functions is accomplished by one or any combination of the following three operations:

1. The partial removal of a constant $Z(\infty)$ from $Z(s)$.
2. The partial removal of a constant $Y(0)$ from $Y(s)$.
3. The partial removal of a pole from $Z(s)$ or $Y(s)$.

The first operation permits a series resistance to be removed so that the resulting impedance is still positive real and possesses a desired zero of transmission:

$$Z_1(s) = Z(s) - k_p Z(\infty), \qquad k_p \le 1 \tag{76.19}$$

the zeros of which occur at those values of σ satisfying

$$Z(\sigma) = k_p Z(\infty), \qquad k_p \le 1 \tag{76.20}$$

Observe that from Fig. 76.8 all zeros are shifted toward $s = \sigma = -\infty$ by the partial removal of $Z(\infty)$ because the slope is negative for the RC impedances.

The second operation corresponds to the removal of a shunt resistance, and the remaining admittance

$$Y_1(s) = Y(s) - k_p Y(0), \qquad k_p \le 1 \tag{76.21}$$

is still positive real, the zeros of which occur at those values of σ satisfying

$$Y(\sigma) = k_p Y(0), \qquad k_p \le 1 \tag{76.22}$$

Observe from Fig. 76.9 that these zeros again are shifted toward $s = 0$ in relation to those of $Y(s)$.

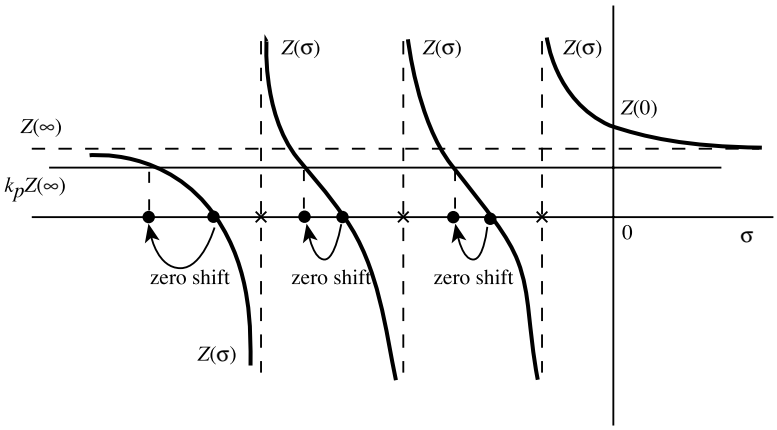

FIGURE 76.8 Zero shifting by the partial removal of $Z(\infty)$.

© 2003 by CRC Press LLC

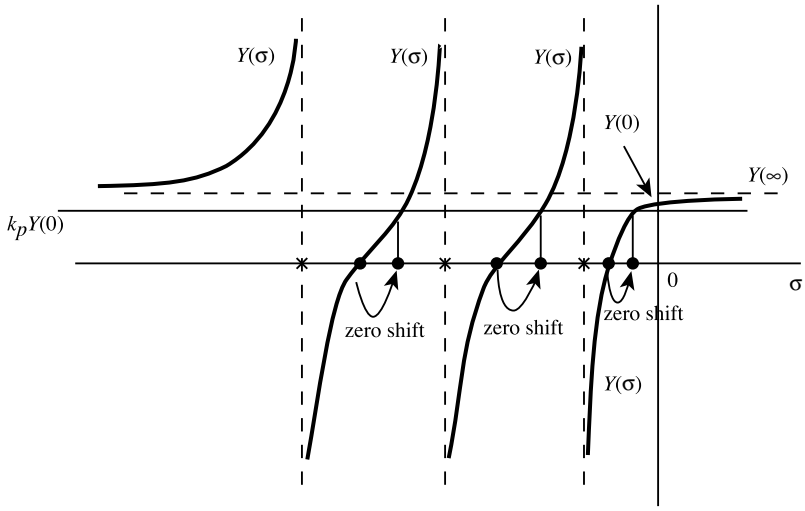

FIGURE 76.9 Zero shifting by partial removal of $Y(0)$.

Finally, the partial removal of a pole of $Z(s)$ results in a parallel connection of a resistor and a capacitor, and the remaining impedance becomes

$$Z_2(s) = Z(s) - k_p \frac{K_i}{s+\sigma_i}, \qquad k_p < 1 \tag{76.23}$$

the zeros of which occur at those values of σ satisfying

$$Z(\sigma) = k_p \frac{K_i}{\sigma+\sigma_i}, \qquad k_p < 1 \tag{76.24}$$

As indicated in Fig. 76.10, these zeros are again shifted toward the pole at $s = -\sigma_i$ being partially weakened.

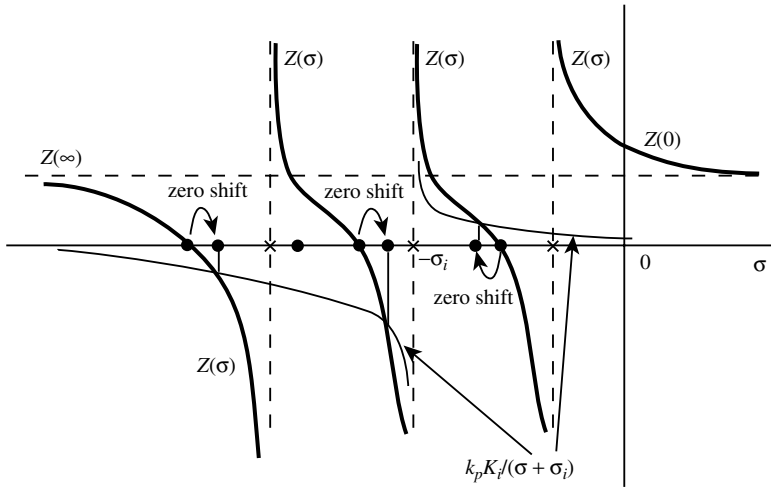

FIGURE 76.10 Zero shifting by partial removal of a pole of an RC impedance.

© 2003 by CRC Press LLC

Therefore, the partial removal of a constant or a pole shifts the zeros of the remaining function toward the quantity being weakened. The amount of shift depends on the value of k_p and the proximity of a zero to that quantity. Once a zero is shifted to an appropriate location, its realization is accomplished by the complete removal of the pole of the reciprocal function corresponding to the shifted zero.

Example 2. We wish to realize the transfer impedance

$$Z_{12}(s) = K\frac{s(s+1)}{2s^2+18s+34} \tag{76.25}$$

of an RC two-port network terminated in a 1-Ω resistor.

From (76.3), the transfer impedance can be written as

$$Z_{12}(s) = \frac{V_2}{I_1} = \frac{-I_2\times 1}{I_1} = \frac{-I_2}{I_1} = \frac{z_{21}}{z_{22}+1} = \frac{K\dfrac{s(s+1)}{(s+2)(s+5)}}{\dfrac{(s+3)(s+8)}{(s+2)(s+5)}+1} \tag{76.26}$$

identifying

$$z_{21}(s) = K\frac{s(s+1)}{(s+2)(s+5)}, \qquad z_{22}(s) = \frac{(s+3)(s+8)}{(s+2)(s+5)} \tag{76.27}$$

The zeros of transmission are located at $s = 0$ and $s = -1$. Suppose that we wish to realize these zeros in the order of –1 and 0. For this we consider the reciprocal function $y_1(s) = 1/z_{22}(s)$, the zeros and poles of which are shown in Fig. 76.11. Clearly, the zero at $s = -2$ can be shifted to $s = -1$ by partial removal of the constant $y_1(0) = 5/12$,

$$y_2(-1) = y_1(-1) - k_p y_1(0) = 0 \tag{76.28}$$

obtaining $k_p = 24/35$ and

$$y_2(s) = y_1(s) - \frac{24}{35}y_1(0) = \frac{(s+1)(5s+22)}{7(s^2+11s+24)} \tag{76.29}$$

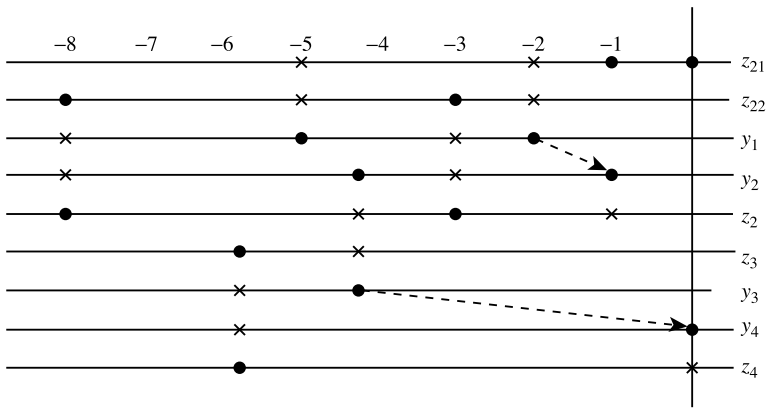

FIGURE 76.11 The zeros and poles of RC immittances.

© 2003 by CRC Press LLC

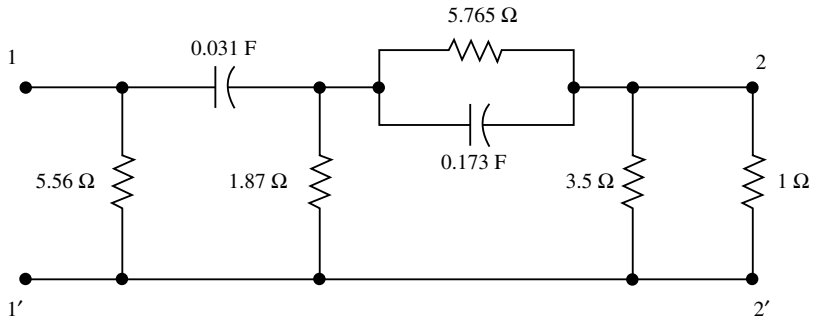

FIGURE 76.12 An RC ladder realization of the transfer impedance $Z_{12}(s)$.

This admittance has a zero at $s = -1$, as expected. The partially removed constant $k_p y_1(0)$ corresponds to a shunt resistor of resistance 3.5 Ω. To realize the zero of transmission at $s = -1$, we consider the reciprocal function $z_2(s) = 1/y_2(s)$ by the complete removal of its pole at $s = -1$. The remaining impedance $z_3(s)$ becomes

$$z_3(s) = z_2(s) - \frac{\frac{98}{17}}{s+1} = \frac{7}{5} \times \frac{s + \frac{100}{17}}{s + \frac{22}{5}} \tag{76.30}$$

The removed pole corresponds to a parallel connection of a resistor of resistance 98/17 Ω and a capacitor of capacitance 17/98 F, as illustrated in Fig. 76.12.

For the zero of transmission at $s = 0$, we consider the reciprocal function $y_3(s) = 1/z_3(s)$. The zero of $y_3(s)$ at s = –22/5 can be shifted to 0 by partial removal of the constant $y_3(0) = 187/350$, or

$$y_4(0) = y_3(0) - k_p y_3(0) = 0 \tag{76.31}$$

yielding $k_p = 1$. The remaining admittance $y_4(s)$ becomes

$$y_4(s) = y_3(s) - y_3(0) = \frac{\frac{9}{50}s}{s + \frac{100}{17}} \tag{76.32}$$

showing a zero at the origin, as anticipated. This zero is realized by the complete removal of the pole at the origin of its reciprocal $z_4(s) = 1/y_4(s)$, yielding

$$z_5(s) = z_4(s) - \frac{32.68}{s} = 5.56 \tag{76.33}$$

The complete realization is presented in Fig. 76.12, from which the constant K is found to be $K = 1$.

76.4 The Parallel or Series Ladders

The zeros of transmission of the LC ladders are restricted to the $j\omega$-axis and those of the RC ladders to the negative real axis of the s-plane. For complex zeros of transmission such as those needed for certain phase-correction applications, they cannot be realized by a single LC or RC ladder because there is only a single transmission path from the input to the output. The use of parallel or series

© 2003 by CRC Press LLC

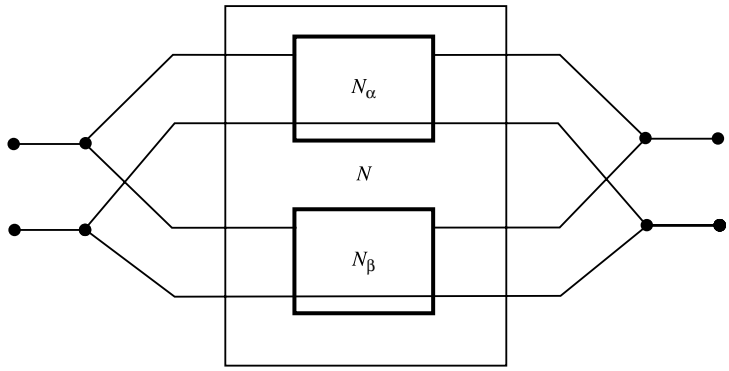

FIGURE 76.13 The parallel connection of two ladder networks.

ladders, on the other hand, provides a conduit for multiple path signal transmission, so that the signals arriving at the output through the various paths may cancel one another, resulting in the zero output for a finite input. Therefore, they are capable of producing complex zeros of transmission. This structure was first suggested by Guillemin [10].

Figure 76.13 is the parallel connection of the ladder networks N_α and N_β. The y-parameters y_{ij} of the composite two-port N can be expressed in terms of those $y'_{ij\alpha}$ and $y'_{ij\beta}$ of the component two-ports N_α and N_β by the equation

$$y_{ij} = y'_{ij\alpha} + y'_{ij\beta}, \qquad i, j = 1, 2 \tag{76.34}$$

Thus, to realize $-y_{21}(s)$ and $y_{22}(s)$, we may separate them into pairs like $-y'_{21\alpha}$, $y'_{22\alpha}$ and $-y'_{21\beta}$, $y'_{22\beta}$, and realize an individual pair as an LC or RC ladder. Then connect these individual ladders in parallel to realize $-y_{21}(s)$ and $y_{22}(s)$. In order for the procedure to succeed, we must resolve the following problem. Recall than in the Cauer development of LC and RC ladders, $-y_{21}(s)$ is realized only within the multiplicative constant k. Thus, the transfer admittances realized by the component two-ports actually will be $-k_\alpha y'_{21\alpha}$ and $-k_\beta y'_{21\beta}$. The sum of these two functions will not result in the desired $-ky_{21}$ unless $k = k_\alpha = k_\beta$. To circumvent this difficulty, we introduce an additional degree of freedom by adjusting the admittance level of the α-ladder N_α by a factor b_α and the β-ladder N_β by b_β. Then the functions of the resulting realizations become

$$-y'_{21\alpha} = -b_\alpha k_\alpha y_{21\alpha}, \qquad y'_{22\alpha} = b_\alpha y_{22\alpha} \tag{76.35a}$$

$$-y'_{21\beta} = -b_\beta k_\beta y_{21\beta}, \qquad y'_{22\beta} = b_\beta y_{22\beta} \tag{76.35b}$$

where $y_{ij} = y_{ij\alpha} + y_{ij\beta}$, $i, j = 1, 2$. Substituting these in (76.34) gives

$$y_{21} = b_\alpha k_\alpha y_{21\alpha} + b_\beta k_\beta y_{21\beta} \tag{76.36a}$$

$$y_{22} = b_\alpha y_{22\alpha} + b_\beta y_{22\beta} \tag{76.36b}$$

Our objective is to choose b_α and b_β to satisfy the above equations, once k_α and k_β are known. One way to meet these requirements is to let $y'_{22\alpha}$ and $y'_{22\beta}$ have the same zeros and poles as y_{22} but different scale factors such that $y'_{22\alpha} = b_\alpha y_{22}$ and $y'_{22\beta} = b_\beta y_{22}$, obtaining from (76.36b)

$$b_\alpha + b_\beta = 1 \tag{76.37}$$

© 2003 by CRC Press LLC

Since we can only realize y_{21} within a multiplicative constant, we replace y_{21} by ky_{21} in (76.36a), and set

$$b_\alpha k_\alpha = b_\beta k_\beta = k \tag{76.38}$$

These two equations can be solved to yield the desired scale factors b_α and b_β.

In general, for m ladders in parallel, we require

$$b_1 + b_2 + \cdots + b_m = 1 \tag{76.39a}$$

$$b_1 k_1 = b_2 k_2 = \cdots = b_m k_m = k \tag{76.39b}$$

where b_i is the admittance scale factor for the ith ladder, and k_i is the realized multiplicative constant of the transfer admittance of the ith ladder. Once k_i are known, these m simultaneous equations can be solved for the m unknowns b_i, and the admittance level of each ladder can be scaled accordingly. The scaled ladders are connected in parallel to realize the $-y_{21}(s)$ specifications within the multiplicative constant k, and the $y_{22}(s)$ specifications exactly.

Similar results are obtained by using the z-parameters $z_{ij}(s)$ and the series connection of the component two-port networks, the details of which are omitted. However, a design example will be presented below.

Example 3. We wish to realize an RC two-port network to meet the following specifications:

$$-y_{21}(s) = k\frac{s^2+1}{(s+5)(s+9)} \tag{76.40a}$$

$$y_{22}(s) = \frac{(s+3)(s+7)}{(s+5)(s+9)} \tag{76.40b}$$

Since the zeros of transmission are located at $s = \pm j1$, they cannot be realized by a single RC ladder. For our purposes, we choose the y-parameters of the component two-ports as

$$-y_{21\alpha}(s) = k_\alpha \frac{s^2}{(s+5)(s+9)}, \qquad y_{22\alpha}(s) = y_{22}(s) \tag{76.41a}$$

$$-y_{21\beta}(s) = \frac{k_\beta}{(s+5)(s+9)}, \qquad y_{22\beta}(s) = y_{22}(s) \tag{76.41b}$$

For the α-ladder, since the zeros of transmission are all at the origin, they can be realized by the second Cauer canonical form shown in Fig. 76.14 with $k_\alpha = 0.043$. For the β-ladder, since the zeros of transmission are all at the infinity, they can be realized by the first Cauer canonical form of Fig. 76.15 with $k_\beta = 21$.

Our next task is to adjust the admittance level of the individual ladders so that when they are connected in parallel, the $y_{22}(s)$ specifications are realized exactly, and the $-y_{21}(s)$ specifications are realized to within a multiplicative constant k. Appealing to (76.37) and (76.38), we have

$$b_\alpha + b_\beta = 1 \tag{76.42a}$$

$$0.043 b_\alpha = 21 b_\beta = k \tag{76.42b}$$

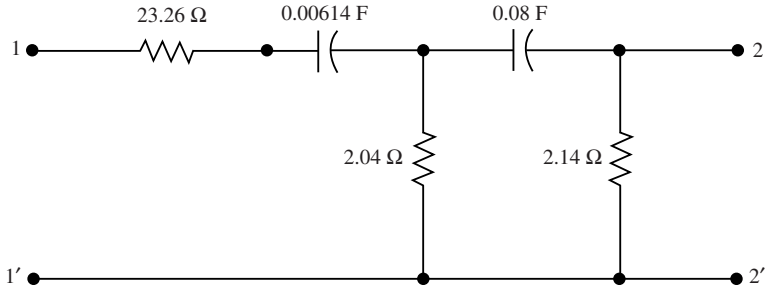

FIGURE 76.14 An RC α-ladder realization.

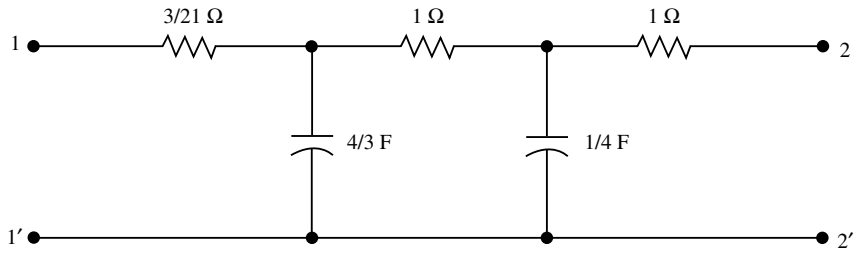

FIGURE 76.15 An RC β-ladder realization.

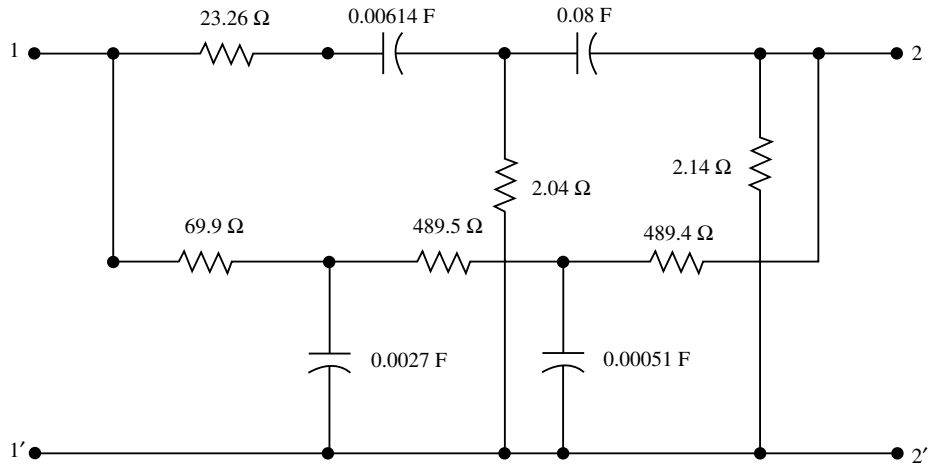

FIGURE 76.16 The parallel RC ladder realization of $-y_{21}(s)$ and $y_{22}(s)$.

yielding

$$b_\alpha = 0.998 \cong 1, \qquad b_\beta = 2.043 \times 10^{-3} \tag{76.43}$$

We now adjust the admittance level of the β-ladder by a factor $b_\beta = 2.043 \times 10^{-3}$, leaving the α-ladder intact. The final realization is achieved by the parallel connection of the α-ladder and the resulting β-ladder shown in Fig. 76.16. The realized multiplicative constant for the overall transfer admittance $-y_{21}(s)$ is found to be $k = 0.043$.

© 2003 by CRC Press LLC

Example 4. We wish to realize the open-circuit transfer voltage ratio

$$G_{12}(s)=\frac{z_{21}(s)}{z_{11}(s)}=k\frac{s^2-2s+10}{s^2+8s+15} \tag{76.44}$$

by an RC two-port network.

First, we multiply the numerator and denominator of $G_{12}(s)$ by the factor $(s+2)$ to yield

$$G_{12}(s)=\frac{z_{21}(s)}{z_{11}(s)}=k\frac{s^3+6s+20}{(s+2)(s+3)(s+5)} \tag{76.45}$$

and then divide by $(s+1)(s+2.5)(s+4)$ in order to make the following identifications:

$$z_{21}(s)=k\frac{s^3+6s+20}{(s+1)(s+2.5)(s+4)} \tag{76.46a}$$

$$z_{11}(s)=\frac{(s+2)(s+3)(s+5)}{(s+1)(s+2.5)(s+4)} \tag{76.46b}$$

We next decompose the pairs into three pairs as follows:

$$z_{21\alpha}(s)=k_\alpha\frac{s^3}{(s+1)(s+2.5)(s+4)},\qquad z_{11\alpha}(s)=z_{11}(s) \tag{76.47a}$$

$$z_{21\beta}(s)=k_\beta\frac{6s}{(s+1)(s+2.5)(s+4)},\qquad z_{11\beta}(s)=z_{11}(s) \tag{76.47b}$$

$$z_{21\gamma}(s)=k_\gamma\frac{20}{(s+1)(s+2.5)(s+4)},\qquad z_{11\gamma}(s)=z_{11}(s) \tag{76.47c}$$

1. ***The α-ladder.*** Since all the zeros of transmission are located at the origin, it can be realized by the second Cauer canonical form of Fig. 76.17 with $k_\alpha = 1$.
2. ***The β-ladder.*** Since one of the zeros of transmission is located at the origin, and two others at the infinity, the first half of the β-ladder can be realized as the second Cauer canonical form and the second half of the β-ladder by the first Cauer canonical forms as illustrated in Fig. 76.18 with $k_\beta = 0.0117$.
3. **The γ-ladder.** Since all of its zeros of transmission are located at the infinity, it can be realized by the first Cauer canonical form of Fig. 76.19 with $k_\psi = 0.0145$.

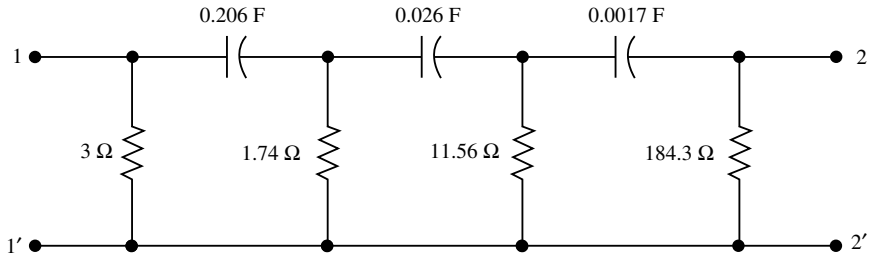

FIGURE 76.17 The α-ladder.

© 2003 by CRC Press LLC

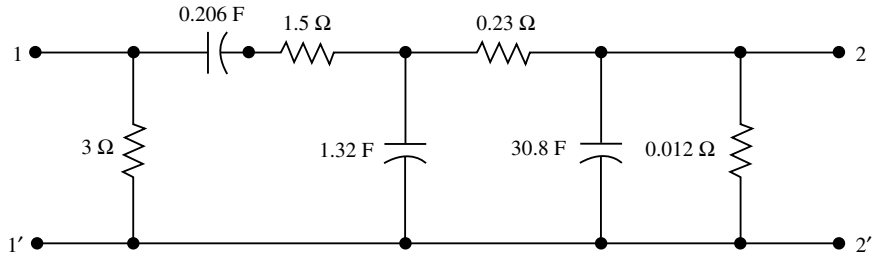

FIGURE 76.18 The β-ladder.

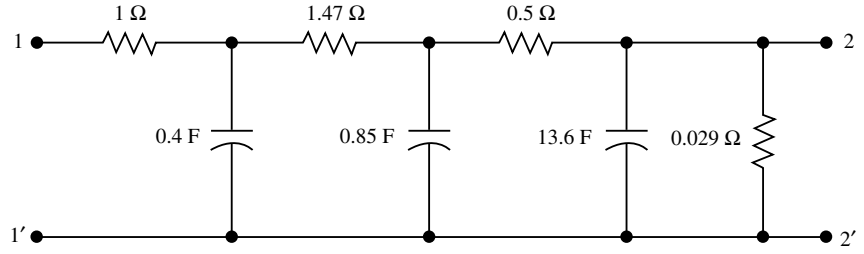

FIGURE 76.19 The γ-ladder.

We next adjust the admittance level of the ladders so that when they are connected in parallel, the desired specifications are realized. From (76.39) we require that

$$b_\alpha + b_\beta + b_\gamma = 1 \tag{76.48a}$$

$$b_\alpha k_\alpha = b_\beta k_\beta = b_\gamma k_\gamma = k \tag{76.48b}$$

These equations can be solved to yield

$$b_\alpha = 0.0064, \qquad b_\beta = 0.552, \qquad b_\gamma = 0.4416 \tag{76.49}$$

with $k = 0.0064$. The final two-port network is shown in Fig. 76.20.

Design of Resistively Terminated Networks[1]

Wai-Kai Chen
University of Illinois, Chicago

77.1 Introduction
77.2 Double-Terminated Butterworth Networks
77.3 Double-Terminated Chebyshev Networks

77.1 Introduction

In the design of communication systems, it is frequently required to synthesize a coupling network that will transform a given frequency-dependent load impedance into another specified one. We refer to this operation as **impedance matching** or **equalization**, and the resulting coupling network as a **matching network** or **equalizer**.

Refer to the network configuration of Fig. 77.1 where the source is represented either by its Thévenin equivalent or by its Norton equivalent. Our objective here is to design a lossless two-port network or equalizer *N*, which when inserted between a resistive source and a resistive load will yield a preassigned transducer power-gain characteristic over the entire sinusoidal frequency spectrum. Explicit formulas for the design of Butterworth and Chebyshev LC ladder networks will be given. The more complicated situation where the load is frequency dependent will be dealt with in Chapter 78.

In the networks of Fig. 77.1, let $Z_{11}(s)$ and $Z_{22}(s)$ be the impedances looking into the input and output ports when the output and input ports are terminated in $z_2(s)$ and $z_1(s)$, respectively. The input and output **reflection coefficients** are defined by

$$\rho_{11}(s) = \frac{Z_{11}(s) - z_1(-s)}{Z_{11}(s) + z_1(s)} \tag{77.1a}$$

$$\rho_{22}(s) = \frac{Z_{22}(s) - z_2(-s)}{Z_{22}(s) + z_2(s)} \tag{77.1b}$$

respectively. We now demonstrate that the **transducer power gain** $G(\omega^2)$ defined as the ratio of average power delivered to the load to the maximum available average power at the source is given by

$$G(\omega^2) = 1 - |\rho_{11}(j\omega)|^2 \equiv |\rho_{21}(j\omega)|^2 \tag{77.2}$$

[1]References for this Chapter can be found on page 2421.

© 2003 by CRC Press LLC

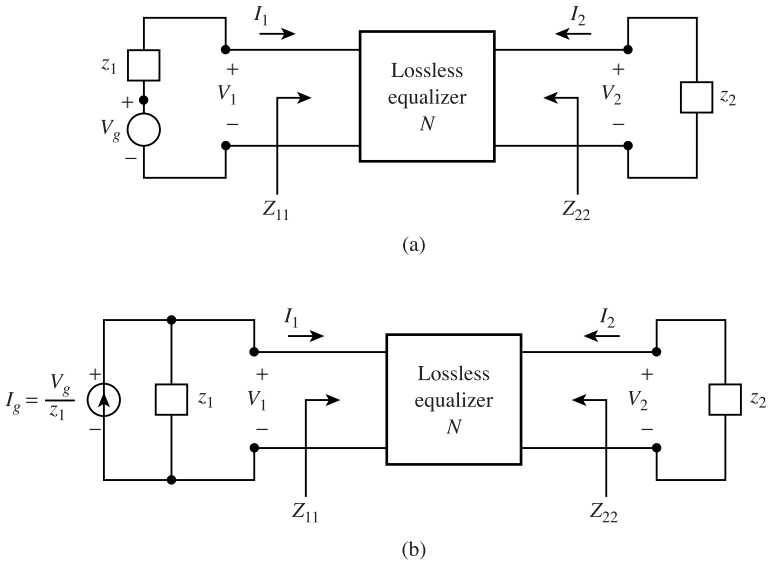

FIGURE 77.1 General broadband matching configuration.

where $\rho_{21}(s)$ is known as the **transmission coefficient**. To prove this, we first compute

$$1-\rho_{11}(s)\rho_{11}(-s)=\frac{4r_1(s)R_{11}(s)}{\left[Z_{11}(s)+z_1(s)\right]\left[Z_{11}(-s)+z_1(-s)\right]} \tag{77.3}$$

where

$$r_1(s)=\text{Ev}\,z_1(s)=\frac{1}{2}\left[z_1(s)+z_1(-s)\right] \tag{77.4a}$$

$$R_{11}(s)=\text{Ev}\,Z_{11}(s)=\frac{1}{2}\left[Z_{11}(s)+Z_{11}(-s)\right] \tag{77.4b}$$

are the even parts of $z_1(s)$ and $Z_{11}(s)$, respectively. Thus, the impedance facing the voltage source V_g is given by

$$\frac{V_g(s)}{I_1(s)}=Z_{11}(s)+z_1(s) \tag{77.5}$$

On the $j\omega$-axis, (77.3) reduces to

$$1-\left|\rho_{11}(j\omega)\right|^2=\frac{4r_1(j\omega)R_{11}(j\omega)}{\left|Z_{11}(j\omega)+z_1(j\omega)\right|^2}=\frac{|I_1(j\omega)|^2\,R_{11}(j\omega)}{|V_g(j\omega)|^2/4r_1(j\omega)} \tag{77.6}$$

The power input to the network of Fig. 77.1(a) under sinusoidal steady state is

$$P_{\text{in}}=\left|I_1(j\omega)\right|^2 R_{11}(j\omega) \tag{77.7}$$

while the power output to the load is

© 2003 by CRC Press LLC

$$P_{\text{out}} = \left|I_2(j\omega)\right|^2 r_2(j\omega) \tag{77.8}$$

where

$$r_2(s) = \text{Ev}\, z_2(s) = \frac{1}{2}\left[z_2(s) + z_2(-s)\right] \tag{77.9}$$

is the even part of $z_2(s)$. Since the two-port N is lossless, the power input must be equal to power output or

$$\left|I_1(j\omega)\right|^2 R_{11}(j\omega) = \left|I_2(j\omega)\right|^2 r_2(j\omega) \tag{77.10}$$

The maximum average power that the source combination is capable of delivering to the network occurs when the input port is conjugately matched or $Z_{11}(j\omega) = \bar{z}_1(j\omega)$. Under this condition, the maximum available average power from the source combination is

$$P_{\text{ava}} = \frac{\left|V_g(j\omega)\right|^2}{4r_1(j\omega)} \tag{77.11}$$

Substituting (77.8) and (77.11) in (77.6) yields

$$1 - \left|\rho_{11}(j\omega)\right|^2 = \frac{\left|I_2(j\omega)\right|^2 r_2(j\omega)}{\left|V_g(j\omega)\right|^2 / 4r_1(j\omega)} = \frac{P_{\text{out}}}{P_{\text{ava}}} = G(\omega^2) \tag{77.12}$$

Using (77.2) shows that

$$\left|\rho_{11}(j\omega)\right|^2 + \left|\rho_{21}(j\omega)\right|^2 = 1 \tag{77.13}$$

or

$$\begin{aligned} \left|\rho_{11}(j\omega)\right|^2 &= 1 - \frac{\text{average power to load}}{\text{average power available}} \\ &= \frac{\text{average power available} - \text{average power to load}}{\text{average power available}} \\ &= \frac{\text{“average reflected” power}}{\text{average power available}} \end{aligned} \tag{77.14}$$

$$\left|\rho_{21}(j\omega)\right|^2 = \frac{\text{average power to load}}{\text{average power available}} \tag{77.15}$$

Therefore, the magnitude squared of the reflection coefficient $|\rho_{11}(j\omega)|^2$ denotes the fraction of the maximum available average power that is reflected back to the source, and the magnitude squared of the transmission coefficient $|\rho_{21}(j\omega)|^2$ represents the fraction of the maximum available average power that is transmitted to the load from the source. In fact, their names are suggested by these interpretations. We remark that since the transducer power gain G is a function of ω^2, it is written as $G(\omega^2)$ to emphasize this.

© 2003 by CRC Press LLC

We next express the transmission coefficient in terms of other specifications. From (77.12), we have

$$\left|\rho_{21}[j\omega]\right|^2 = 4r_1(j\omega)r_2(j\omega)\left|\frac{I_2(j\omega)}{V_g(j\omega)}\right|^2 \tag{77.16}$$

Substituting $V_g(j\omega) = z_1(j\omega)I_g(j\omega)$ in (77.16) gives

$$\left|\rho_{21}(j\omega)\right|^2 = \frac{4r_1(j\omega)\,r_2(j\omega)}{\left|z_1(j\omega)\right|^2}\left|\frac{I_2(j\omega)}{I_g(j\omega)}\right|^2 \tag{77.17}$$

In terms of the transfer voltage ratio and transfer impedance, we apply the relation $V_2(j\omega) = -I_2(j\omega)z_2(j\omega)$ and obtain

$$\left|\rho_{21}(j\omega)\right|^2 = \frac{4r_1(j\omega)\,r_2(j\omega)}{\left|z_2(j\omega)\right|^2}\left|\frac{V_2(j\omega)}{V_g(j\omega)}\right|^2 \tag{77.18}$$

$$\left|\rho_{21}(j\omega)\right|^2 = \frac{4r_1(j\omega)r_2(j\omega)}{\left|z_1(j\omega)z_2(j\omega)\right|^2}\left|\frac{V_2(j\omega)}{I_g(j\omega)}\right|^2 \tag{77.19}$$

Similarly, we can derive a relation between the output reflection coefficient $\rho_{22}(j\omega)$ and the transmission coefficient $\rho_{12}(j\omega)$ magnitude squared as

$$\left|\rho_{12}(j\omega)\right|^2 \equiv 1 - \left|\rho_{22}(j\omega)\right|^2 \tag{77.20}$$

In fact, for the lossless reciprocal two-port network N we have

$$\left|\rho_{21}(j\omega)\right|^2 = \left|\rho_{12}(j\omega)\right|^2 = 1 - \left|\rho_{11}(j\omega)\right|^2 = 1 - \left|\rho_{22}(j\omega)\right|^2 \tag{77.21}$$

77.2 Double-Terminated Butterworth Networks

In this part, we show how to design a lossless two-port network operating between a resistive generator with internal resistance R_1 and a resistive load with resistance R_2 to yield the nth-order Butterworth transducer power-gain characteristic

$$G(\omega^2) = \left|\rho_{21}(j\omega)\right|^2 = \frac{K_n}{1 + (\omega/\omega_c)^{2n}} \tag{77.22}$$

Since for a passive network $G(\omega^2)$ is bounded between 0 and 1, the DC gain K_n is restricted by

$$0 \le K_n \le 1 \tag{77.23}$$

Substituting (77.22) in (77.12) yields the squared magnitude of the input reflection coefficient as

$$\left|\rho_{11}(j\omega)\right|^2 = 1 - G(\omega^2) = 1 - \left|\rho_{21}(j\omega)\right|^2 = \frac{1 - K_n + (\omega/\omega_c)^{2n}}{1 + (\omega/\omega_c)^{2n}} \tag{77.24}$$

© 2003 by CRC Press LLC

or

$$\rho_{11}(j\omega)\,\rho_{11}(-j\omega) = \alpha^{2n}\,\frac{1+\left(\omega/\alpha\omega_c\right)^{2n}}{1+\left(\omega/\omega_c\right)^{2n}} \tag{77.25}$$

where

$$\alpha = \left(1-K_n\right)^{1/2n} \tag{77.26}$$

Appealing to analytic continuation by substituting ω by $-js$ results in

$$\rho_{11}(s)\rho_{11}(-s) = \alpha^{2n}\frac{1+(-1)^n x^{2n}}{1+(-1)^n y^{2n}} \tag{77.27}$$

where

$$y = \frac{s}{\omega_c}, \qquad x = \frac{y}{\alpha} \tag{77.28}$$

To obtain the input reflection coefficient $\rho_{11}(s)$ from $\rho_{11}(s)\,\rho_{11}(-s)$, we need to assign the zeros and poles of (77.27). Since $\rho_{11}(s)$ is devoid of poles in the closed RHS, we must assign all the LHS poles to $\rho_{11}(s)$. The zeros of $\rho_{11}(s)$, however, may lie in the RHS, so that in general a number of different numerators are possible. For our purposes, we choose only the LHS zeros for $\rho_{11}(s)$. Define a **minimum-phase reflection coefficient** to be one that is devoid of zeros in the open RHS. Then, the minimum-phase solution of (77.27) can be written as

$$\rho_{11}(s) = \pm\alpha^n\frac{q(x)}{q(y)} \tag{77.29}$$

where $q(x)$ is the Hurwitz polynomial with unity leading coefficient formed by the LHS roots of the equation $1 + (-1)^n x^{2n} = 0$. From (77.1a), the input impedance is found to be

$$Z_{11}(s) = R_1\frac{1+\rho_{11}(s)}{1-\rho_{11}(s)} \tag{77.30}$$

Combining this with (77.29) yields

$$Z_{11}(s) = R_1\frac{q(y)\pm\alpha^n q(x)}{q(y)\mp\alpha^n q(x)} \tag{77.31}$$

If both R_1 and R_2 are specified, then the DC gain K_n cannot be chosen independently. In fact, by substituting $s = 0$ in (77.31) and assuming that $K_n \neq 0$ we obtain

$$\frac{R_2}{R_1} = \left(\frac{1+\alpha^n}{1-\alpha^n}\right)^{\pm 1} \tag{77.32}$$

where the $\pm$ signs are determined, respectively, according to $R_2 \geq R_1$ and $R_2 \leq R_1$. Therefore, if any two of the three quantities R_1, R_2, and K_n are specified, the third one is fixed.

© 2003 by CRC Press LLC

We now show that the input impedance $Z_{11}(s)$ can be realized by an LC ladder terminated in a resistor. In fact, explicit formulas for their element values will be given, thereby reducing the design problem to simple arithmetic. Depending upon the choice of the plus and minus signs in (77.32), two cases are distinguished.

CASE 1. $\rho_{11}(0) \geq 0$. With the choice of the plus sign, the input impedance becomes

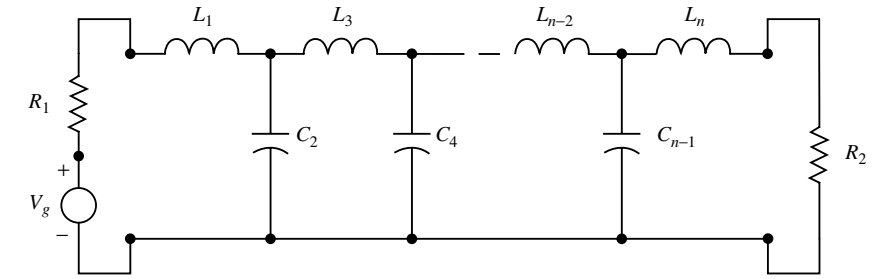
$$Z_{11}(s) = R_1 \frac{q(y) + \alpha^n q(x)}{q(y) - \alpha^n q(x)} \tag{77.33}$$

which can be expanded in a continued fraction about infinity, as in the first Cauer canonical form, and results in an LC ladder terminated in a resistor:

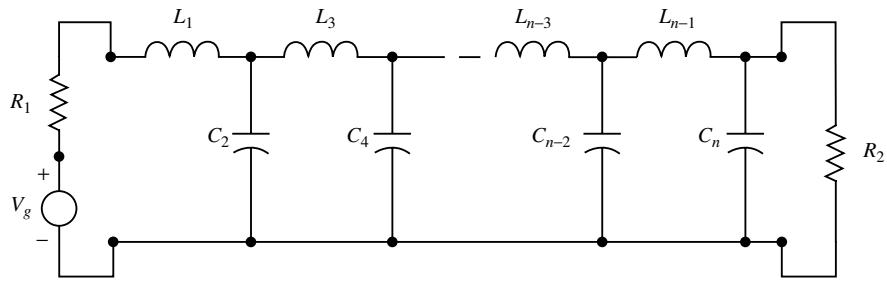
$$Z_{11}(s) = L_1 s + \cfrac{1}{C_2 S + \cfrac{1}{L_3 s + \cfrac{1}{\ddots + \cfrac{1}{W}}}} \tag{77.34}$$

where W is a constant representing either a resistance or conductance. Depending upon whether n is odd or even, the LC ladder has the configuration of Fig. 77.2. The element values can be computed by the following recurrence formulas:

$$L_1 = \frac{2R_1 \sin \pi/2n}{(1-\alpha)\omega_c} \tag{77.35}$$



(a) n odd



(b) n even

FIGURE 77.2 The Butterworth LC ladder networks for $\rho_{11}(0) \geq 0$.

© 2003 by CRC Press LLC

$$L_{2m-1}C_{2m} = \frac{4\sin\gamma_{4m-3}\sin\gamma_{4m-1}}{\omega_c^2\left(1-2\alpha\cos\gamma_{4m-2}+\alpha^2\right)} \tag{77.36a}$$

$$L_{2m+1}C_{2m} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2\left(1-2\alpha\cos\gamma_{4m}+\alpha^2\right)} \tag{77.36b}$$

for $m = 1, 2, \ldots, \lceil n/2 \rceil$, the largest integer not greater than $n/2$; where

$$\gamma_m = \frac{m\pi}{2n} \tag{77.37}$$

The values of the final elements can also be calculated directly by

$$L_n = \frac{2R_2\sin\pi/2n}{(1+\alpha)\omega_c}, \qquad n \text{ odd} \tag{77.38a}$$

$$C_n = \frac{2\sin\pi/2n}{R_2(1+\alpha)\omega_c}, \qquad n \text{ even} \tag{77.38b}$$

A complete derivation of these formulas was first given by Bossé [1]. Hence we can calculate the element values starting from either the first or the last element. When $R_1 = R_2$, formulas (77.36) reduce to

$$L_{2m-1} = \frac{2R_1\sin\gamma_{4m-3}}{\omega_c} \tag{77.39a}$$

$$C_{2m} = \frac{2\sin\gamma_{4m-1}}{R_1\omega_c} \tag{77.39b}$$

Example 1. Given

$$R_1 = 70\ \Omega, \qquad R_2 = 200\ \Omega, \qquad \omega_c = 10^5\ \text{rad/s}, \quad n = 4 \tag{77.40}$$

obtain a Butterworth LC ladder to meet these specifications.

Since $R_2 > R_1$, we choose the plus sign in (77.32) and obtain $\rho_{11}(0) \geq 0, \alpha = 0.833,$ and $\gamma_m = 22.5m$. Thus, from (77.35) and (77.36) the element values are found to be

$$L_1 = \frac{2\times 70\sin 22.5^\circ}{(1-0.833)\times 10^5} = 3.2081\ \text{mH} \tag{77.41a}$$

$$C_2 = \frac{4\sin 22.5^\circ\sin 67.5^\circ}{L_1\left(1.6939-1.666\cos 45^\circ\right)\times 10^{10}} = 0.085456\ \mu\text{F} \tag{77.41b}$$

$$L_3 = \frac{4\sin 67.5^\circ\sin 112.5^\circ}{C_2\left(1.6939-1.666\cos 90^\circ\right)\times 10^{10}} = 2.3587\ \text{mH} \tag{77.41c}$$

$$C_4 = \frac{4\sin 112.5^\circ\sin 157.5^\circ}{L_3\left(1.6939-1.666\cos 135^\circ\right)\times 10^{10}} = 0.020877\ \mu\text{F} \tag{77.41d}$$

© 2003 by CRC Press LLC

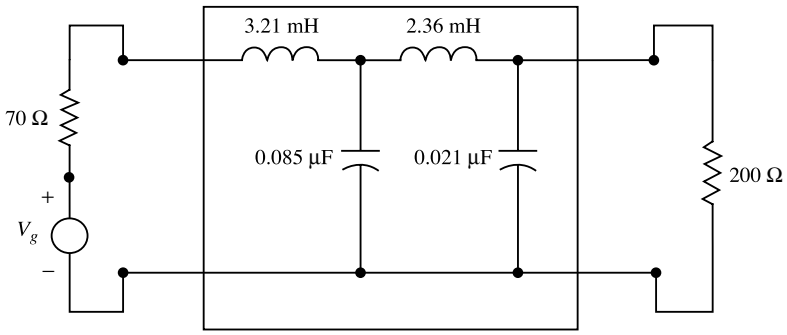


FIGURE 77.3 A fourth-order Butterworth LC ladder network.

Alternatively, C_4 can be computed directly from (77.39b) as

$$C_4 = \frac{2\sin 22.5^\circ}{200\times\left(1+0.833\right)\times 10^5} = 0.020877\ \mu\text{F} \tag{77.42}$$

The ladder network together with its termination is presented in Fig. 77.3. This network possesses the fourth-order Butterworth transducer power-gain response with a DC gain

$$K_4 = 1-\alpha^8 = 0.7682 \tag{77.43}$$

CASE 2. $\rho_{11}(0) < 0$. With the choice of the minus sign, the input impedance can be expanded in a continued fraction as

$$\frac{1}{Z_{11}(s)} = C_1 s + \cfrac{1}{L_2 s + \cfrac{1}{C_3 s + \cfrac{1}{\ddots + \cfrac{1}{W}}}} \tag{77.44}$$

which can be realized by the LC ladder networks of Fig. 77.4, depending on whether W is even or odd, where W is the terminating resistance or conductance. Formulas for the element values are similar to those given in (77.35)–(77.39) except that the roles of C's and L's are interchanged and R_1 and R_2 are replaced by their reciprocals.

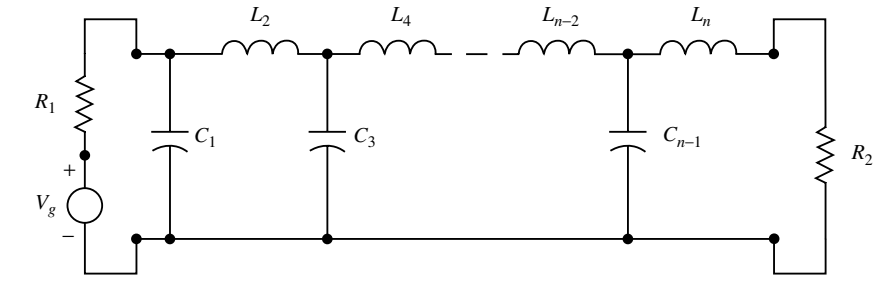
$$C_1 = \frac{2\sin \pi/2n}{R_1(1-\alpha)\omega_c} \tag{77.45a}$$

$$C_{2m-1}L_{2m} = \frac{4\sin\gamma_{4m-3}\sin\gamma_{4m-1}}{\omega_c^2\left(1-2\alpha\cos\gamma_{4m-2}+\alpha^2\right)} \tag{77.45b}$$

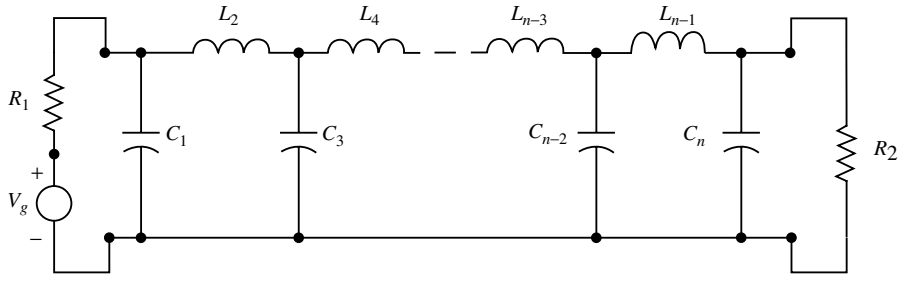
$$C_{2m+1}L_{2m} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2\left(1-2\alpha\cos\gamma_{4m}+\alpha^2\right)} \tag{77.45c}$$

for $m = 1, 2, \ldots, \lceil n/2 \rceil$. The values of the final elements can also be calculated directly by

© 2003 by CRC Press LLC



(a) n even



(b) n odd

FIGURE 77.4 The Butterworth LC ladder networks for $\rho_{11}(0) < 0$.

$$C_n = \frac{2\sin \pi/2n}{R_2(1+\alpha)\omega_c}, \qquad n \text{ odd} \tag{77.46a}$$

$$L_n = \frac{2R_2 \sin \pi/2n}{(1+\alpha)\omega_c}, \qquad n \text{ even} \tag{77.46b}$$

77.3 Double-Terminated Chebyshev Networks

Now, we consider the problem of synthesizing an LC ladder which when connected between a resistive source of internal resistance R_1 and a resistive load of resistance R_2 will yield a preassigned Chebyshev transducer power-gain characteristic

$$G(\omega^2) = |\rho_{21}(j\omega)|^2 = \frac{K_n}{1+\varepsilon^2 C_n^2(\omega/\omega_c)} \tag{77.47}$$

with K_n bounded between 0 and 1. Following (77.24), the squared magnitude of the input reflection coefficient can be written as

$$|\rho_{11}(j\omega)|^2 = 1 - G(\omega^2) = 1 - |\rho_{21}(j\omega)|^2 = \frac{1 - K_n + \varepsilon^2 C_n^2(\omega/\omega_c)}{1+\varepsilon^2 C_n^2(\omega/\omega_c)} \tag{77.48}$$

Appealing to analytic continuation, we obtain

$$\rho_{11}(s)\rho_{11}(-s) = (1-K_n)\,\frac{1+\hat{\varepsilon}^2 C_n^2(-jy)}{1+\varepsilon^2 C_n^2(-jy)} \tag{77.49}$$

© 2003 by CRC Press LLC

where

$$\hat{\varepsilon} = \frac{\varepsilon}{\sqrt{1-K_n}} \tag{77.50}$$

As in the Butterworth case, we assign LHS poles to $\rho_{11}(s)$ and the minimum-phase solution of (77.49) becomes

$$\rho_{11}(s) = \pm\frac{\hat{p}(y)}{p(y)} \tag{77.51}$$

where $p(y)$ and $\hat{p}(y)$ are the Hurwitz polynomials with unity leading coefficient formed by the LHS roots of the equations $1 + \varepsilon^2 C_n^2(-jy) = 0$ and $1 + \hat{\varepsilon}^2 C_n^2(-jy) = 0$, respectively. From (77.1a), the input impedance of the LC ladder when the output port is terminated in R_2 is found to be

$$Z_{11}(s) = R_1\,\frac{p(y) \pm \hat{p}(y)}{p(y) \mp \hat{p}(y)} \tag{77.52}$$

A relationship among the quantities R_1, R_2, and K_n is given by

$$\frac{R_2}{R_1} = \left(\frac{1+\sqrt{1-K_n}}{1-\sqrt{1-K_n}}\right)^{\pm 1}, \qquad n \text{ odd} \tag{77.53a}$$

$$= \left(\frac{\sqrt{1+\varepsilon^2}+\sqrt{1+\varepsilon^2-K_n}}{\sqrt{1+\varepsilon^2}-\sqrt{1+\varepsilon^2-K_n}}\right)^{\pm 1}, \qquad n \text{ even} \tag{77.53b}$$

where the $\pm$ signs are determined, respectively, according to $R_2 \geq R_1$ and $R_2 \leq R_1$. Therefore if n is odd and the DC gain is specified, the ratio of the terminating resistances is fixed by (77.53a). On the other hand, if n is even and the peak-to-peak ripple in the passband and K_n or the DC gain is specified, the ratio of the resistances is given by (77.53b).

We now show that the input impedance $Z_{11}(s)$ can be realized by an LC ladder terminated in a resistor. Again, explicit formulas for their element values will be given, thereby reducing the design problem to simple arithmetic. Depending upon the choice of the plus and minus signs in (77.51), two cases are distinguished.

CASE 1. $\rho_{11}(0) \geq 0$. With the choice of the plus sign, the input impedance becomes

$$Z_{11}(s) = R_1\,\frac{p(y) + \hat{p}(y)}{p(y) - \hat{p}(y)} \tag{77.54}$$

which can be expanded in a continued fraction as in (77.34). Depending on whether n is odd or even, the corresponding LC ladder network has the configurations of Fig. 77.2. The element values can be computed by the following recurrence formulas:

$$L_1 = \frac{2R_1 \sin \pi/2n}{\left(\sinh a - \sinh \hat{a}\right)\dot{\omega}_c} \tag{77.55}$$

$$L_{2m-1}C_{2m} = \frac{4 \sin \gamma_{4m-3} \sin \gamma_{4m-1}}{\omega_c^2 f_{2m-1}\left(\sinh a, \sinh \hat{a}\right)} \tag{77.56a}$$

© 2003 by CRC Press LLC

$$L_{2m+1}C_{2m} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2 f_{2m}(\sinh a, \sinh \hat{a})} \tag{77.56b}$$

for $m = 1, 2, \ldots, \lceil n/2 \rceil$, where

$$\gamma_m = \frac{m\pi}{2n} \tag{77.57a}$$

$$\hat{a} = \frac{1}{n}\sinh^{-1}\left(\frac{\sqrt{1-K_n}}{\varepsilon}\right) \tag{77.57b}$$

$$f_m(u, v) = u^2 + v^2 + \sin^2\gamma_{2m} - 2uv\cos\gamma_{2m} \tag{77.57c}$$

In addition, the values of the last elements can also be computed directly by the equations

$$L_n = \frac{2R_2\sin\pi/2n}{(\sinh a + \sinh\hat{a})\omega_c}, \qquad n \text{ odd} \tag{77.58a}$$

$$C_n = \frac{2\sin\pi/2n}{R_2(\sinh a + \sinh\hat{a})\omega_c}, \qquad n \text{ even} \tag{77.58b}$$

A formal proof of these formulas was first given by Takahasi [13]. Hence, we can calculate the element values starting from either the first or the last element.

Example 2. Given

$$R_1 = 150\,\Omega, \qquad R_2 = 470\,\Omega, \qquad \omega_c = 10^8\pi \text{ rad/s}, \qquad n = 4 \tag{77.59}$$

find a Chebyshev LC ladder network to meet these specifications with peak-to-peak ripple in the passband not exceeding 1.5 dB.

Since R_1 and R_2 are both specified, the minimum passband gain $G_{\min}$ is fixed by (77.53b) as

$$G_{\min} \equiv \frac{K_n}{1+\varepsilon^2} = 1 - \left(\frac{\frac{470}{150}-1}{\frac{470}{150}+1}\right)^2 = 0.7336 \tag{77.60}$$

For the 1.5-dB ripple in the passband, the corresponding ripple factor is given by

$$\varepsilon = \sqrt{10^{0.15}-1} = 0.64229 \tag{77.61}$$

obtaining $K_4 = 1.036$, which is too large for the network to be physically realizable. Thus, let $K_4 = 1$, the maximum permissible value, and the corresponding ripple factor becomes

$$\varepsilon = \sqrt{\frac{1}{G_{\min}}-1} = \sqrt{\frac{1}{0.7336}-1} = 0.6026 \text{ or } 1.345 \text{ dB} \le 1.5 \text{ dB} \tag{77.62}$$

We next compute the quantities

$$\gamma_m = \frac{m\pi}{2n} = 22.5m \tag{77.63a}$$

© 2003 by CRC Press LLC

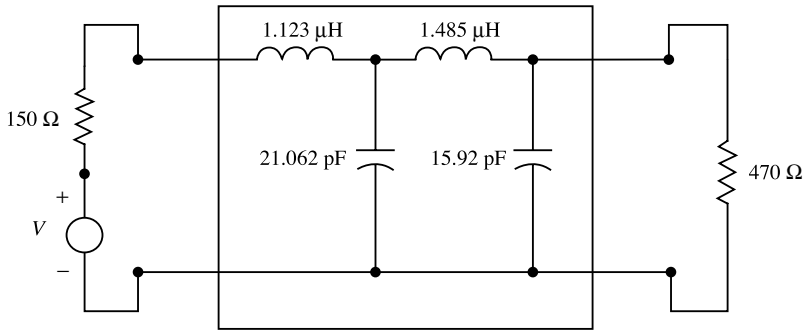


FIGURE 77.5 A fourth-order Chebyshev LC ladder network for $\rho_{11}(0) \geq 0$.

$$a = \frac{1}{4}\sinh^{-1}\frac{1}{0.6026} = 0.32, \quad \hat{a} = 0 \tag{77.63b}$$

$$f_m(\sinh\ 0.32, 0) = \sinh^2 0.32 + \sin^2 \gamma_{2m} = 0.1059 + \sin^2 \gamma_{2m} \tag{77.63c}$$

Appealing to formulas (77.55) and (77.56), the element values are calculated as follows:

$$L_1 = \frac{2 \times 150\ \sin 22.5^\circ}{(\sinh\ 0.32 - \sinh\ 0) \times 10^8 \pi} = 1.123\ \mu\text{H} \tag{77.64a}$$

$$C_2 = \frac{4 \sin 22.5^\circ \sin 67.5^\circ}{L_1 10^{16} \pi^2 (\sinh^2 0.32 + \sin^2 45^\circ)} = 21.062\ \text{pF} \tag{77.64b}$$

$$L_3 = \frac{4 \sin 67.5^\circ \sin 112.5^\circ}{C_2 10^{16} \pi^2 (\sinh^2 0.32 + \sin^2 90^\circ)} = 1.485\ \mu\text{H} \tag{77.64c}$$

$$C_4 = \frac{4 \sin 112.5^\circ \sin 157.5^\circ}{L_3 10^{16} \pi^2 (\sinh^2 0.32 + \sin^2 135^\circ)} = 15.924\ \text{pF} \tag{77.64d}$$

Alternatively, the last capacitance can also be computed directly from (77.58b) as

$$C_4 = \frac{2 \sin\ 22.5^\circ}{470 \times (\sinh\ 0.32 + \sinh\ 0) \times 10^8 \pi} = 15.925\ \text{pF} \tag{77.65}$$

The LC ladder together with its terminations is presented in Fig. 77.5.

CASE 2. $\rho_{11}(0) < 0$. With the choice of the minus sign in (77.51), the input impedance, aside from the constant R_1, becomes the reciprocal of (77.54)

$$Z_{11}(s) = R_1 \frac{p(y) - \hat{p}(y)}{p(y) + \hat{p}(y)} \tag{77.66}$$

and can be expanded in a continued fraction as that shown in (77.44). Depending on whether n is even or odd, the LC ladder network has the configurations of Fig. 77.4. Formulas for the element

© 2003 by CRC Press LLC

values are similar to those given in (77.55)–(77.58) except that the roles of C's and L's are interchanged and R_1 and R_2 are replaced by their reciprocals:

$$C_1 = \frac{2\sin\pi/2n}{R_1\left(\sinh a - \sinh\hat{a}\right)\omega_c} \tag{77.67a}$$

$$C_{2m-1}L_{2m} = \frac{4\sin\gamma_{4m-3}\sin\gamma_{4m-1}}{\omega_c^2 f_{2m-1}\left(\sinh a, \sinh\hat{a}\right)} \tag{77.67b}$$

$$C_{2m+1}L_{2m} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2 f_{2m}\left(\sinh a, \sinh\hat{a}\right)} \tag{77.67c}$$

for $m = 1, 2, \ldots, \lceil n/2 \rceil$, where γ_m and $f_m(\sinh a, \sinh\hat{a})$ are defined in (77.57). In addition, the values of the last elements can also be computed directly by the formulas

$$C_n = \frac{2\sin\pi/2n}{R_2\left(\sinh a + \sinh\hat{a}\right)\omega_c}, \quad n \text{ odd} \tag{77.68a}$$

$$L_n = \frac{2R_2\sin\pi/2n}{\left(\sinh a + \sinh\hat{a}\right)\omega_c}, \quad n \text{ even} \tag{77.68b}$$

Design of Broadband Matching Networks[1]

78.1 Introduction
78.2 Basic Coefficients Constraints
78.3 Design Procedure
78.4 Explicit Formulas for the RLC Load
Butterworth Networks • Chebyshev Networks

Wai-Kai Chen
University of Illinois, Chicago

78.1 Introduction

Refer to the network configuration of Fig. 78.1 where the source is represented either by its Thévenin equivalent or by its Norton equivalent. The load impedance $z_2(s)$ is assumed to be strictly passive over a frequency band of interest, because the matching problem cannot be meaningfully defined if the load is purely reactive. Our objective is to design an "optimum" lossless two-port network or equalizer N to match out the load impedance $z_2(s)$ to the resistive source impedance $z_1(s) = R_1$, and to achieve a preassigned transducer power-gain characteristic $G(\omega^2)$ over the entire sinusoidal frequency spectrum.

As stated in Chapter 77, the output reflection coefficient is given by

$$\rho_{22}(s) = \frac{Z_{22}(s) - z_2(-s)}{Z_{22}(s) + z_2(s)} \tag{78.1}$$

where $Z_{22}(s)$ is the impedance looking into the output port when the input port is terminated in the source resistance R_1. As shown in Chapter 77, the transducer power gain $G(\omega^2)$ is related to the transmission and reflection coefficients by the equation

$$G(\omega^2) = |\rho_{21}(j\omega)|^2 = |\rho_{12}(j\omega)|^2 = 1 - |\rho_{11}(j\omega)|^2 = 1 - |\rho_{22}(j\omega)|^2 \tag{78.2}$$

Recall that in computing $\rho_{11}(s)$ from $\rho_{11}(s)\rho_{11}(-s)$ we assign all of the LHS poles of $\rho_{11}(s)\rho_{11}(-s)$ to $\rho_{11}(s)$ because with resistive load $z_2(s) = R_2$, $\rho_{11}(s)$ is devoid of poles in the RHS. For the complex load, the poles of $\rho_{22}(s)$ include those of $z_2(-s)$, which may lie in the open RHS. As a result, the assignment of poles of $\rho_{22}(s)\rho_{22}(-s)$ is not unique. Furthermore, the nonanalyticity of $\rho_{22}(s)$ leaves much to be desired in terms of our ability to manipulate. For these reasons, we consider the normalized reflection coefficient defined by

[1]References for this Chapter can be found on page 2421.

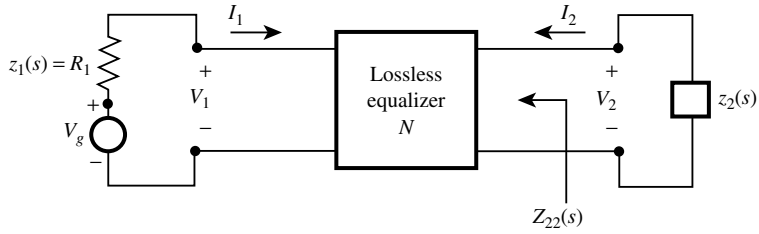

FIGURE 78.1 The schematic of broadband matching.

$$\rho(s) = A(s)\rho_{22}(s) = A(s)\frac{Z_{22}(s) - z_2(-s)}{Z_{22}(s) + z_2(s)} \tag{78.3}$$

where

$$A(s) = \prod_{i=1}^{q} \frac{s - s_i}{s + s_i}, \quad \text{Re } s_i > 0 \tag{78.4}$$

is the real all-pass function defined by the open RHS poles s_i (i = 1, 2, …, q) of $z_2(-s)$. An **all-pass function** is a function whose zeros are all located in the open RHS and whose poles are located at the LHS mirror image of the zeros. Therefore, it is analytic in the closed RHS and such that

$$A(s)A(-s) = 1 \tag{78.5}$$

On the $j\omega$-axis, the magnitude of $A(j\omega)$ is unity, being flat for all sinusoidal frequencies, and we have

$$|\rho(j\omega)| = |A(j\omega)\rho_{22}(j\omega)| = |\rho_{22}(j\omega)| \tag{78.6}$$

and (78.2) becomes

$$G(\omega^2) = 1 - |\rho(j\omega)|^2 \tag{78.7}$$

This equation together with the normalized reflection coefficient $\rho(s)$ of (78.3) forms the cornerstone of Youla's theory of broadband matching [14].

78.2 Basic Coefficient Constraints

In Chapter 76, we define the zeros of transmission for a terminate two-port network as the frequencies at which a zero output results for a finite input. We extend this concept by defining the zeros of transmission for a one-port impedance.

Definition 1. *Zero of transmission.* For a given impedance $z_2(s)$, a closed RHS zero of multiplicity k of the function

$$w(s) \equiv \frac{r_2(s)}{z_2(s)} \tag{78.8}$$

where $r_2(s)$ is the even part of $z_2(s)$, is called a **zero of transmission** of order k of $z_2(s)$.

© 2003 by CRC Press LLC

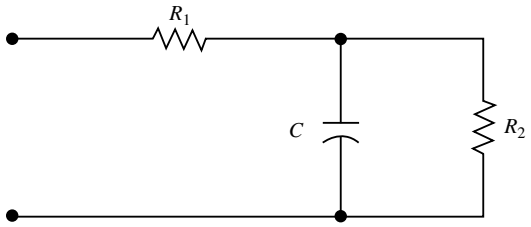

FIGURE 78.2 An RC one-port network.

The reason for this name is that if we realize the impedance $z_2(s)$ as the input impedance of a lossless two-port network terminated in a 1-Ω resistor, the magnitude squared of the transfer impedance function $Z_{12}(j\omega)$ between the 1-Ω resistor and the input equals the real part of the input impedance,

$$\left|Z_{12}(j\omega)\right|^2 = \mathrm{Re}\, z_2(j\omega) = r_2(j\omega) \tag{78.9}$$

After appealing to analytic continuation by substituting ω by $-js$, the zeros of $r_2(s)$ are seen to be the zeros of transmission of the lossless two-port.

Consider, for example, the RC impedance $z_2(s)$ of Fig. 78.2,

$$z_2(s) = R_1 + \frac{R_2}{R_2Cs+1} \tag{78.10}$$

the even part of which is given by

$$r_2(s) = \frac{1}{2}\left[z_2(s) + z_2(-s)\right] = \frac{R_1 + R_2 - R_1R_2^2C^2s^2}{1 - R_2^2C^2s^2} \tag{78.11}$$

obtaining

$$w(s) = \frac{r_2(s)}{z_2(s)} = \frac{R_2Cs^2 - \left(R_1+R_2\right)/R_1R_2C}{\left(R_2Cs-1\right)\left[s + \left(R_1+R_2\right)/R_1R_2C\right]} \tag{78.12}$$

Thus, the impedance $z_2(s)$ has a zero of transmission of order 1 located at

$$s = \sigma_0 = \frac{1}{R_2C}\sqrt{1+\frac{R_2}{R_1}} \tag{78.13}$$

For our purposes, the zeros of transmission are divided into four mutually exclusive classes.

Definition 2. *Classification of zeros of transmission.* Let $s_0 = \sigma_0 + j\omega_0$ be a zero of transmission of an impedance $z_2(s)$. Then s_0 belongs to one of the following four mutually exclusive classes depending on σ_0 and $z_2(s_0)$, as follows:

Class I: $\sigma_0 > 0$, which includes all the open RHS zeros of transmission.
Class II: $\sigma_0 = 0$ and $z_2(\omega_0) = 0$.
Class III: $\sigma_0 = 0$ and $0 < |z_2(j\omega_0)| < \infty$.
Class IV: $\sigma_0 = 0$ and $|z_2(j\omega_0)| = \infty$.

For the impedance $z_2(s)$ of (78.10), its zero of transmission given in (78.13) belongs to Class I of order 1. If $z_2(s)$ is the load of the network of Fig. 78.1, it imposes the basic constraints on the normalized reflection coefficient $\rho(s)$. These constraints are important in that they are necessary and

© 2003 by CRC Press LLC

sufficient for $\rho(s)$ to be physically realizable, and are most conveniently formulated in terms of the coefficients of the Laurent series expansions of the following quantities about a zero of transmission $s_0 = \sigma_0 + j\omega_0$ of order k of $z_2(s)$:

$$\rho(s) = \rho_0 + \rho_1(s - s_0) + \rho_2(s - s_0)^2 + \cdots = \sum_{m=0}^{\infty} \rho_m (s - s_0)^m \tag{78.14a}$$

$$A(s) = A_0 + A_1(s - s_0) + A_2(s - s_0)^2 + \cdots = \sum_{m=0}^{\infty} A_m (s - s_0)^m \tag{78.14b}$$

$$F(s) \equiv 2r_2(s)A(s) = F_0 + F_1(s - s_0) + F_2(s - s_0)^2 + \cdots = \sum_{m=0}^{\infty} F_m (s - s_0)^m \tag{78.14c}$$

We remark that the expansions of the Laurent type can be found by any method because it is unique, and the resulting expansion is *the* Laurent series expansion. For the zero of transmission at infinity, the expansions take the form

$$\rho(s) = \rho_0 + \frac{\rho_1}{s} + \frac{\rho_2}{s^2} + \frac{\rho_3}{s^3} + \cdots = \sum_{m=0}^{\infty} \frac{\rho_m}{s^m} \tag{78.15a}$$

$$A(s) = A_0 + \frac{A_1}{s} + \frac{A_2}{s^2} + \frac{A_3}{s^3} + \cdots = \sum_{m=0}^{\infty} \frac{A_m}{s^m} \tag{78.15b}$$

$$F(s) = F_0 + \frac{F_1}{s} + \frac{F_2}{s^2} + \frac{F_3}{s^3} + \cdots = \sum_{m=0}^{\infty} \frac{F_m}{s^m} \tag{78.15c}$$

In fact, they can be obtained by means of the binomial expansion formula

$$(s + c)^n = s^n + ns^{n-1}c + \frac{n(n-1)}{2!} s^{n-2}c^2 + \cdots \tag{78.16}$$

which is valid for all values of n if $|s| > |c|$, and is valid only for nonnegative integers n if $|s| \le |c|$.

Example 1. Assume that the network of Fig. 78.1 is terminated in the passive impedance

$$z_2(s) = \frac{s}{s^2 + 2s + 1} \tag{78.17}$$

and possesses the transducer power-gain characteristic

$$G(\omega^2) = \frac{K\omega^2}{\omega^4 - \omega^2 + 1}, \qquad 0 \le K \le 1 \tag{78.18}$$

We first compute the even part

$$r_2(s) = \frac{1}{2}\left[z_2(s) + z_2(-s)\right] = \frac{-2s^2}{(s^2 + 2s + 1)(s^2 - 2s + 1)} \tag{78.19}$$

© 2003 by CRC Press LLC

of $z_2(s)$, and obtain the function

$$w(s) = \frac{r_2(s)}{z_2(s)} = \frac{-2s}{s^2 - 2s + 1} \tag{78.20}$$

showing that $z_2(s)$ possesses two Class II zeros of transmission at $s = 0$ and ∞. Since the pole of $z_2(-s)$ is located at $s = 1$ of order 2, the all-pass function $A(s)$ takes the form

$$A(s) = \frac{s^2 - 2s + 1}{s^2 + 2s + 1} \tag{78.21}$$

The other required functions are found to be

$$F(s) = 2A(s)r_2(s) = -\frac{4s^2}{(s^2 + 2s + 1)^2} \tag{78.22}$$

$$\rho(s)\rho(-s) = 1 - G(-s^2) = \frac{s^4 + (1+K)s^2 + 1}{s^4 + s^2 + 1} \tag{78.23}$$

The minimum-phase solution of (78.23) is determined as

$$\pm\hat{\rho}(s) = \frac{s^2 + \sqrt{1-K}\,s + 1}{s^2 + s + 1} \tag{78.24}$$

Now, we expand the functions $A(s)$, $F(s)$ and $\hat{\rho}(s)$ in Laurent series about the zeros of transmission at the origin and at infinity, and obtain

$$A(s) = 1 - 4s + \cdots = 1 - \frac{4}{s} + \cdots \tag{78.25}$$

$$F(s) = 0 + 0 - 4s^2 + \cdots = 0 + 0 - \frac{4}{s^2} + \cdots \tag{78.26}$$

$$\pm\hat{\rho}(s) = 1 + \left(\sqrt{1-K} - 1\right)s + \cdots = 1 + \frac{\sqrt{1-K} - 1}{s} + \cdots \tag{78.27}$$

In both expansions, we can make the following identifications:

$$A_0 = 1, \qquad F_0 = 0, \qquad \rho_0 = 1 \tag{78.28a}$$

$$A_1 = -4, \qquad F_1 = 0, \qquad \rho_1 = \sqrt{1-K} - 1 \tag{78.28b}$$

$$F_2 = -4 \tag{78.28c}$$

Basic Coefficient Constraints on $\rho(s)$

The basic constraints imposed on the normalized reflection coefficient $\rho(s)$ by a load impedance $z_2(s)$ are most succinctly expressed in terms of the coefficients of the Laurent series expansions (78.14) of the functions $\rho(s)$, $A(s)$, and $F(s)$ about each zero of transmission $s_0 = \sigma_0 + j\omega_0$. Depending on the classification of the zero of transmission, one of the following four sets of coefficient conditions must be satisfied:

© 2003 by CRC Press LLC

Class I: For $x = 0, 1, 2, \ldots, k-1$

$$A_x = \rho_x \tag{78.29a}$$

Class II: $A_x = \rho_x$ for $x = 0, 1, 2, \ldots, k-1$, and

$$\frac{A_k - \rho_k}{F_{k+1}} \geq 0 \tag{78.29b}$$

Class III: $A_x = \rho_x$ for $x = 0, 1, 2, \ldots, k-2$, $k \geq 2$, and

$$\frac{A_{k-1} - \rho_{k-1}}{F_k} \geq 0 \tag{78.29c}$$

Class IV: $A_x = \rho_x$ for $x = 0, 1, 2, \ldots, k-1$, and

$$\frac{F_{k-1}}{A_k - \rho_k} \geq a_{-1}, \quad \begin{array}{l}\text{the residue of } z_2(s) \text{ evaluated} \\ \text{at the pole } s = j\omega_0\end{array} \tag{78.29d}$$

To determine the normalized reflection coefficient $\rho(s)$ from a preassigned transducer power-gain characteristic $G(\omega^2)$, we appeal to (78.7) and analytic continuation by replacing ω by $-js$ and obtain

$$\rho(s)\rho(-s) = 1 - G(-s^2) \tag{78.30}$$

Since the zeros and poles of $\rho(s)\rho(-s)$ must appear in quadrantal symmetry, being symmetric with respect to both the real and imaginary axes of the s-plane, and since $\rho(s)$ is analytic in the closed RHS, the open LHS poles of $\rho(s)\rho(-s)$ belong to $\rho(s)$ whereas those in the open RHS belong to $\rho(-s)$. For a lumped system, $\rho(s)$ is devoid of poles on the $j\omega$-axis. For the zeros, no unique ways are available to assign them. The only requirement is that the complex-conjugate pair of zeros must be assigned together. However, if we specify that $\rho(s)$ be made a minimum-phase function, then all the open LHS zeros of $\rho(s)\rho(-s)$ are assigned to $\rho(s)$. The $j\omega$-axis zeros of $\rho(s)\rho(-s)$ are of even multiplicity, and thus they are divided equally between $\rho(s)$ and $\rho(-s)$. Therefore, $\rho(s)$ is uniquely determined by the zeros and poles of $\rho(s)\rho(-s)$ only if $\rho(s)$ is required to be minimum-phase.

Let $\hat{\rho}(s)$ be the minimum-phase solution of (78.30). Then, any solution of the form

$$\rho(s) = \pm\eta(s)\hat{\rho}(s) \tag{78.31}$$

is admissible, where $\eta(s)$ is an arbitrary real all-pass function possessing the property that

$$\eta(s)\eta(-s) = 1 \tag{78.32}$$

The significance of these coefficient constraints is that they are both necessary and sufficient for the physical realizability of $\rho(s)$, and is summarized in the following theorem. The proof of this result can be found in [5].

Theorem 1: *Given a strictly passive impedance $z_2(s)$, the function defined by the equation*

$$Z_{22}(s) \equiv \frac{F(s)}{A(s) - \rho(s)} - z_2(s) \tag{78.33}$$

is positive real if and only if $|\rho(j\omega)| \leq 1$ for all ω and the coefficient conditions (78.29) are satisfied.

© 2003 by CRC Press LLC

The function $Z_{22}(s)$ defined in (78.33) is actually the back-end impedance of a desired equalizer. To see this, we solve for $Z_{22}(s)$ in (78.3) and obtain

$$Z_{22}(s) = \frac{A(s)\left[z_2(s) + z_2(-s)\right]}{A(s) - \rho(s)} - z_2(s) = \frac{F(s)}{A(s) - \rho(s)} - z_2(s) \tag{78.34}$$

which is guaranteed to be positive real by Theorem 1. This impedance can be realized as the input impedance of a lossless two-port network terminated in a resistor. The removal of this resistor gives the desired matching network. An ideal transformer may be needed at the input port to compensate for the actual level of the generator resistance R_1.

Example 2. Design a lossless matching network to equalize the load impedance

$$z_2(s) = \frac{s}{s^2 + 2s + 1} \tag{78.35}$$

to a resistive generator of internal resistance of 0.5 Ω and to achieve the transducer power-gain characteristic

$$G(\omega^2) = \frac{K\omega^2}{\omega^4 - \omega^2 + 1}, \qquad 0 \le K \le 1 \tag{78.36}$$

From Example 1, the load possesses two Class II zeros of transmission of order 1 at $s = 0$ and $s = \infty$. The coefficients of the Laurent series expansions of the functions $A(s)$, $F(s)$, and $\rho(s)$ about the zeros of transmission at $s = 0$ and $s = \infty$ were computed in Example 1 as

$$A_0 = 1, \quad F_0 = 0, \quad \rho_0 = 1 \tag{78.37a}$$

$$A_1 = -4, \quad F_1 = 0, \quad \rho_1 = \sqrt{1 - K} - 1 \tag{78.37b}$$

$$F_2 = -4 \tag{78.37c}$$

The coefficient constraints (78.29b) for the Class II zeros of transmission of order 1 become

$$A_0 = \rho_0, \qquad \frac{A_1 - \rho_1}{F_2} \ge 0 \tag{78.38}$$

Clearly, the first condition is always satisfied. To meet the second requirement, we set

$$\frac{-4 - \left(\sqrt{1 - K} - 1\right)}{-4} \ge 0 \tag{78.39}$$

or $0 \le K \le 1$, showing that the maximum realizable K is 1. For our purposes, set $K = 1$ and choose the plus sign in (78.24). From (78.34), the equalizer back-end impedance is computed as

$$\begin{aligned} Z_{22}(s) = \frac{F(s)}{A(s) - \hat{\rho}(s)} - z_2(s) &= \frac{\dfrac{-4s^2}{\left(s^2 + 2s + 1\right)^2}}{\dfrac{s^2 - 2s + 1}{s^2 + 2s + 1} - \dfrac{s^2 + 1}{s^2 + s + 1}} - \frac{s}{s^2 + 2s + 1} \\ &= \frac{s}{3s^2 + 2s + 3} \end{aligned} \tag{78.40}$$

© 2003 by CRC Press LLC

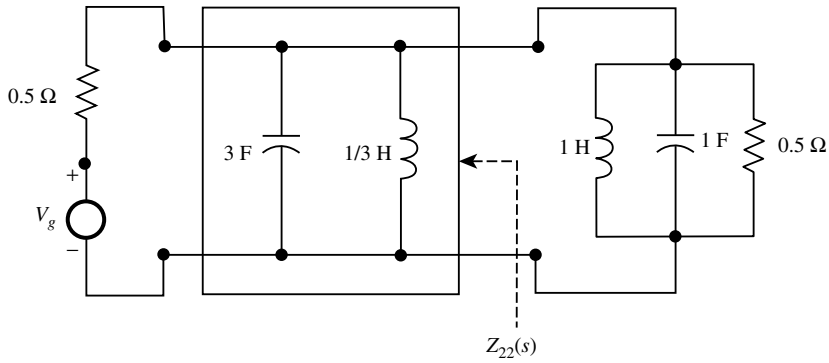

FIGURE 78.3 An equalizer having transducer power-gain characteristics (78.36).

This impedance can be realized as the input impedance of the parallel connection of an inductor $L = 1/3$ H, a capacitor $C = 3$F, and a resistor $R = 0.5$ Ω. The resulting equalizer together with the load is presented in Fig. 78.3.

78.3 Design Procedure

We now outline an eight-step procedure for the design of an optimum lossless matching network that equalizes a frequency-dependent load impedance $z_2(s)$ to a resistive generator of internal resistance R_1 and achieves a preassigned transducer power-gain characteristic $G(\omega^2)$ over the entire sinusoidal frequency spectrum.

STEP 1. From a preassigned transducer power-gain characteristic $G(\omega^2)$, verify that $G(\omega^2)$ is an even rational real function and satisfies the inequality

$$0 \le G\left(\omega^2\right) \le 1 \quad \text{for all } \omega \tag{78.41}$$

The gain level is usually not specified to allow some flexibility.

STEP 2. From a prescribed strictly passive load impedance $z_2(s)$, compute

$$r_2(s) \equiv \text{Ev}\, z_2(s) = \frac{1}{2}\left[z_2(s) + z_2(-s)\right] \tag{78.42}$$

$$A(s) = \prod_{i=1}^{q} \frac{s - s_i}{s + s_i}, \quad \text{Re}\, s_i > 0 \tag{78.43}$$

where s_i $(i = 1, 2, \ldots, q)$ are the open RHS poles of $z_2(-s)$, and

$$F(s) = 2A(s)r_2(s) \tag{78.44}$$

STEP 3. Determine the locations and the orders of the zeros of transmission of $z_2(s)$, which are defined as the closed RHS zeros of the function

$$w(s) = \frac{r_2(s)}{z_2(s)} \tag{78.45}$$

and divide them into respective classes according to Definition 2.

© 2003 by CRC Press LLC

STEP 4. Perform the unique factorization of the function

$$\hat{\rho}(s)\hat{\rho}(-s) = 1 - G(-s^2) \tag{78.46}$$

in which the numerator of the minimum-phase solution $\hat{\rho}(s)$ is a Hurwitz polynomial and the denominator $\hat{\rho}(s)$ is a strictly Hurwitz polynomial.

STEP 5. Obtain the Laurent series expansions of the functions $A(s)$, $F(s)$, and $\hat{\rho}(s)$ about each zero of transmission s_0 of $z_2(s)$, as follows:

$$A(s) = \sum_{m=0}^{\infty} A_m (s - s_0)^m \tag{78.47a}$$

$$F(s) = \sum_{m=0}^{\infty} F_m (s - s_0)^m \tag{78.47b}$$

$$\hat{\rho}(s) = \sum_{m=0}^{\infty} \rho_m (s - s_0)^m \tag{78.47c}$$

They may be obtained by any available methods.

STEP 6. According to the classes of zeros of transmission, list the basic constraints (78.29) imposed on the coefficients of (78.47). The gain level is ascertained from these constraints. If not all the constraints are satisfied, consider the more general solution

$$\rho(s) = \pm\eta(s)\hat{\rho}(s) \tag{78.48}$$

where $\eta(s)$ is an arbitrary real all-pass function. Then repeat Step 5 for $\rho(s)$, starting with lower-order $\eta(s)$. If the constraints still cannot be satisfied, modify the preassigned transducer power-gain characteristics $G(\omega^2)$. Otherwise, no match exists.

STEP 7. Having successfully carried out Step 6, the equalizer back-end impedance is determined by the equation

$$Z_{22}(s) \equiv \frac{F(s)}{A(s) - \rho(s)} - z_2(s) \tag{78.49}$$

where $\rho(s)$ may be $\hat{\rho}(s)$ and $Z_{22}(s)$ is guaranteed to be positive real.

STEP 8. Realize $Z_{22}(s)$ as the input impedance of a lossless two-port network terminated in a resistor. An ideal transformer may be required at the input port to compensate for the actual level of the generator resistance R_1. This completes the design of an equalizer.

Example 3. Design a lossless matching network to equalize the RLC load as shown in Fig. 78.4 to a resistive generator and to achieve the fifth-order Butterworth transducer power-gain characteristic with a maximal DC gain. The cut-off frequency is 10^8 rad/s.

To simplify the computation, we magnitude-scale the network by a factor of 10^{-2} and frequency-scale it by a factor of 10^{-8}. Thus, s denotes the normalized complex frequency and ω the normalized real frequency. The load impedance becomes

© 2003 by CRC Press LLC

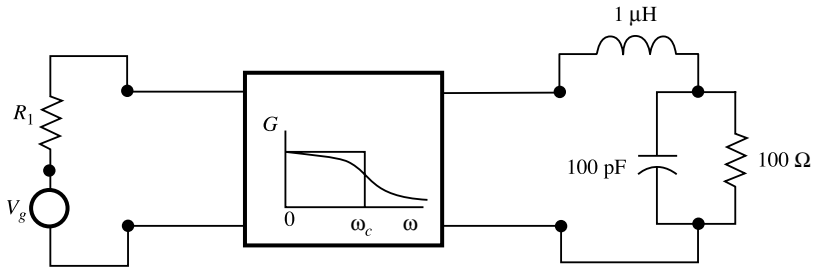

FIGURE 78.4 The broadband matching of an RLC load to a resistive generator.

$$z_2(s) = \frac{s^2 + s + 1}{s + 1} \tag{78.50}$$

We now follow the eight steps outlined above to design a lossless equalizer to meet the desired specifications.

STEP 1. The fifth-order Butterworth transducer power-gain characteristic is given by

$$G(\omega^2) = \frac{K_5}{1 + \omega^{10}}, \quad 0 \le K_5 \le 1 \tag{78.51}$$

Our objective is to maximize the DC gain K_5.

STEP 2. From the load impedance $z_2(s)$, we compute the functions

$$r_2(s) = \frac{1}{2}\left[z_2(s) + z_2(-s)\right] = \frac{1}{1 - s^2} \tag{78.52}$$

$$A(s) = \frac{s - 1}{s + 1} \tag{78.53}$$

where $s = 1$ is the open RHS pole of $z_2(-s)$, and

$$F(s) = 2A(s)r_2(s) = \frac{-2}{(s+1)^2} \tag{78.54}$$

STEP 3. The zeros of transmission $z_2(s)$ are defined by the closed RHS zero of the function.

$$w(s) = \frac{r_2(s)}{z_2(s)} = \frac{1}{(s^2 + s + 1)(1 - s)} \tag{78.55}$$

indicating that $s = \infty$ is a Class IV zero of transmission of order 3.

STEP 4. Substituting (78.51) in (78.46) with $-js$ replacing ω gives

$$\rho(s)\rho(-s) = 1 - G(-s^2) = 1 - \frac{K_5}{1 - s^{10}} = \alpha^{10}\frac{1 - x^{10}}{1 - s^{10}} \tag{78.56}$$

where

© 2003 by CRC Press LLC

$$\alpha = \left(1 - K_5\right)^{1/10}, \qquad x = \frac{s}{\alpha} \tag{78.57}$$

The minimum-phase solution of (78.56) is found to be

$$\hat{\rho}(s) = \frac{s^5 + 3.23607\alpha s^4 + 5.23607\alpha^2 s^3 + 5.23607\alpha^3 s^2 + 3.23607\alpha^4 s + \alpha^5}{s^5 + 3.23607 s^4 + 5.23607 s^3 + 5.23607 s^2 + 3.23607 s + 1} \tag{78.58}$$

The maximum attainable DC gain will be ascertained later from the coefficient conditions.

STEP 5. The Laurent series expansions of the functions $A(s)$, $F(s)$, and $\hat{\rho}(s)$ about the zero of transmission $s_0 = \infty$ of $z_2(s)$ are obtained as follows:

$$A(s) = \frac{s-1}{s+1} = 1 - \frac{2}{s} + \frac{2}{s^2} - \frac{2}{s^3} + \cdots \tag{78.59a}$$

$$F(s) = \frac{-2}{(s+1)^2} = 0 + 0 - \frac{2}{s^2} + \frac{4}{s^3} + \cdots \tag{78.59b}$$

$$\begin{aligned}\hat{\rho}(s) = 1 &+ \frac{3.23607(\alpha - 1)}{s} + \frac{5.23607(\alpha - 1)^2}{s^2} \\ &+ \frac{5.23607\left(\alpha^3 - 3.23607\alpha^2 + 3.23607\alpha - 1\right)}{s^3} + \cdots\end{aligned} \tag{78.59c}$$

STEP 6. For a Class IV zero of transmission of order 3, the coefficient conditions are, from (78.29d) with $k = 3$,

$$A_m = \rho_m, \quad m = 0,\ 1,\ 2 \tag{78.60a}$$

$$\frac{F_2}{A_3 - \rho_3} \geq a_{-1}(\infty) = 1 \tag{78.60b}$$

where $a_{-1}(\infty)$ is the residue of $z_2(s)$ evaluated at the pole $s = \infty$, which is also the zero of transmission of $z_2(s)$. Substituting the coefficients of (78.59) in (78.60) yields the constraints imposed on K_5 as

$$A_0 = 1 = \rho_0 \tag{78.61a}$$

$$A_1 = -2 = \rho_1 = 3.23607(\alpha - 1) \tag{78.61b}$$

$$A_2 = 2 = \rho_2 = 5.23607(\alpha - 1)^2 \tag{78.61c}$$

yielding $\alpha = 0.3819664$, and

$$\begin{aligned}\frac{F_2}{A_3 - p_3} &= \frac{-2}{-2 - 5.23607\left(\alpha^3 - 3.23607\alpha^2 + 3.23607\alpha - 1\right)} \\ &\geq a_{-1}(\infty) = 1\end{aligned} \tag{78.62}$$

© 2003 by CRC Press LLC

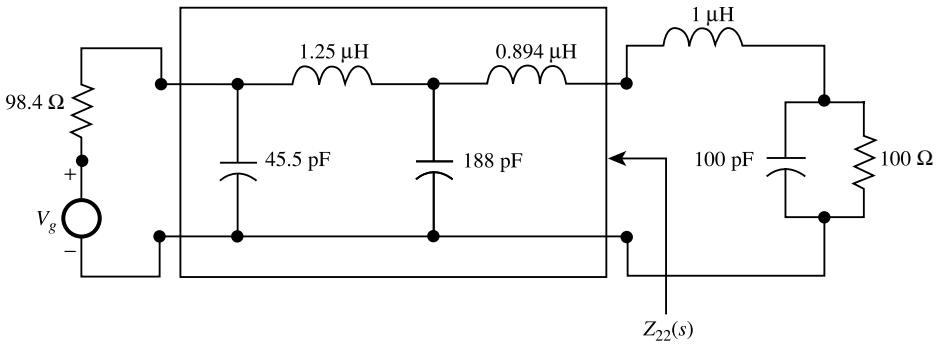

FIGURE 78.5 A fifth-order Butterworth broadband matching equalizer.

This inequality is satisfied for $\alpha = 0.3819664$. Hence, we choose $\alpha = 0.3819664$ and obtain from (78.57) the maximum realizable DC gain K_5 as

$$K_5 = 1 - \alpha^{10} = 0.99993 \tag{78.63}$$

With this value of K_5, the minimum-phase reflection coefficient becomes

$$\hat{p}(s) = \frac{s^5 + 1.23607s^4 + 0.76393s^3 + 0.2918s^2 + 0.068884s + 0.0081307}{s^5 + 3.23607s^4 + 5.23607s^3 + 5.23607s^2 + 3.23607s + 1} \tag{78.64}$$

STEP 7. The equalizer back-end impedance is determined by

$$\begin{aligned} Z_{22}(s) &\equiv \frac{F(s)}{A(s) - \hat{\rho}(s)} - z_2(s) = \frac{\dfrac{-2}{(s+1)^2}}{\dfrac{s-1}{s+1} - \hat{\rho}(s)} - \frac{s^2 + s + 1}{s+1} \\ &= \frac{0.94427s^4 + 2.1115s^3 + 2.6312s^2 + 2.1591s + 0.9919}{1.0557s^3 + 2.3607s^2 + 2.3131s + 1.0081} \end{aligned} \tag{78.65}$$

STEP 8. Expanding $Z_{22}(s)$ in a continued fraction results in

$$Z_{22}(s) = 0.894s + \cfrac{1}{1.88s + \cfrac{1}{1.25s + \cfrac{1}{0.455s + \cfrac{1}{0.984}}}} \tag{78.66}$$

which can be identified as an LC ladder network terminated in a resistor. Denormalizing the element values with regard to magnitude-scaling by a factor of 100 and frequency-scaling by a factor 10^8 gives the final design of the equalizer of Fig. 78.5.

Example 4. Design a lossless equalizer to match the load

$$z_2(s) = \frac{s^2 + 9s + 8}{s^2 + 2s + 2} \tag{78.67}$$

© 2003 by CRC Press LLC

to a resistive generator and to achieve the largest flat transducer power gain over the entire sinusoidal frequency spectrum.

STEP 1. For truly-flat transducer power gain, let

$$G\left(\omega^2\right) = K, \quad 0 \le K \le 1 \tag{78.68}$$

STEP 2. The following functions are computed from $z_2(s)$*:*

$$r_2(s)\frac{\left(s^2-4\right)^2}{\left(s^2+2s+2\right)\left(s^2-2s+2\right)} \tag{78.69a}$$

$$A(s) = \frac{s^2-2s+2}{s^2+2s+2} \tag{78.69b}$$

$$F(s) = \frac{2\left(s^4-8s^2+16\right)}{\left(s^2+2s+2\right)^2} \tag{78.69c}$$

STEP 3. Since

$$w(s) = \frac{r_2(s)}{z_2(s)} = \frac{\left(s^2-4\right)^2}{\left(s^2-2s+2\right)\left(s^2+9s+8\right)} \tag{78.70}$$

the load impedance $z_2(s)$ possesses a Class I zero of transmission of order 2 at $s = 2$.

STEP 4. Substituting (78.68) in (78.46) yields

$$\rho(s)\rho(-s) = 1-K \tag{78.71a}$$

the minimum-phase solution of which is found to be

$$\hat{\rho}(s) = \pm\sqrt{1-K} \tag{78.71b}$$

STEP 5. For a Class I zero of transmission of order 2, the coefficient conditions (78.29a) become

$$A(2) = \hat{\rho}(2) \tag{78.72a}$$

$$A_1 = \left.\frac{dA(s)}{ds}\right|_{s=2} = \rho_1 = \left.\frac{d\rho(s)}{ds}\right|_{s=2} \tag{78.72b}$$

The Laurent series expansions of the functions $A(s)$, $F(s)$, and $\hat{\rho}(s)$ about the zero of transmission at $s = 2$ are not needed.

STEP 6. Substituting (78.69b) and (78.71b) in (78.72) gives

$$A_0 = A(2) = 0.2 = \rho_0 = \pm\sqrt{1-K} \tag{78.73a}$$

© 2003 by CRC Press LLC

$$A_1 = \left.\frac{dA(s)}{ds}\right|_{s=2} = 0.08 \neq \rho_1 = 0 \tag{78.73b}$$

Since the coefficient conditions cannot all be satisfied without the insertion of a real all-pass function, let

$$\rho(s) = \eta(s)\hat{\rho}(s) = \frac{s-\sigma_1}{s+\sigma_1}\hat{\rho}(s) \tag{78.74}$$

Using this $\rho(s)$ in (78.72) results in the new constraints.

$$A_0 = 0.2 = \rho_0 = \pm\frac{2-\sigma_1}{2+\sigma_1}\sqrt{1-K} \tag{78.75a}$$

$$A_1 = 0.08 = \rho_1 = \pm\frac{2\sigma_1\sqrt{1-K}}{(2+\sigma_1)^2} \tag{78.75b}$$

which can be combined to yield

$$\sigma_1^2 + 5\sigma_1 - 4 = 0 \tag{78.76}$$

obtaining $\sigma_1 = 0.70156$ or -5.7016. Choosing $\sigma_1 = 0.70156$ and the plus sign for $\rho(s)$, the maximum permissible flat transducer power gain is found to be

$$K_{max} = 0.82684 \tag{78.77}$$

STEP 7. The equalizer back-end impedance is determined as

$$Z_{22}(s) \equiv \frac{F(s)}{A(s)-\rho(s)} - z_2(s) = \frac{1.4161s + 0.8192}{0.58388s + 0.49675} \tag{78.78}$$

STEP 8. The positive-real impedance $Z_{22}(s)$ can be realized as the input impedance of a lossless two-port network terminated in a resistor. The overall network is presented in Fig. 78.6.

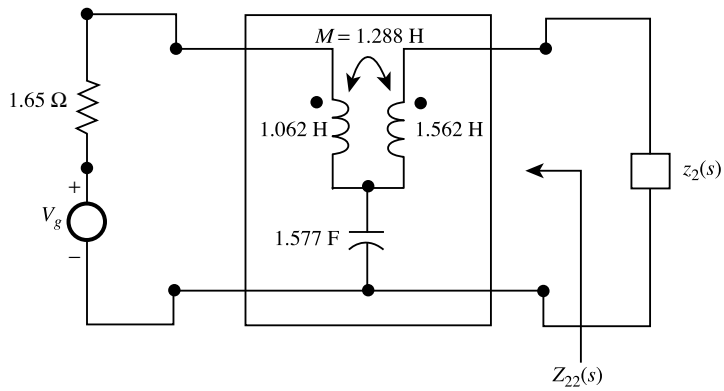

FIGURE 78.6 A lossless equalizer having a truly flat transducer power gain.

© 2003 by CRC Press LLC

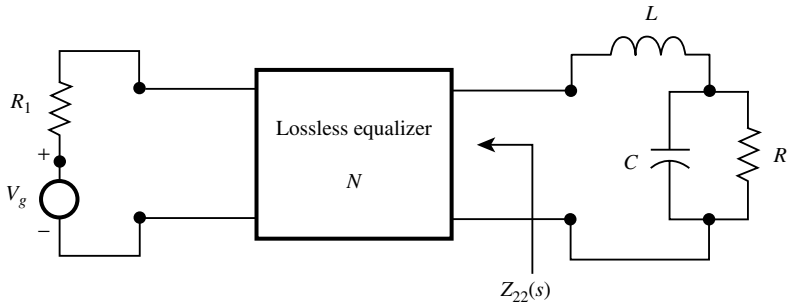

FIGURE 78.7 Broadband matching of an RLC load to a resistive source.

78.4 Explicit Formulas for the RLC Load

In many practical cases, the source can usually be represented by an ideal voltage source in series with a pure resistor, which may be the Thévenin equivalent of some other network, and the load is composed of the parallel combination of a resistor and a capacitor and then in series with an inductor, as shown in Fig. 78.7, which may include the parasitic effects of a physical device. The problem is to match out this load and source over a preassigned frequency band to within a given tolerance, and to achieve a prescribed transducer power-gain characteristic $G(\omega^2)$. In the case that $G(\omega^2)$ is of Butterworth or Chebyshev type of response, explicit formulas for the design of such optimum matching networks for any RLC load of the type shown in Fig. 78.7 are available, thereby avoiding the necessity of applying the coefficient constraints and solving the nonlinear equations for selecting the optimum design parameters. As a result, we reduce the design of these equalizers to simple arithmetic.

Butterworth Networks

Refer to Fig. 78.7. We wish to match out the load impedance

$$z_2(s) = Ls + \frac{R}{RCs+1} \tag{78.79}$$

to a resistive generator and to achieve the nth-order Butterworth transducer power-gain characteristic

$$G(\omega^2) = \frac{K_n}{1+(\omega/\omega_c)^{2n}}, \quad 0 \le K_n \le 1 \tag{78.80}$$

with maximum attainable DC gain K_n, where ω_c is the 3-dB bandwith or the radian cutoff frequency.

The even part $r_2(s)$ of $z_2(s)$ is found to be

$$r_2(s) = \frac{-R}{R^2C^2s^2-1} \tag{78.81}$$

Since $z_2(-s)$ has an open RHS pole at $s = 1/RC$, the all-pass real function defined by this pole is given by

$$A(s) = \frac{s-1/RC}{s+1/RC} = \frac{RCs-1}{RCs+1} \tag{78.82}$$

© 2003 by CRC Press LLC

yielding

$$F(s) = 2A(s)r_2(s) = \frac{-2R}{(RCs+1)^2} \tag{78.83}$$

We next replace ω by $-js$ in (78.80) and substitute the resulting equation in (78.46) to obtain

$$\rho(s)\rho(-s) = \alpha^{2n}\frac{1+(-1)^n x^{2n}}{1+(-1)^n y^{2n}} \tag{78.84}$$

where

$$y = \frac{s}{\omega_c}, \quad x = \frac{y}{\alpha} \tag{78.85a}$$

$$\alpha = (1-K_n)^{1/2n} \tag{78.85b}$$

As previously shown in (77.29), the minimum-phase solution $\hat{\rho}(s)$ of (78.84) is found to be

$$\hat{\rho}(s) = \alpha^n \frac{q(x)}{q(y)} \tag{78.86}$$

For our purposes, we consider the more general solution

$$\rho(s) = \pm\eta(s)\hat{\rho}(s) \tag{78.87}$$

where $\eta(s)$ is an arbitrary first-order real all-pass function of the form

$$\eta(s) = \frac{s-\sigma_1}{s+\sigma_1}, \qquad \sigma_1 \geq 0 \tag{78.88}$$

Since the load impedance $z_2(s)$ possesses a Class IV zero of transmission at infinity of order 3, the coefficient constraints become

$$A_m = \rho_m, \qquad m = 0,\ 1,\ 2 \tag{78.89a}$$

$$L_a \equiv \frac{F_2}{A_3 - \rho_3} \geq L \tag{78.89b}$$

After substituting the coefficients F_2, A_3, and ρ_3 from the Laurent series expansions of $F(s)$, $A(s)$, and $\rho(s)$ in (78.89), (78.89a) can all be satisfied by requiring that the DC gain be

$$K_n = 1 - \left[1 - \frac{2(1-RC\sigma_1)\sin\gamma_1}{RC\omega_c}\right]^{2n} \tag{78.90}$$

where γ_m is defined in (77.37), and after considerable mathematical manipulations the constraint (78.89b) becomes

$$L_a = \frac{4R\sin\gamma_1\sin\gamma_3}{(1-RC\sigma_1)\left[RC\omega_c^2(\alpha^2 - 2\alpha\cos\gamma_2 + 1) + 4\sigma_1\sin\gamma_1\sin\gamma_3\right]} \geq L \tag{78.91}$$

© 2003 by CRC Press LLC

The details of these derivations can be found in [6]. Thus, with K_n as specified in (78.90), a match is possible if and only if the series inductance L does not exceed a critical inductance L_a. To show that any RLC load can be matched, we must demonstrate that there exists a nonnegative real σ_1 such that L_a can be made at least as large as the given inductance L and satisfies the constraint (78.90) with $0 \le K_n \le 1$. To this end, four cases are distinguished. Let

$$L_{a1} = \frac{R^2 C\omega_c \sin\gamma_3}{\left[\left(RC\omega_c - \sin\gamma_1\right)^2 + \cos^2\gamma_1\right]\omega_c \sin\gamma_1} > 0 \tag{78.92}$$

$$L_{a2} = \frac{8R\sin^2\gamma_1 \sin\gamma_3}{\left[\left(RC\omega_c - \sin\gamma_3\right)^2 + \left(1 + 4\sin^2\gamma_1\right)\sin\gamma_1 \sin\gamma_3\right]\omega_c} > 0 \tag{78.93}$$

CASE 1. $RC\omega_c \ge 2 \sin\gamma_1$ and $L_{a1} \ge L$. Under this situation, $\sigma_1 = 0$ and the maximum attainable K_n is given by (78.90). The equalizer back-end impedance $Z_{22}(s)$ can be expanded in a continued fraction as

$$Z_{22}(s) = \left(L_{a1} - L\right)s + \cfrac{1}{C_2 s + \cfrac{1}{L_3 s + \cfrac{1}{\ddots + \cfrac{1}{W}}}} \tag{78.94}$$

where W is a constant representing either a resistance or a conductance, and

$$L_1 = L_{a1} \tag{78.95a}$$

$$C_{2m}L_{2m-1} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2\left(1 - 2\alpha\cos\gamma_{4m} + \alpha^2\right)}, \quad m \le \frac{1}{2}\left(n-1\right) \tag{78.95b}$$

$$C_{2m}L_{2m+1} = \frac{4\sin\gamma_{4m+1}\sin\gamma_{4m+3}}{\omega_c^2\left(1 - 2\alpha\cos\gamma_{4m+2} + \alpha^2\right)}, \quad m < \frac{1}{2}\left(n-1\right) \tag{78.95c}$$

where $m = 1, 2, \ldots, \left\lceil \frac{1}{2}(n-1) \right\rceil$, $n > 1$. In addition, the final reactive element can also be computed directly by the formulas

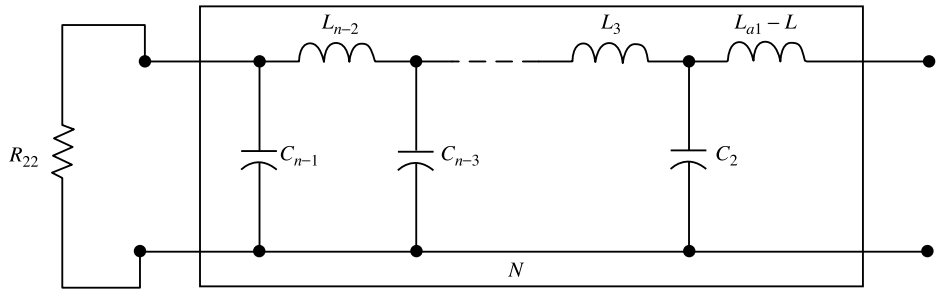
$$C_{n-1} = \frac{2\left(1 + \alpha^n\right)\sin\gamma_1}{R\left(1 - \alpha^n\right)\left(1 + \alpha\right)\omega_c}, \quad n \text{ odd} \tag{78.96a}$$

$$L_{n-1} = \frac{2R\left(1 - \alpha^n\right)\sin\gamma_1}{\left(1 + \alpha^n\right)\left(1 + \alpha\right)\omega_c}, \quad n \text{ even} \tag{78.96b}$$

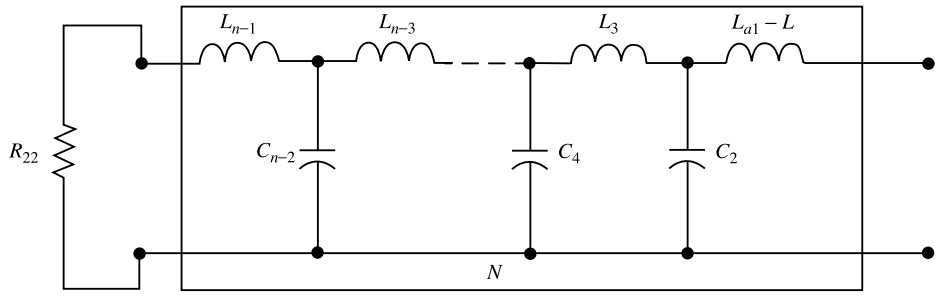
Equation (78.94) can be identified as an LC ladder terminated in a resistor, as depicted in Fig. 78.8. The terminating resistance is determined by

$$R_{22} = R\frac{1 - \alpha^n}{1 + \alpha^n} \tag{78.97}$$

© 2003 by CRC Press LLC



(a) n odd



(b) n even

FIGURE 78.8 The nth-order Butterworth ladder network N.

CASE 2. $RC\omega_c \geq 2\sin\gamma_1$ and $L_{a1} < L$. Under this situation, σ_1 is nonzero and can be determined by the formula

$$\sigma_1 = \frac{1}{RC}\left(1 + 2\sqrt{p}\sinh\frac{\varphi}{3} - \frac{2RC\omega_c\sin^2\gamma_1 + \sin\gamma_3}{3\sin\gamma_1}\right) \tag{78.98}$$

where

$$p = \frac{\left(RC\omega_c - 2\sin\gamma_1\right)^2\sin\gamma_3}{9\sin\gamma_1} > 0 \tag{78.99a}$$

$$w = \frac{\left(2RC\omega_c\sin^2\gamma_1 + \sin\gamma_3\right)}{54\sin^3\gamma_1}\left[3\left(RC\omega_c - 2\sin\gamma_1\right)^2\sin\gamma_1\sin\gamma_3 + \left(2RC\omega_c\sin^2\gamma_1 + \sin\gamma_3\right)^2\right] - \frac{R^2C\sin\gamma_3}{2L\sin\gamma_1} \tag{78.99b}$$

$$\varphi = \sinh^{-1}\frac{w}{\left(\sqrt{p}\right)^3} \tag{78.99c}$$

Using this value of σ_1, the DC gain K_n is computed by (78.90).

© 2003 by CRC Press LLC

CASE 3. $RC\omega_c < 2\sin\gamma_1$ and $L_{a2} \geq L$. Then, we have

$$K_n = 1 \tag{78.100a}$$

$$\sigma_1 = \frac{1}{RC}\left(1 - \frac{RC\omega_c}{2\sin\gamma_1}\right) > 0 \tag{78.100b}$$

CASE 4. $RC\omega_c < 2\sin\gamma_1$ and $L_{a2} < L$. Then the desired value of σ_1 can be computed by formula (78.98). Using this value of σ_1, the DC gain K_n is computed by (78.90).

Example 5. Let

$$R = 100\ \Omega, \quad C = 100\ \text{pF}, \quad L = 0.5\ \mu\text{F} \tag{78.101a}$$

$$n = 6, \qquad \omega_c = 10^8\ \text{rad/s} \tag{78.101b}$$

From (78.92), we first compute

$$L_{a1} = \frac{100\sin 45^\circ}{\left[\left(1 - \sin 15^\circ\right)^2 + \cos^2 15^\circ\right] \times 10^8 \sin 15^\circ} = 1.84304\ \mu\text{H} \tag{78.102}$$

Since $L_{a1} > L$ and

$$RC\omega_c = 1 > 2\sin 15^\circ = 0.517638 \tag{78.103}$$

Case 1 applies and the matching network can be realized as an LC ladder terminating in a resistor as shown in Fig. 78.8b. With $\sigma_1 = 0$, the maximum attainable DC gain K_6 is from (78.90)

$$K_6 = 1 - \left(1 - \frac{2\sin 15^\circ}{RC\omega_c}\right)^{12} = 0.999841 \tag{78.104}$$

giving from (78.85b)

$$\alpha = \left(1 - K_6\right)^{1/12} = 0.482362 \tag{78.105}$$

Applying formulas (78.95) yields the element values of the LC ladder network, as follows:

$$L_1 = L_{a1} = 1.84304\ \mu\text{H} \tag{78.106a}$$

$$C_2 = \frac{4\sin 45^\circ \sin 75^\circ}{1.84304 \times 10^{-6} \times 10^{16}\left(1 - 2 \times 0.482362\cos 60^\circ + 0.482362^2\right)} = 197.566\ \text{pF} \tag{78.106b}$$

$$L_3 = \frac{4\sin 75^\circ \sin 105^\circ}{197.566 \times 10^{-12} \times 10^{16}\left(1 - 2 \times 0.482362\cos 90^\circ + 0.482362^2\right)} = 1.53245\ \mu\text{H} \tag{78.106c}$$

© 2003 by CRC Press LLC

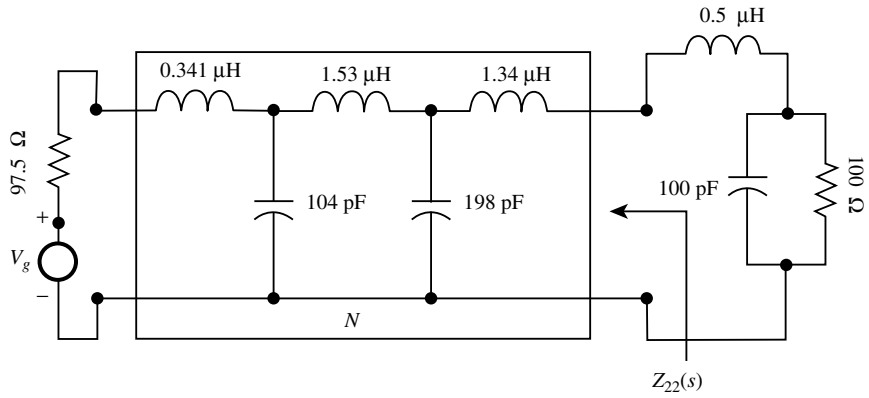


FIGURE 78.9 A sixth-order Butterworth matching network.

$$C_4 = \frac{4\sin 105^\circ \sin 135^\circ}{1.53245\times 10^{-6}\times 10^{16}\left(1-2\times 0.482362\cos 120^\circ + 0.482362^2\right)} \tag{78.106d}$$

$$= 103.951 \text{ pF}$$

$$L_5 = \frac{4\sin 135^\circ \sin 165^\circ}{103.951\times 10^{-12}\times 10^{16}\left(1-2\times 0.482362\cos 150^\circ + 0.482362^2\right)} \tag{78.106e}$$

$$= 0.34051 \text{ μH}$$

The last reactive elements L_5 can also be calculated directly from (78.96b) as

$$L_5 = \frac{2\times 100\left(1-0.482362^6\right)\sin 15^\circ}{\left(1+0.482362^6\right)\left(1+0.482362\right)10^8} = 0.34051\mu\text{H} \tag{78.107}$$

Finally, the terminating resistance is determined from (78.97) as

$$R_{22} = 100\frac{1-0.482362^6}{1+0.482362^6} = 97.512\,\Omega \tag{78.108}$$

The matching network together with its terminations is presented in Fig. 78.9. We remark that for computational accuracy we retain five significant figures in all the calculations. In practice, one or two significant digits are sufficient, as indicated in the figure.

Example 6. Let

$$R = 100\,\Omega, \qquad C = 50 \text{ pF}, \qquad L = 0.5\,\mu\text{F} \tag{78.109a}$$

$$n = 5, \qquad \omega_c = 10^8 \text{ rad/s} \tag{78.101b}$$

Since

$$RC\omega_c = 0.5 < 2\sin 18^\circ = 0.618 \tag{78.110}$$

and from (78.93),

$$L_{a2} = 1.401 \text{ μH} > \text{L} = 0.5 \text{ μH} \tag{78.111}$$

© 2003 by CRC Press LLC

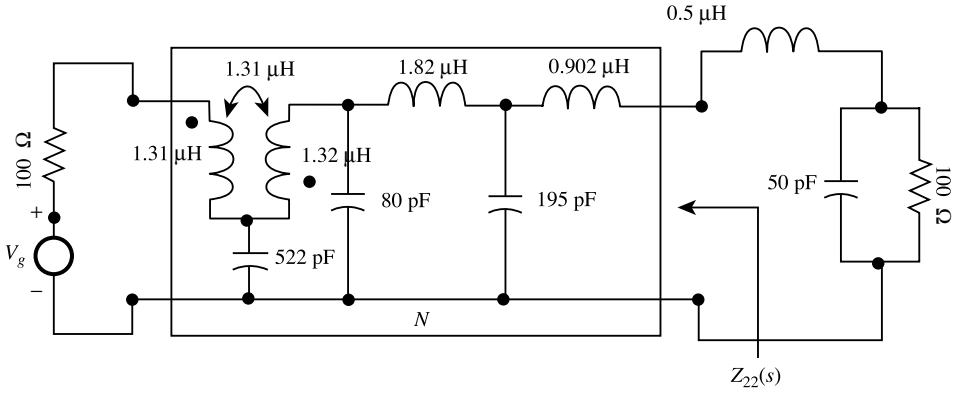

FIGURE 78.10 A fifth-order Butterworth matching network.

Case 3 applies, and we have $K_5 = 1$ and from (78.100b)

$$\sigma_1 = 0.381966 \times 10^8 \tag{78.112}$$

The normalized reflection coefficient is found to be

$$\rho(y) = \frac{(y - 0.381966)y^5}{(y + 0.381966)(y^5 + 3.23607y^4 + 5.23607y^3 + 5.23607y^2 + 3.23607y + 1)} \tag{78.113}$$

where $y = s/10^8$. Finally, we compute the equalizer back-end impedance as

$$\begin{aligned}
\frac{Z_{22}(s)}{100} &= \frac{F(y)}{A(y) - \rho(y)} - z_2(y) \\
&= \frac{\dfrac{-2}{(0.5y+1)^2}}{\dfrac{0.5y-1}{0.5y+1} - \rho(s)} - 0.5y - \frac{1}{0.5y+1} \\
&= \frac{2.573y^5 + 4.1631y^4 + 5.177y^3 + 4.2136y^2 + 2.045y + 0.38197}{2.8541y^4 + 4.618y^3 + 4.118y^2 + 2.045y + 0.38197} \\
&= 0.9015y + \cfrac{1}{1.949y + \cfrac{1}{1.821y + \cfrac{1}{0.8002y + \cfrac{1}{\cfrac{1.005y + 0.3822}{0.9944y + 0.3822}}}}}
\end{aligned} \tag{78.114}$$

The final matching network together with its terminations is presented in Fig. 78.10.

Example 7. Let

$$R = 100\ \Omega, \qquad C = 50\ \text{pF}, \qquad L = 3\ \mu\text{F} \tag{78.115a}$$

$$n = 4, \qquad \omega_c = 10^8\ \text{rad/s} \tag{78.115b}$$

© 2003 by CRC Press LLC

Since

$$RC\omega_c = 0.5 < 2\sin 22.5^\circ = 0.76537 \tag{78.116}$$

and from (78.93)

$$L_{a2} = 1.462\ \mu\text{H} < L = 3\ \mu\text{H} \tag{78.117}$$

Case 4 applies, and from (78.98)

$$\sigma_1 = 1.63129 \times 10^8 \tag{78.118}$$

where (78.99)

$$p = 0.0188898, \qquad w = 0.2304, \qquad \varphi = 5.17894 \tag{78.119}$$

From (78.90), the maximum attainable DC gain is obtained as

$$\begin{aligned} K_4 &= 1 - \left[1 - \frac{2\left(1 - 100 \times 50 \times 10^{-12} \times 1.63129 \times 10^8\right)\sin 22.5^\circ}{100 \times 50 \times 10^{-12} \times 10^8}\right]^8 \\ &= 0.929525 \end{aligned} \tag{78.120}$$

giving from (78.85b)

$$\alpha = \left(1 - K_4\right)^{1/8} = 0.717802 \tag{78.121}$$

Finally, the normalized reflection coefficient $\rho(s)$ is obtained as

$$\rho(s) = \frac{\left(y - 1.63129\right)\left(y^4 + 1.87571y^3 + 1.75913y^2 + 0.966439y + 0.265471\right)}{\left(y + 1.63129\right)\left(y^4 + 2.61313y^3 + 3.41421y^2 + 2.61313y + 1\right)} \tag{78.122}$$

where $y = s/10^8$. Finally, we compute the equalizer back-end impedance as

$$\begin{aligned} \frac{Z_{22}(s)}{100} &= \frac{F(y)}{A(y) - \rho(y)} - z_2(y) = \frac{\dfrac{-2}{(0.5y+1)^2}}{\dfrac{0.5y-1}{0.5y+1} - \rho(s)} - 0.5y - \frac{1}{0.5y+1} \\ &= \frac{3.3333y^4 + 7.4814y^3 + 8.6261y^2 + 5.9748y + 2.0642}{1.3333y^3 + 2.9926y^2 + 2.9195y + 1.1982} \\ &= 2.5y + \cfrac{1}{1.0046y + \cfrac{1}{1.5691y + \cfrac{1}{\cfrac{1.0991y + 2.0642}{0.84591y + 1.1982}}}} \end{aligned} \tag{78.123}$$

The final matching network together with its terminations is presented in Fig. 78.11.

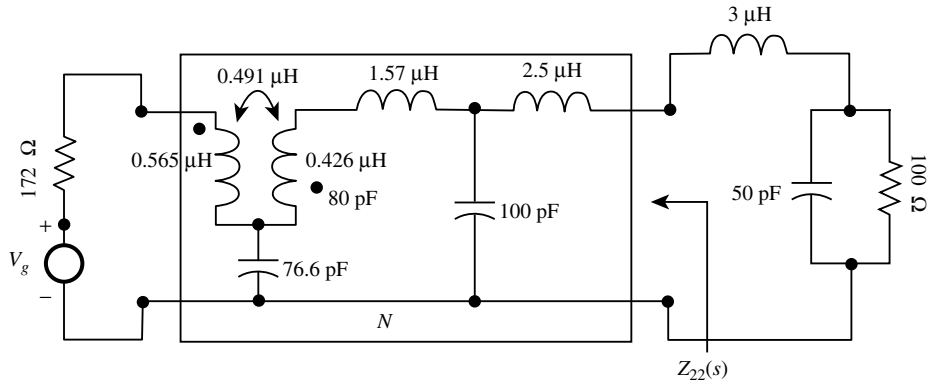

FIGURE 78.11 A fourth-order Butterworth matching network.

Chebyshev Networks

Refer again to Fig. 78.7. We wish to match out the load impedance

$$z_2(s) = Ls + \frac{R}{RCs+1} \tag{78.124}$$

to a resistive generator and to achieve the *n*th-order Chebyshev transducer power-gain characteristic

$$G(\omega^2) = \frac{K_n}{1+\varepsilon^2 C_n^2(\omega/\omega_c)}, \qquad 0 \le K_n \le 1 \tag{78.125}$$

with maximum attainable constant K_n. Following (78.84), we obtain

$$\rho(s)\rho(-s) = (1-K_n)\frac{1+\hat{\varepsilon}^2 C_n^2(-jy)}{1+\varepsilon^2 C_n^2(-jy)} \tag{78.126}$$

where $y = s/\omega_c$ and

$$\hat{\varepsilon} = \frac{\varepsilon}{\sqrt{1-K_n}} \tag{78.127}$$

As in (78.86), let $\hat{\rho}(s)$ be the minimum-phase solution of (78.126). For our purposes, we consider the more general solution

$$\rho(s) = \pm\eta(s)\hat{\rho}(s) \tag{78.128}$$

where $\eta(s)$ is an arbitrary first-order real all-pass function of the form

$$\eta(s) = \frac{s-\sigma_1}{s+\sigma_1}, \qquad \sigma_1 \ge 0 \tag{78.129}$$

Since the load impedance $z_2(s)$ possesses a Class IV zero of transmission at infinity of order 3, the coefficient constraints become

$$A_m = \rho_m, \qquad m = 0, 1, 2 \tag{78.130a}$$

© 2003 by CRC Press LLC

$$\frac{F_2}{A_3 - \rho_3} \geq L \tag{78.130b}$$

After substituting the coefficients F_2, A_3, and ρ_3 from the Laurent series expansions of $F(s)$, $A(s)$, and $\rho(s)$ in (78.130a), they lead to the constraints on the constant K_n as

$$K_n = 1 - \varepsilon^2 \sinh^2 \left\{ n \sinh^{-1} \left[\sinh a - \frac{2(1 - RC\sigma_1)\sin\gamma_1}{RC\omega_c} \right] \right\} \tag{78.131}$$

where γ_m is defined in (77.37), and

$$a = \frac{1}{n} \sinh^{-1} \frac{1}{\varepsilon} \tag{78.132}$$

To apply the constraint (78.130b), we rewrite it as

$$L_b \equiv \frac{F_2}{A_3 - \rho_3} \geq L \tag{78.133}$$

After substituting the coefficients F_2, A_3, and ρ_3 from the Laurent series expansions of $F(s)$, $A(s)$, and $\rho(s)$ in (78.133) and after considerable mathematical manipulations, we obtain

$$L_b = \frac{4R \sin\gamma_1 \sin\gamma_3}{(1 - RC\sigma_1)[RC\omega_c^2 f_1(\sin a, \sinh \hat{a}) + 4\sigma_1 \sin\gamma_1 \sin\gamma_3]} \geq L \tag{78.134}$$

where

$$\hat{a} = \frac{1}{n} \sinh^{-1} \frac{1}{\hat{\varepsilon}} = \frac{1}{n} \sinh^{-1} \frac{\sqrt{1 - K_n}}{\varepsilon} \tag{78.135}$$

$$f_m(x, y) = x^2 + y^2 - 2xy \cos\gamma_{2m} + \sin^2 \gamma_{2m}, \quad m = 1, 2, \ldots, \left\lceil \frac{1}{2} n \right\rceil \tag{78.136}$$

The details of these derivations can be found in [6]. Thus, with K_n as specified in (78.131), a match is possible if and only if the series inductance L does not exceed a critical inductance L_b. To show that any RLC load can be matched, we must demonstrate that there exists a nonnegative real σ_1 such that L_b can be made at least as large as the given inductance L and satisfies the constraint (78.131) with $0 \leq K_n \leq 1$. To this end, four cases are distinguished. Let

$$L_{b1} = \frac{R^2 C \omega_c \sin\gamma_3}{\left[\left(1 - RC\omega_c \sinh a \sin\gamma_1\right)^2 + R^2 C^2 \omega_c^2 \cosh^2 a \cos^2 \gamma_1 \right] \omega_c \sin\gamma_1} > 0 \tag{78.137}$$

$$L_{b2} = \frac{8R \sin^2 \gamma_1 \sin\gamma_3}{\left[\left(RC\omega_c \sinh a - \sin\gamma_3\right)^2 + \left(1 + 4\sin^2 \gamma_1\right) \sin\gamma_1 \sin\gamma_3 + R^2 C^2 \omega_c^2 \sin^2 \gamma_2 \right] \omega_c \sinh a} > 0 \tag{78.138}$$

Observe that both L_{b1} and L_{b2} are positive.

© 2003 by CRC Press LLC

CASE 1. $RC\omega_c \sinh a \geq 2\sin\gamma_1$ and $L_{b1} \geq L$. Under this situation, $\sigma_1 = 0$ and the maximum attainable K_n is given by

$$K_n = 1 - \varepsilon^2 \sinh^2\left\{ n \sinh^{-1}\left[\sinh a - \frac{2\sin\gamma_1}{RC\omega_c} \right] \right\} \tag{78.139}$$

The equalizer back-end impedance $Z_{22}(s)$ can be expanded in a continued fraction as in (78.94) with L_{b1} replacing L_{a1} and realized by the LC ladders Fig. 78.8 with

$$L_1 = L_{b1} \tag{78.140a}$$

$$C_{2m}L_{2m-1} = \frac{4\sin\gamma_{4m-1}\sin\gamma_{4m+1}}{\omega_c^2 f_{2m}(\sinh a, \sinh\hat{a})}, \quad m \leq \frac{1}{2}(n-1) \tag{78.140b}$$

$$C_{2m}L_{2m+1} = \frac{4\sin\gamma_{4m+1}\sin\gamma_{4m+3}}{\omega_c^2 f_{2m+1}(\sinh a, \sinh\hat{a})}, \quad m < \frac{1}{2}(n-1) \tag{78.140c}$$

where $m = 1, 2, \ldots, \left\lceil \frac{1}{2}(n-1) \right\rceil$, $n > 1$. In addition, the final reactive element can also be computed directly by the formulas

$$C_{n-1} = \frac{2(\sinh na + \sinh n\hat{a})\sin\gamma_1}{R\omega_c(\sinh a + \sinh\hat{a})(\sinh na - \sinh n\hat{a})}, \quad n \text{ odd} \tag{78.141a}$$

$$L_{n-1} = \frac{2R(\cosh na - \cosh n\hat{a})\sin\gamma_1}{\omega_c(\sinh a + \sinh\hat{a})(\cosh na + \cosh n\hat{a})}, \quad n \text{ even} \tag{78.141b}$$

The terminating resistance is determined by

$$R_{22} = R\frac{\sinh na - \sinh n\hat{a}}{\sinh na + \sinh n\hat{a}}, \quad n \text{ odd} \tag{78.142a}$$

$$R_{22} = R\frac{\cosh na - \cosh n\hat{a}}{\cosh na + \cosh n\hat{a}}, \quad n \text{ even} \tag{78.142b}$$

CASE 2. $RC\omega_c \sinh a \geq 2\sin\gamma_1$ and $L_{b1} < L$. Under this situation, σ_1 is nonzero and can be determined by the formula

$$\sigma_1 = \frac{1}{RC}\left(1 + 2\sqrt{q}\sinh\frac{\varphi}{3} - \frac{2RC\omega_c\sin^2\gamma_1\sinh a + \sin\gamma_3}{3\sin\gamma_1} \right) \tag{78.143}$$

where

$$q = \frac{(RC\omega_c\sinh a - 2\sin\gamma_1)^2\sin\gamma_3 + 3R^2C^2\omega_c^2\sin\gamma_1\cos^2\gamma_1}{9\sin\gamma_1} > 0 \tag{78.144a}$$

$$\begin{aligned}\zeta = {} & \frac{(2RC\omega_c\sin^2\gamma_1\sinh a + \sin\gamma_3)}{54\sin^3\gamma_1} \\ & \times \left[3(RC\omega_c\sinh a - 2\sin\gamma_1)^2\sin\gamma_1\sin\gamma_3 \right.\end{aligned} \tag{78.144b}$$

© 2003 by CRC Press LLC

$$+ 2.25R^2C^2\omega_c^2 \sin^2\gamma_2 + \left(2RC\omega_c \sin^2\gamma_1 \sinh a + \sin\gamma_3\right)^2\Big]$$

$$- \frac{R^2C\sin\gamma_3}{2L\sin\gamma_1}$$

$$\varphi = \sinh^{-1}\frac{\zeta}{\left(\sqrt{q}\right)^3} \tag{78.144c}$$

Using this value of σ_1, the constant K_n is computed by (78.131).

CASE 3. $RC\omega_c \sinh a < 2\sin\gamma_1$ and $L_{b2} \geq L$. Then, we have

$$K_n = 1 \tag{78.145a}$$

$$\sigma_1 = \frac{1}{RC}\left(1 - \frac{RC\omega_c \sinh a}{2\sin\gamma_1}\right) > 0 \tag{78.145b}$$

CASE 4. $RC\omega_c \sinh a < 2\sin\gamma_1$ and $L_{b2} < L$. Then the desired value of σ_1 can be computed by formula (78.143). Using this value of σ_1, the constant K_n is computed by (78.131).

Example 8. Let

$$R = 100\,\Omega, \qquad C = 500\text{ pF}, \qquad L = 0.5\,\mu\text{F} \tag{78.146a}$$

$$n = 6, \qquad \varepsilon = 0.50885\left(1 - \text{dB ripple}\right), \qquad \omega_c = 10^8\text{ rad/s} \tag{78.146b}$$

From (78.137), we first compute

$$L_{b1} = \frac{500\sin 45^\circ}{\left[\left(1 - 5\sinh 0.237996\sin 15^\circ\right)^2 + 25\cosh^2 0.237996\cos^2 15^\circ\right]10^8\sin 15^\circ} \tag{78.147}$$

$$= 0.54323\ \mu\text{H}$$

Since $L_{b1} > L$ and

$$RC\omega_c \sinh a = 5\sinh 0.237996 = 1.20125 > 2\sin 15^\circ = 0.517638 \tag{78.148}$$

Case 1 applies and the matching network can be realized as an LC ladder terminating in a resistor as shown in Fig. 78.8. With $\sigma_1 = 0$, the maximum attainable DC gain K_6 is from (78.131)

$$K_6 = 1 - 0.50885^2\sinh^2\left\{6\sinh^{-1}\left[\sinh 0.237996 - \frac{2\sin 15^\circ}{5}\right]\right\} = 0.78462 \tag{78.149}$$

giving from (78.127) and (78.135)

$$\hat{\varepsilon} = \frac{0.50885}{\sqrt{1 - 0.78462}} = 1.0964 \tag{78.150a}$$

© 2003 by CRC Press LLC

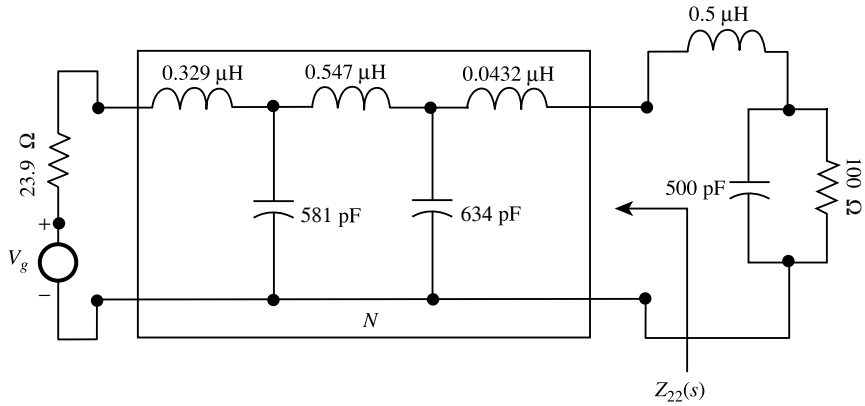

FIGURE 78.12 A sixth-order Chebyshev matching network.

$$\hat{\alpha} = \frac{1}{6}\sinh^{-1}\frac{1}{1.0964} = 0.13630 \tag{78.150b}$$

Applying formulas (78.140) yields the element values of the LC ladder network, as follows:

$$L_1 = L_{b1} = 0.54323\ \mu\text{H}, \quad C_2 = 634\ \text{pF}, \quad L_3 = 0.547\ \mu\text{H} \tag{78.151a}$$

$$C_4 = 581\ \text{pF}, \quad L_5 = 0.329\ \mu\text{H} \tag{78.151b}$$

The last reactive element L_5 can be calculated directly from (78.141b) as

$$L_5 = \frac{2\times 100\left[\cosh(6\times 0.237996) - \cosh(6\times 0.13630)\right]\sin 15^\circ}{10^8\left(\sinh 0.237996 + \sinh 0.13630\right)\left[\cosh(6\times 0.237996) + \cosh(6\times 0.13630)\right]} \tag{78.152}$$
$$= 0.328603\ \mu\text{H}$$

Finally, the terminating resistance is determined from (78.142b) as

$$R_{22} = 100\frac{\cosh(6\times 0.237996) - \cosh(6\times 0.13630)}{\cosh(6\times 0.237996) + \cosh(6\times 0.13630)} = 23.93062\ \Omega \tag{78.153}$$

The matching network together with its terminations is presented in Fig. 78.12. We remark that for computational accuracy we retain five significant figures in all the calculations. In practice, one or two significant digits are sufficient, as indicated in the figure.

Example 9. Let

$$R = 100\ \Omega, \quad C = 500\ \text{pF}, \quad L = 1\ \mu\text{H} \tag{78.154a}$$

$$n = 5, \quad \varepsilon = 0.50885\ (1\text{-dB ripple}), \ \omega_c = 10^8\ \text{rad/s} \tag{78.154b}$$

From (78.137), we first compute

$$L_{b1} = 0.52755\ \mu\text{H} \tag{78.155}$$

© 2003 by CRC Press LLC

Since $L_{b1} < L$ and

$$RC\omega_c \sinh a = 5\sinh 0.28560 = 1.44747 > 2\sin 18^\circ = 0.61803 \tag{78.156}$$

Case 2 applies. From (78.144), we obtain

$$q = 7.73769, \quad \zeta = 7.84729, \quad \varphi = 0.356959 \tag{78.157}$$

Substituting these in (78.143) gives

$$\sigma_1 = 0.0985305 \times 10^8 \tag{78.158}$$

From (78.131), the maximum attainable constant K_5 is found to be

$$K_5 = 0.509206 \tag{78.159}$$

The rest of the calculations proceed exactly as in the previous example, and the details are omitted.

Example 10. Let

$$R = 100\ \Omega, \quad C = 100\ \text{pF}, \quad L = 0.5\ \mu\text{F} \tag{78.160a}$$

$$n = 5, \quad \varepsilon = 0.76478\ (\text{2-dB ripple}), \quad \omega_c = 10^8\ \text{rad/s} \tag{78.160b}$$

We first compute

$$a = \frac{1}{5}\sinh^{-1}\frac{1}{\varepsilon} = 0.2166104 \tag{78.161}$$

and from (78.138)

$$L_{b2} = 2.72234\,\mu\text{H} \tag{78.162}$$

Since $L_{b2} \geq L$ and

$$RC\omega_c \sinh a = \sinh 0.2166104 = 0.218308 < 2\sin 18^\circ = 0.618034 \tag{78.163}$$

Case 3 applies. Then $K_5 = 1$ and from (78.145b)

$$\sigma_1 = \frac{1}{10^{-8}}\left(1 - \frac{\sinh 0.2166104}{2\sin 18^\circ}\right) = 0.64677 \times 10^8 \tag{78.164}$$

For $K_5 = 1$, (78.126) degenerates into

$$\rho(y)\rho(-y) = \frac{\varepsilon^2 C_5^2(-jy)}{1 + \varepsilon^2 C_5^2(-jy)} \tag{78.165}$$

where $y = s/10^8$, the minimum-phase solution of which is found to be

$$\hat{\rho}(y) = \frac{y^5 + 1.25y^3 + 0.3125y}{y^5 + 0.706461y^4 + 1.49954y^3 + 0.693477y^2 + 0.459349y + 0.0817225} \tag{78.166}$$

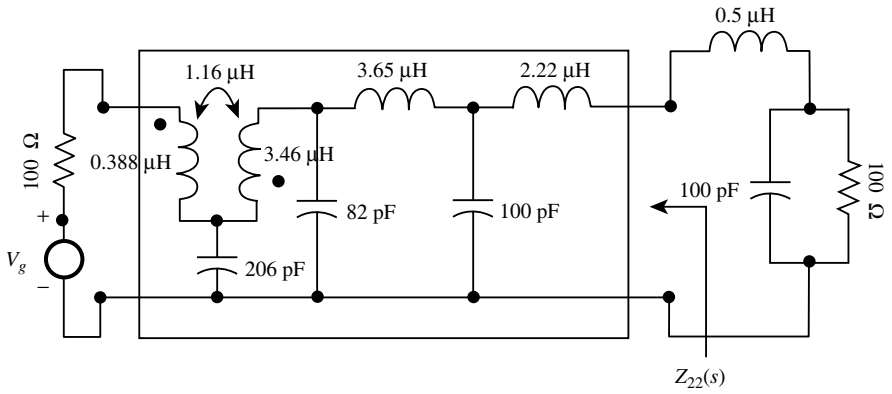

FIGURE 78.13 A fifth-order Chebyshev matching network.

A more general solution is given by

$$\rho(y)=\frac{y-0.64677\times10^{8}}{y+0.64677\times10^{8}}\hat{\rho}(y) \tag{78.167}$$

Finally, we compute the equalizer back-end impedance as

$$\begin{aligned}\frac{Z_{22}(y)}{100}&=\frac{F(y)}{A(y)-\rho(y)}-z_2(y)\\&=\frac{\dfrac{-2}{(y+1)^2}}{\dfrac{y-1}{y+1}-\rho(x)}-0.5y-\frac{1}{y+1}\\&=\frac{1.63267y^5+0.576709y^4+2.15208y^3+0.533447y^2+0.554503y+0.0528557}{0.734663y^4+0.259505y^3+0.639438y^2+0.123844y+0.0528557}\\&=2.222y+\cfrac{1}{1.005y+\cfrac{1}{3.651y+\cfrac{1}{0.8204y+\cfrac{1}{\cfrac{0.2441y+0.05286}{0.02736y+0.05286}}}}}\end{aligned} \tag{78.168}$$

The final matching network together with its terminations is presented in Fig. 78.13.

Example 11. Let

$$R=100\ \Omega,\quad C=100\ \text{pF},\quad L=3\ \mu\text{F} \tag{78.169a}$$

$$n=4,\quad \varepsilon=0.76478\ (\text{2-dBripple}),\quad \omega_c=10^8\ \text{rad/s} \tag{78.169b}$$

We first compute

$$a=\frac{1}{4}\sinh^{-1}\frac{1}{0.76478}=0.27076 \tag{78.170}$$

© 2003 by CRC Press LLC

and from (78.138)

$$L_{b2} = 2.66312\,\mu\text{H} \tag{78.171}$$

Since $L_{b2} < L$ and

$$RC\omega_c \sinh a = \sinh 0.27076 = 0.27408 < 2\sin 22.5^\circ = 0.765367 \tag{78.172}$$

Case 4 applies. From (78.144), we obtain

$$q = 0.349261, \quad \zeta = 0.390434, \quad \varphi = 1.39406 \tag{78.173}$$

Substituting these in (78.143) gives

$$\sigma_1 = 0.694564 \times 10^8 \tag{78.174}$$

obtaining from (78.127) and (78.131)

$$K_4 = 0.984668, \quad \hat{\varepsilon} = 6.17635 \tag{78.175}$$

From (78.126),

$$\rho(y)\rho(-y) = (1 - K_4)\frac{1 + \hat{\varepsilon}^2 C_4^2(-jy)}{1 + \varepsilon^2 C_4^2(-jy)} \tag{78.176}$$

where $y = s/10^8$, the minimum-phase solution of which is found to be

$$\hat{\rho}(y) = \frac{y^4 + 0.105343y^3 + 1.00555y^2 + 0.0682693y + 0.126628}{y^4 + 0.716215y^3 + 1.25648y^2 + 0.516798y + 0.205765} \tag{78.177}$$

A more general solution is given by

$$\rho(y) = \frac{y - 0.694564 \times 10^8}{y + 0.694564 \times 10^8}\hat{\rho}(s) \tag{78.178}$$

Finally, we compute the equalizer back-end impedance as

$$\begin{aligned}\frac{Z_{22}(y)}{100} = \frac{F(y)}{A(y) - \rho(y)} - z_2(y) &= \frac{\dfrac{-2}{(y+1)^2}}{\dfrac{y-1}{y+1} - \rho(s)} - \frac{3y^2 + 3y + 1}{y + 1} \\ &= \frac{0.780486y^2 + 0.320604y + 0.23087}{0.666665y^3 + 0.273851y^2 + 0.413057y + 0.0549659} \\ &= \cfrac{1}{0.8542y + \cfrac{1}{3.616y + \cfrac{1}{\cfrac{0.1219y + 0.2309}{0.2159y + 0.05497}}}}\end{aligned} \tag{78.179}$$

The final matching network together with its terminations is presented in Fig. 78.14.

79.1 Introduction

Active filters consist of only amplifiers, resistors, and capacitors. Complex roots are achieved by the use of feedback eliminating the need for inductors. The gain of the amplifier can be finite or infinite (an op-amp). This section describes active filters using low-gain or finite-gain amplifiers. Filter design equations and examples will be given along with the performance limits of low-gain amplifier filters.

79.2 First- and Second-Order Transfer Functions

Before discussing the characteristics and the synthesis of filters it is important to understand the transfer functions of first- and second-order filters. Later we will explain the implementations of these filters and show how to construct higher order filters from first- and second-order sections. The transfer functions of most first- and second-order filters are examined in the following.

First-Order Transfer Functions

A standard form of the transfer function of a first-order low-pass filter is

$$T_{\mathrm{LP}}(s) = \frac{T_{\mathrm{LP}}(j0)\omega_o}{s+\omega_o} \tag{79.1}$$

where $T_{\mathrm{LP}}(j0)$ is the value of $T_{\mathrm{LP}}(s)$ at dc and ω_o is the **pole frequency**. It is common practice to normalize both the magnitude and frequency. Normalizing (79.1) yields

$$T_{\mathrm{LP}n}(s_n) = \frac{T_{\mathrm{LP}}(s_n\omega_o)}{\left|T_{\mathrm{LP}}(j0)\right|} = \frac{1}{s_n+1} \tag{79.2}$$

© 2003 by CRC Press LLC

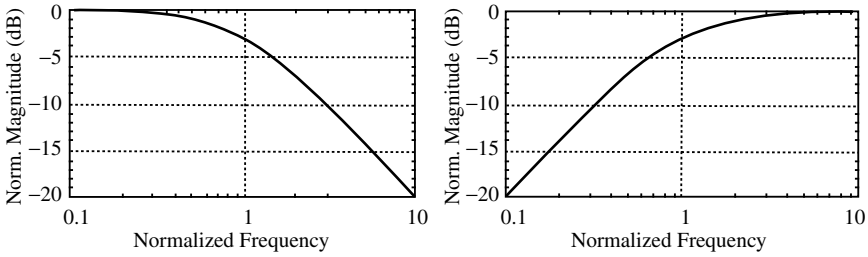

FIGURE 79.1 Normalized magnitude response of (a) first-order low-pass and (b) first-order high-pass filters.

where $s_n = s/\omega_o$ and amplitude has been normalized as

$$T_{\mathrm{LP}n}(s) = \frac{T_{\mathrm{LP}}(s)}{\left|T_{\mathrm{LP}}(j0)\right|} \tag{79.3}$$

The equivalent normalized forms of a first-order high-pass filter are

$$T_{\mathrm{HP}}(s) = \frac{T_{\mathrm{HP}}(j\infty)s}{s+\omega_o} \tag{79.4}$$

and

$$T_{\mathrm{HP}n}(s_n) = \frac{T_{\mathrm{HP}}(s_n\omega_o)}{\left|T_{\mathrm{HP}}(j\infty)\right|} = \frac{s_n}{s_n+1} \tag{79.5}$$

where $T_{\mathrm{HP}}(j\infty) = T_{\mathrm{HP}}(s) \mid$ at $\omega = \infty$. The normalized magnitude responses of these functions are shown in Fig. 79.1.

Second-Order Transfer Functions

The standard form of a second-order low-pass filter is given as

$$T_{\mathrm{LP}}(s) = \frac{T_{\mathrm{LP}}(j0)\omega_o^2}{s^2 + \left(\frac{\omega_o}{Q}\right)s + \omega_o^2} \tag{79.6}$$

where $T_{\mathrm{LP}}(j0)$ is the value of $T_{\mathrm{LP}}(s)$ at dc, ω_o is the pole frequency, and Q is the **pole Q** or the **pole quality factor**. The **damping factor ζ**, which may be better known to the reader, is given as

$$\zeta = \frac{1}{2Q} \tag{79.7}$$

The poles of the transfer function of (79.7) are

$$p_1, p_2 = \frac{-\omega_o}{2Q} \pm j\left(\frac{\omega_o}{2Q}\right)\sqrt{4Q^2-1} \tag{79.8}$$

© 2003 by CRC Press LLC

Normalization of (79.6) in both amplitude and frequency gives

$$T_{\mathrm{LP}n}(s_n) = \frac{T_{\mathrm{LP}}(s_n\omega_o)}{|T_{\mathrm{LP}}(j0)|} = \frac{1}{s_n^2 + \frac{s_n}{Q} + 1} \tag{79.9}$$

where $s_n = s/\omega_o$. The standard second-order, high-pass and bandpass transfer functions are

$$T_{\mathrm{HP}}(s) = \frac{T_{\mathrm{HP}}(j\infty)s^2}{s^2 + \left(\frac{\omega_o}{Q}\right)s + \omega_o^2} \tag{79.10}$$

and

$$T_{\mathrm{BP}}(s) = \frac{T_{\mathrm{BP}}(j\omega_o)\left(\frac{\omega_o}{Q}\right)s}{s^2 + \left(\frac{\omega_o}{Q}\right)s + \omega_o^2} \tag{79.11}$$

where $T_{\mathrm{BP}}(j\omega_o) = T_{\mathrm{BP}}(s)$ at $s = j\omega = j\omega_o$. The poles of the second-order high-pass and bandpass transfer functions are given by (79.8).

We can normalize these equations as we did for $T_{\mathrm{LP}}(s)$ to get

$$T_{\mathrm{HP}n}(s_n) = \frac{T_{\mathrm{HP}}(s_n\omega_o)}{|T_{\mathrm{HP}}(j\infty)|} = \frac{s_n^2}{s_n^2 + \frac{s_n}{Q} + 1} \tag{79.12}$$

$$T_{\mathrm{BP}n}(s_n) = \frac{T_{\mathrm{BP}}(s_n\omega_o)}{|T_{\mathrm{BP}}(j\omega_o)|} = \frac{\frac{s_n}{Q}}{s_n^2 + \frac{s_n}{Q} + 1} \tag{79.13}$$

where

$$T_{\mathrm{HP}n}(s) = \frac{T_{\mathrm{HP}}(s)}{|T_{\mathrm{HP}}(j\infty)|} \tag{79.14}$$

and

$$T_{\mathrm{BP}n}(s) = \frac{T_{\mathrm{BP}}(s)}{|T_{\mathrm{BP}}(j\omega_o)|} \tag{79.15}$$

Two other types of second-order transfer function filters that we have not covered here are the bandstop and the all-pass. These transfer functions have the same poles as the previous ones. However, the zeros of the bandstop transfer function are on the $j\omega$ axis while the zeros of the all-pass transfer function are quadratically symmetric to the poles (they are mirror images of the poles in the right-half plane). Both of these transfer functions can be implemented by a second-order biquadratic transfer function whose transfer function is given as

© 2003 by CRC Press LLC

$$T_{BQ}(s) = \frac{K\left(s^2 \pm \left(\frac{\omega_z}{Q_z}\right)s + \omega_z^2\right)}{s^2 + \left(\frac{\omega_p}{Q_p}\right)s + \omega_p^2} \tag{79.16}$$

where K is a constant, ω_z is the zero frequency, Q_z the zero Q, ω_p is the pole frequency, and Q_p the pole Q.

Frequency Response (Magnitude and Phase)

The magnitude and phase response of the normalized second-order low-pass transfer function is shown in Fig. 79.2, where Q is a parameter. In this figure we see that Q influences the frequency response near ω_o. If Q is greater than 0.707, then the normalized magnitude response has a peak value of

$$\left|T_n\left[\omega_n(\max)\right]\right| = \frac{Q}{\sqrt{1-\left(1/4Q^2\right)}} \tag{79.17}$$

at a frequency of

$$\omega_n(\max) = \sqrt{1-\frac{1}{2Q^2}} \tag{79.18}$$

If the transfer function is multiplied by –1, the phase shift is shifted vertically by ±180°.

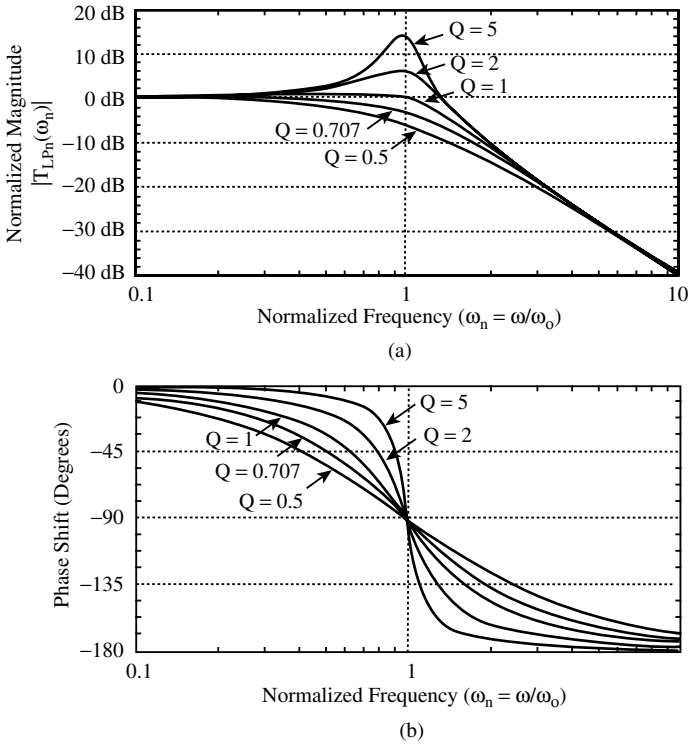

FIGURE 79.2 (a) Normalized magnitude and (b) phase response of the standard second-order low-pass transfer function with Q as a parameter.

© 2003 by CRC Press LLC

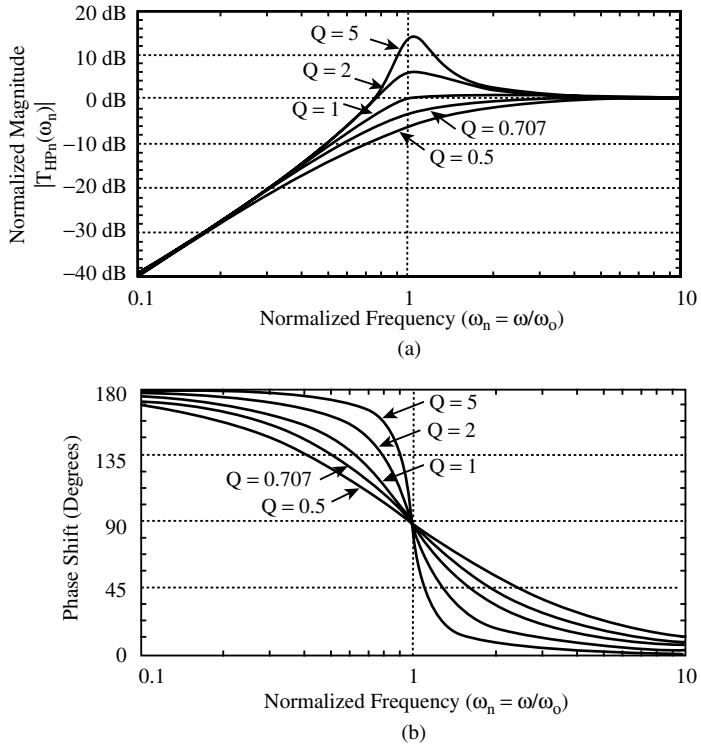

FIGURE 79.3 (a) Normalized magnitude and (b) phase response of the standard second-order high-pass transfer function with Q as a parameter.

The magnitude and phase response of the normalized second-order high-pass transfer function is shown in Fig. 79.3. For Q greater than 0.707 the peak value of the normalized magnitude response is as

$$\omega_n(\max) = \frac{1}{\sqrt{1-\frac{1}{2Q^2}}} \tag{79.19}$$

The normalized frequency response of the standard second-order bandpass transfer function is shown in Fig. 79.4. The slopes of the normalized magnitude curves at frequencies much greater or much less than ω_o are ±20 dB/decade rather than ±40 dB/decade of the second-order high- and low-pass transfer functions. This difference is because one pole is causing the high-frequency roll-off while the other pole is causing the low-frequency roll-off. The peak of the magnitude occurs at $\omega = \omega_o$ or $\omega_n = 1$.

Tuning Active Filters

A general tuning procedure for most second-order active filters is outlined below. This method is illustrated for adjusting the magnitude of the frequency response of a low-pass filter. The filter parameters are assumed to be the pole frequency f_o, the pole Q, and the gain $T(j0)$.

1. The component(s) which set(s) the parameter f_o is (are) tuned by adjusting the magnitude of the filter response to be $T(j0)/10$ or $T(j0)$ (dB) –20 dB at $10f_o$.
2. The component(s) that set(s) the parameter $T(j0)$ is (are) tuned by adjusting the magnitude to $T(j0)$ at $f_o/10$.
3. The component(s) that set(s) the parameter Q is (are) tuned by adjusting the magnitude of the peak (if there is one) to the value given by Fig. 79.2. If there is no peaking, then adjust so that the magnitude at f_o is correct (i.e., –3 dB for $Q = 0.707$).

© 2003 by CRC Press LLC

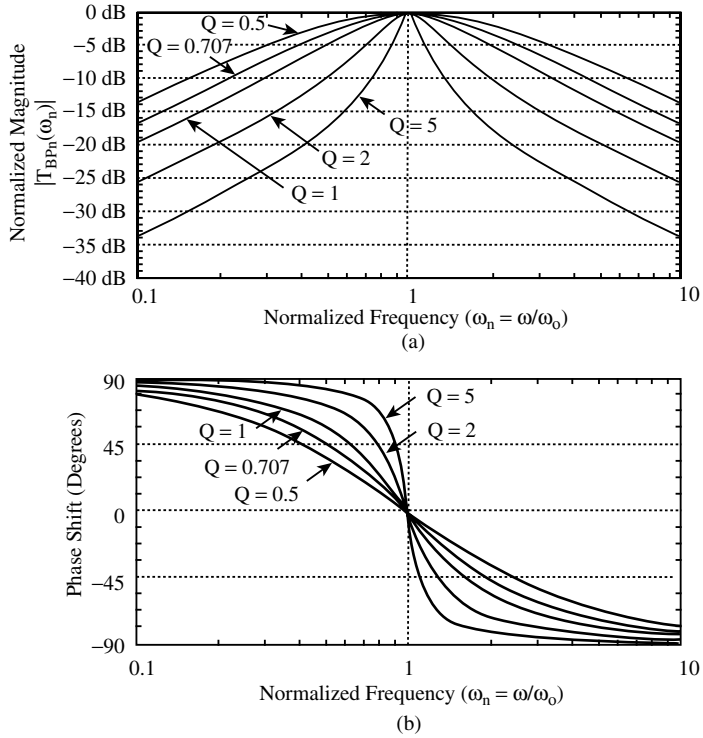

FIGURE 79.4 (a) Normalized magnitude and (b) phase response of the standard second-order bandpass transfer function with Q as a parameter.

The tuning procedure should follow in the order of steps 1 through 3 and may be repeated if necessary. One could also use the phase shift to help in the tuning of the filter. The concept of the above tuning procedure is easily adaptable to other types of second-order filters.

79.3 First-Order Filter Realizations

A first-order filter has only one pole and zero. For stability, the pole must be on the negative real axis but the zero may be on the negative or positive real axis. A single-amplifier low-gain realization of a first-order low-pass filter is shown in Fig. 79.5(a). The transfer function for this filter is

$$T(s) = \frac{V_2(s)}{V_1(s)} = \frac{K/RC}{s + 1/RC} = \frac{K\omega_o}{s + \omega_o} = \frac{T_{LP}(0)\omega_o}{s + \omega_o} \tag{79.20}$$

The low-frequency ($\omega \ll \omega_o$) gain magnitude and polarity are set by K.

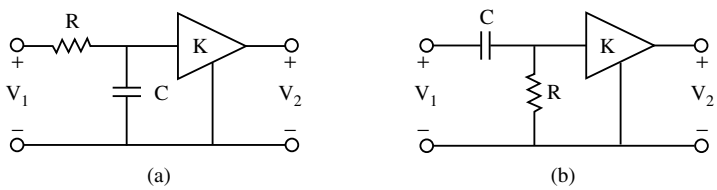

FIGURE 79.5 (a) Low-pass and (b) high-pass first-order filters.

© 2003 by CRC Press LLC

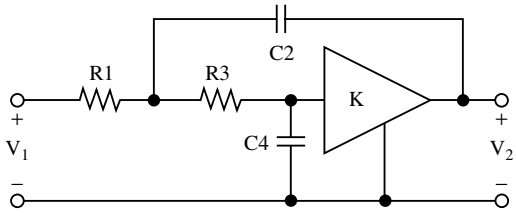

FIGURE 79.6 Low-pass Sallen and Key filter.

First-order high-pass filters can also be realized in a single-amplifier low-gain circuit [see Fig. 79.5(b)]. The transfer function for this filter is given in (79.4), and in this case $T_{HP}(j\infty) = K$. Both low-pass and high-pass magnitude responses are shown in Fig. 79.1. Note that the first-order filters exhibit no peaking and the frequency-dependent part of the magnitude response approaches ±20 dB/decade.

79.4 Second-Order Positive-Gain Filters

Practical realizations for second-order filters using positive gain amplifiers are presented here. These filters are easy to design and have been extensively used in many applications. The first realization is a low-pass Sallen and Key filter and is shown in Fig. 79.6 [8].

The transfer function of Fig. 79.6 is

$$\frac{V_2(s)}{V_1(s)} = \frac{\dfrac{K}{R_1R_3C_2C_4}}{s^2 + s\left(\dfrac{1}{R_3C_4} + \dfrac{1}{R_1C_2} + \dfrac{1}{R_3C_2} - \dfrac{K}{R_3C_4}\right) + \dfrac{1}{R_1R_3C_2C_4}} \tag{79.21}$$

Equating this transfer function with the standard form of a second-order low-pass filter given in (79.6) gives

$$\omega_o = \frac{1}{\sqrt{R_1R_3C_2C_4}} \tag{79.22}$$

$$\frac{1}{Q} = \sqrt{\frac{R_3C_4}{R_1C_2}} + \sqrt{\frac{R_1C_4}{R_3C_2}} + (1-K)\sqrt{\frac{R_1C_2}{R_3C_4}} \tag{79.23}$$

and

$$T_{LP}(j0) = K \tag{79.24}$$

These three equations have five unknowns, giving the designer some freedom in selecting component values. Two examples showing different techniques for defining these values of the circuit in Fig. 79.6 are given below.

Example 1

An Equal-Resistance Equal-Capacitance Low-Pass Filter. For this example, $R = R_1 = R_3$ and $C = C_2 = C_4$. A Butterworth low-pass filter characteristic is needed with $\omega_o = 6283$ rad/s (1 kHz) and $Q = 0.7071$. With these constraints,

$$\omega_o = \frac{1}{RC} \quad \frac{1}{Q} = 3 - K \tag{79.25}$$

and $RC = 159$ μs, $T_{LP}(j0) = K = 1.586$. Selecting $C = 0.1$ μF yields $R = 1.59$ kΩ.

© 2003 by CRC Press LLC

Example 2

A Unity-Gain Low-Pass Filter. For this example let $K = 1$. Therefore, (79.23) becomes

$$\frac{1}{Q} = \sqrt{\frac{R_3C_4}{R_1C_2}} + \sqrt{\frac{R_1C_4}{R_3C_2}} = \sqrt{\frac{C_4}{C_2}}\left(\sqrt{\frac{R_3}{R_1}} + \sqrt{\frac{R_1}{R_3}}\right) \tag{79.26}$$

The desired transfer function, with the complex frequency normalized by a factor of 10^4 rad/s, is

$$\frac{V_2(s)}{V_1(s)} = \frac{0.988}{s^2 + 0.179s + 0.988} = \frac{T_{LP}(j0)\omega_o^2}{s^2 + \dfrac{\omega_o}{Q}s + \omega_o^2} \tag{79.27}$$

and $\omega_o = 0.994$ rad/s, $Q = 5.553$. To obtain a real-valued resistor ratio, pick

$$\frac{C_4}{C_2} \le \frac{1}{4Q^2} = 0.00811 \tag{79.28}$$

or $C_4/C_2 = 0.001$ in this case. Equation (79.26) yields two solutions for the ratio R_3/R_1, 30.3977 and 0.0329. From (79.22) with $\omega_o = 9.94$ krad/s, $R_1C_2 = 577$ μs. If C_2 is selected as 0.1 μF, then $C_4 = 100$ pF, $R_1 = 5.77$ kΩ, and $R_3 = 175.4$ kΩ.

A Sallen and Key bandpass circuit is shown in Fig. 79.7, and its voltage transfer function is

$$\frac{V_2(s)}{V_1(s)} = \frac{\dfrac{sK}{R_1C_5}}{s^2 + s\left(\dfrac{1}{R_1C_5} + \dfrac{1}{R_2C_5} + \dfrac{1}{R_4C_5} + \dfrac{1}{R_4C_3} - \dfrac{K}{R_2C_5}\right) + \dfrac{1}{R_4C_3C_5}\left(\dfrac{1}{R_1} + \dfrac{1}{R_2}\right)} \tag{79.29}$$

Equating this transfer function to that of (79.11) results in

$$\omega_o = \sqrt{\frac{1 + \dfrac{R_1}{R_2}}{R_1R_4C_3C_5}} \tag{79.30}$$

$$\frac{1}{Q} = \frac{\left(1 + \dfrac{R_1}{R_2}(1-K)\right)\sqrt{\dfrac{R_4C_3}{R_1C_5}} + \sqrt{\dfrac{R_1C_3}{R_4C_5}} + \sqrt{\dfrac{R_1C_5}{R_4C_3}}}{\sqrt{1 + \sqrt{\dfrac{R_1}{R_2}}}} \tag{79.31}$$

and

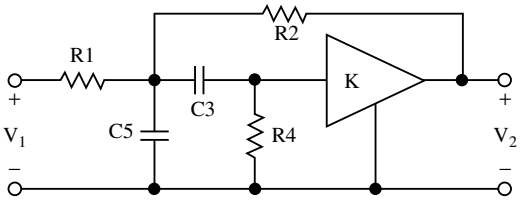

FIGURE 79.7 Bandpass Sallen and Key filter.

© 2003 by CRC Press LLC

$$T_{BP}(j0) = \frac{\dfrac{K}{R_1C_5}}{\dfrac{1}{R_1C_5} + \dfrac{1}{R_2C_5} + \dfrac{1}{R_4C_5} + \dfrac{1}{R_4C_3} + \dfrac{K}{R_2C_5}} \tag{79.32}$$

These three equations contain six unknowns. A common constraint is to set $K = 2$, requiring the gain block to have two equal-valued resistors connected around an op-amp.

Example 3

An Equal-Capacitance Gain-of-2 Bandpass Filter. Design a bandpass filter with $\omega_n = 1$ and $Q = 2$. Arbitrarily select $C_3 = C_5 = 1$ F and $K = 2$. If R_1 is selected to be 1 Ω, then (79.11), (79.29), and (79.30) give

$$\omega_o^2 = \left(1 + \frac{R_1}{R_2}\right)\frac{1}{R_4} = 1 \tag{79.33}$$

and

$$\frac{\omega_o}{Q} = 1 - \frac{1}{R_2} + \frac{2}{R_4} = \frac{1}{2} \tag{79.34}$$

Solving these equations gives $R_2 = 0.7403$ Ω and $R_4 = 2.3508$ Ω. Practical values are achieved after frequency and impedance denormalizations are made.

The high-pass filter, the third type of filter to be discussed, is shown in Fig. 79.8. Its transfer function is

$$\frac{V_2(s)}{V_1(s)} = \frac{s^2K}{s^2 + s\left(\dfrac{1}{R_2C_1} + \dfrac{1}{R_4C_3} + \dfrac{1}{R_4C_1} - \dfrac{K}{R_2C_1}\right) + \dfrac{1}{R_2R_4C_1C_3}} \tag{79.35}$$

Equating (79.35) to (79.10) results in

$$\omega_o = \frac{1}{\sqrt{R_2R_4C_1C_3}} \tag{79.36}$$

$$\frac{1}{Q} = \sqrt{\frac{R_4C_3}{R_2C_1}} + \sqrt{\frac{R_2C_1}{R_4C_3}} + \sqrt{\frac{R_2C_3}{R_4C_1}} - K\sqrt{\frac{R_4C_3}{R_2C_1}} \tag{79.37}$$

and

$$T_{HP}(j\infty) = K \tag{79.38}$$

The design procedure using these equations is similar to that for the low-pass and bandpass filters.

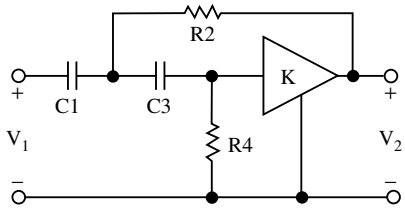

FIGURE 79.8 High-pass Sallen and Key filter.

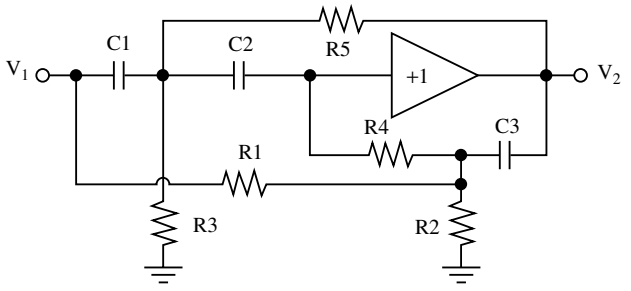
(a)



(b)

FIGURE 79.9 Notch filters derived from center-loaded twin-*T* networks: (a) $\omega_z \le \omega_p$, (b) $\omega_z \le \omega_p$ [10].

The last type of second-order filter in this section is the notch filter, shown in Fig. 79.9. The general transfer function for the notch filter is

$$\frac{V_2(s)}{V_1(s)} = T_N(j0)\frac{s^2+\omega_z^2}{s^2+\frac{\omega_p}{Q_p}s+\omega_p^2} \tag{79.39}$$

where ω_p and ω_z are the pole and zero frequencies (ω_o), respectively, and Q_p is the pole Q. For the circuit of Fig. 79.9(a),

$$T_N(j0) = \frac{\omega_z^2}{\omega_p^2} \quad R_2C_4 = \frac{\sqrt{1+a}}{\omega_p} \tag{79.40}$$

and

$$R_2 = (1+a)R_1 = 2R_3 = aR_4 \quad C_4 = \frac{\omega_z^2}{\omega_p^2}C_1 = C_2 + C_1 = \frac{C_5}{2} \tag{79.41}$$

For the circuit of Fig. 79.9(b).

$$T_N(j0) = 1 \quad R_2C_4 = \frac{\sqrt{1+a}}{\omega_p} \tag{79.42}$$

and

$$R_4 = (1+a)\frac{\omega_z^2}{\omega_p^2}R_1 = (1+a)(R_1+R_2) = aR_3 = 2R_5, \quad C_1 = C_2 = \frac{C_3}{2} \tag{79.43}$$

© 2003 by CRC Press LLC

The Q for both notch circuits is

$$Q = \frac{\sqrt{1+a}}{a} \tag{79.44}$$

so a is a helpful design parameter for these circuits. For typical values of Q, say 0.5, 1, and 5, the corresponding values of a are 4.828, 1.618, and 0.2210, respectively.

79.5 Second-Order Biquadratic Filters

Next, second-order biquadratic functions will be described. These functions are general realizations of the second-order transfer function. Filters implementing biquadratic functions, often referred to as biquads, are found in many signal processing applications.

The Biquadratic Transfer Function

The general form of the second-order biquadratic transfer function is

$$T(s) = H\frac{s^2 + b_1 s + b_0}{s^2 + a_1 s + a_0} = H\frac{s^2 + \frac{\omega_z}{Q_z}s + \omega_z^2}{s^2 + \frac{\omega_p}{Q_p}s + \omega_p^2} \tag{79.45}$$

with the pole locations given by (79.8) and the zero locations by

$$z_1, z_2 = -\frac{\omega_z}{2Q_z} \pm j\omega_z\sqrt{1 - \frac{1}{4Q_z^2}} \tag{79.46}$$

where Q_p and Q_z are the pole and zero Q, respectively. Filters capable of implementing this voltage transfer function are called biquads since both the numerator and denominator of their transfer functions contain biquadratic expressions. The zeros described by the numerator of (79.45) strongly influence the magnitude response of the biquadratic transfer function and determine the filter type (low-pass, high-pass, etc.).

The notch filter form of the biquadratic transfer function is

$$T_{\text{NF}}(s) = H\frac{s^2 + \omega_z^2}{s^2 + \frac{\omega_p}{Q_p}s + \omega_p^2} \tag{79.47}$$

with zeros located at $s = \pm j\omega_z$. Attenuation of high or low frequencies is determined by selection of ω_z relative to ω_p. The low-pass notch filter (LPN) requires $\omega_z > \omega_p$, shown in Fig. 79.10(a) and the high-pass notch filter (HPN) requires $\omega_p > \omega_z$, shown in Fig. 79.10(b).

An all-pass filter implemented using the biquadratic transfer function has the general form

$$T_{\text{AP}}(s) = H\frac{s^2 - \frac{\omega_z}{Q_z}s + \omega_z^2}{s^2 + \frac{\omega_p}{Q_p}s + \omega_p^2} \tag{79.48}$$

The all-pass magnitude response is independent of frequency; i.e., its magnitude is constant. The all-pass filter finds use in shaping the phase response of a system. To accomplish this, the all-pass has right-half plane zeros that are mirror images around the imaginary axis of left-half plane poles.

© 2003 by CRC Press LLC

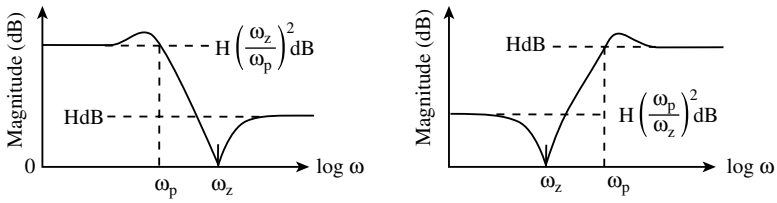


FIGURE 79.10 Frequency response of second-order notch filters. (a) $\omega_z > \omega_p$. (b) $\omega_p > \omega_z$.

Biquad Implementations

A single-amplifier low-gain realization [4] of the biquadratic transfer function with transmission zeros on the $j\omega$ axis is shown in Fig. 79.11. Zeros are generated by the circuit's input "twin-*T*" *RC* network. This filter is well suited for implementing elliptic functions. Its transfer function has the form

$$T(s) = H\frac{s^2+\omega_z^2}{s^2+\frac{\omega_p}{Q_p}s+\omega_p^2} = H\frac{s^2+b_o^2}{s^2+a_1 s+a_o^2} \tag{79.49}$$

The selection of element $Y(s)$ in the filter circuit can be a resistor or capacitor. If the condition $\omega_p > \omega_z$ is desired, $Y = 1/R$ is chosen. For this choice the resulting transfer function has the form

$$T(s) = \frac{V_2(s)}{V_1(s)} = \frac{K\left(s^2+1/a^2\right)}{s^2+\left(m+1/a\right)\left[1/R+\left(2-K\right)/m\right]s+\left[1+\left(m+1\right)/R\right]/a^2} \tag{79.50}$$

where, *K*, *m*, and *a* are defined in Fig. 79.11. The design parameter *m* is used to control the spread of circuit element values. The design equations for this filter resulting from equating (79.49) and (79.50) are

$$a = \frac{1}{\sqrt{b_o}} \tag{79.51}$$

$$R = \frac{m+1}{a_o/b_o - 1} \tag{79.52}$$

$$K = 2+\frac{m}{m+1}\left(\frac{a_o}{b_o}-1-\frac{a_1}{\sqrt{b_o}}\right) \tag{79.53}$$

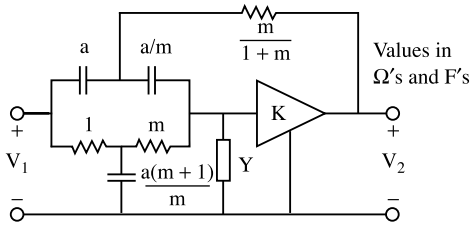

FIGURE 79.11 A low-gain realization for biquadratic network functions [5].

© 2003 by CRC Press LLC

and

$$H = K \tag{79.54}$$

If the condition $\omega_z > \omega_p$ is desired, then $Y = s(aC)$ is chosen. This choice has the following transfer function:

$$\frac{V_2(s)}{V_1(s)} = \frac{\dfrac{K\left(s^2 + 1/a^2\right)}{(m+1)C+1}}{s^2 + \left\{\dfrac{(m+1)\left[C + (2-K)/m\right]}{a\left[(m+1)C+1\right]}\right\}s + \dfrac{1}{a^2\left[(m+1)C+1\right]}} \tag{79.55}$$

The design equations follow from equating (79.49) and (79.55) to get

$$a = \frac{1}{\sqrt{b_o}} \tag{79.56}$$

$$C = \frac{b_o/a_o - 1}{m+1} \tag{79.57}$$

$$K = 2 + \frac{m}{m+1}\left(\frac{b_o}{a_o} - 1 - \frac{a_1\sqrt{b_o}}{a_o}\right) \tag{79.58}$$

and

$$H = \frac{a_o}{b_o}K \tag{79.59}$$

As before, the factor m is chosen arbitrarily to control the spread of element values.

Example 4

A Low-Pass Elliptic Filter. It is desired to realize the elliptic voltage transfer function given as

$$\frac{V_2(s)}{V_1(s)} = \frac{H\left(s^2 + 2.235990\right)}{s^2 + 0.641131s + 1.235820}$$

This transfer function will have a 1-dB ripple in the passband, and at least 6 dB of attenuation for all frequencies greater than 1.2 rad/s [12]. Obviously, the second choice described above applies. From (79.56)–(79.59), with $m = 0.2$, we find that $a = 0.66875$, $C = 0.67443$, $K = 2.0056$, and $H = 1.1085$.

Biquadratic transfer functions can also be implemented using the two-amplifier low-gain configuration in Fig. 79.12 [5]. When zeros located off the $j\omega$ axis are desired, the design equations for the two-amplifier

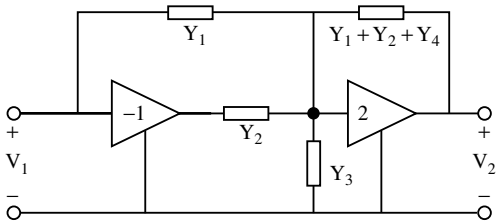

FIGURE 79.12 Two-amplifier low-gain biquad configuration.

© 2003 by CRC Press LLC

low-gain configuration are simpler than those required by the single-amplifier low-gain configuration. Also note that the required gain blocks of –1 and +2 are readily implemented using operational amplifiers. The transfer function for this configuration is

$$\frac{V_2(s)}{V_1(s)} = \frac{2(Y_1 - Y_2)}{Y_3 - Y_4} \tag{79.60}$$

The values of the admittances are determined by separately dividing the numerator and denominator by $s + c$, where c is a convenient value greater than zero. Partial fraction expansion results in expressions that can be implemented using *RC* networks. From the partial fraction expansion of the numerator divided by $s + c$, the pole residue at $s = -c$ is

$$k_b = \frac{H(c^2 - cb_1 + b_o)}{-c} \tag{79.61}$$

Depending on c, b_1, and b_o, the quality k_b can be positive or negative. If positive, Y_1 is

$$Y_1 = \frac{Hs}{2} + \frac{Hb_o}{2c} + \frac{1}{2/k_b + 2c/k_b s} \tag{79.62}$$

with $Y_2 = 0$, removing the inverting gain amplifier from the circuit. The *RC* network used to realize Y_1 when k_b is positive is shown in Fig. 79.13(a). If k_b is negative, Y_1 and Y_2 become

$$Y_1 = \frac{Hs}{2} + \frac{Hb_o}{2c} \text{ and } Y_2 = \frac{1}{2/|k_b| + 2c/|k_b| s} \tag{79.63}$$

Realizations for Y_1 and Y_2 for this case are shown in Fig. 79.13(b). In determining Y_3 and Y_4, the partial fraction expansion of the denominator divided by $s + c$ yields a pole residue at $s = -c$,

$$k_a = \frac{c_2 - ca_1 + a_o}{-c} \tag{79.64}$$

If k_a is positive, then $Y_4 = 0$ and Y_3 is

$$Y_3 = s + \frac{a_o}{c} + \frac{1}{1/k_a + c/k_a s} \tag{79.65}$$

The realization of Y_3 is shown in Fig. 79.14(a). For a negative k_a, Y_3 and Y_4 become

$$Y_3 = s + \frac{a_o}{c} \tag{79.66}$$

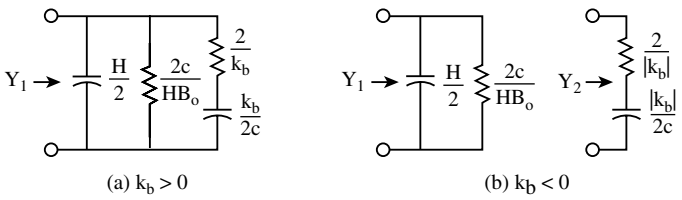

FIGURE 79.13 Realizations for $Y_1(s)$ and $Y_2(s)$ in Fig. 79.12.

© 2003 by CRC Press LLC

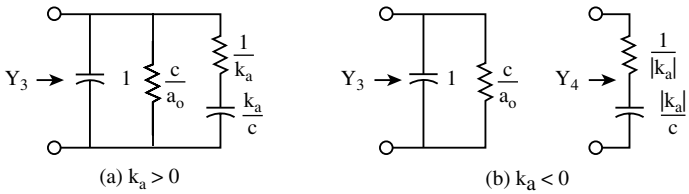

FIGURE 79.14 Realizations for $Y_3(s)$ and $Y_4(s)$ in Fig. 79.12.

and

$$Y_4 = \frac{1}{1/|k_a| + c/|k_a|s} \tag{79.67}$$

RC network realizations for Y_3 and Y_4 are shown in Fig. 79.14(b).

Example 5

An All-Pass Function **[5].** It is desired to use the configuration of Fig. 79.12 to realize the following all-pass function:

$$\frac{V_2(s)}{V_1(s)} = \frac{s^2 - 4s + 4}{s^2 + 4s + 4}$$

The choice of $c = +2$ will simplify the network. For this choice the numerator partial-fraction expansion is

$$\frac{s^2 = 4s + 4}{s + 2} = s + 2 - \frac{8s}{s + 2}$$

Hence $Y_1(s) = (s + 2)/2$ and $Y_2(s) = 4s/(s + 2)$. The denominator partial-fraction expansion is

$$\frac{s^2 + 4s + 4}{s + 2} = s + 2$$

Thus, $Y_3(s) = (s + 2) + [4s/(s + 2)]$ and $Y_4(s) = 0$.

79.6 Higher Order Filters

Many applications require filters of order greater than two. One way to realize these filters is simply to cascade second-order filters to implement the higher order filter. If the order is odd, then one first-order (or third-order) section will be required. The advantage of the cascade approach is that it builds on the precious techniques described in this section. The desired high-order transfer function of the filter $T(s)$ will be broken into second-order functions $T_k(s)$ so that

$$T(s) = T_1(s)T_2(s)T_3(s)\ldots T_{n/2}(s) \tag{79.68}$$

Since the output impedance of the second-order sections is low, the sections can be cascaded without significant interaction.

If $T(s)$ is an odd-order function then a first-order passive network (like those shown in Fig. 79.15) can be added to the cascade of second-order functions. Both of the sections shown have nonzero output impedances, so it is advisable to use them only in the last stage of a cascade filter. Alternatively, Fig. 79.5 could be used.

© 2003 by CRC Press LLC

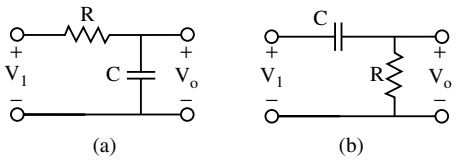

FIGURE 79.15 First-order filter sections: (a) low-pass, (b) high-pass.

Several considerations should be taken into account when cascading second-order sections together. Dynamic range is one of these considerations. To maximize the dynamic range of the filter the peak gain of each of the individual transfer functions should be equal to the maximum gain of the overall transfer function [10].

To maximize the signal-to-noise of the cascade filter, the magnitude curve in the passband of each of the individual transfer functions should be flat when possible. Otherwise, signals with frequencies in a minimum gain region of an individual transfer function will have a lower signal-to-noise ratio than other signals [10]. Another consideration is minimum noise which is achieved by placing high gain stages first.

Designing a higher order filter as a cascade of second-order sections allows the designer many options. For instance, a fourth-order bandpass filter could result from the cascade of two second-order bandpass sections or one second-order low-pass and a second-order high-pass. Since the bandpass section is the easiest of the three types to tune [10] it might be selected instead of the low-pass–high-pass combination. Other guidelines for the cascade of second-order sections include putting the low-pass or bandpass sections at the input of the cascade in order to decrease the high-frequency content of the signal, which could avoid slewing in following sections. Using a bandpass or high-pass section at the output of the cascade can reduce dc offsets or low-frequency ripple.

One option that is now available is to use CAD tools in the design of filters. When high-order filters are needed, CAD tools can save the designer time. The examples that are worked later in this section require the use of filter tables interspersed with calculations. A CAD tool such as MicroSim Filter Designer [6] can hasten this process since it eliminates the need to refer to tables. The designer can also compare filters of different orders and different approximation methods (Butterworth, Chebyshev, etc.) to determine which one is the most practical for a specific application. The Filter Designer is able to design using the cascade method as discussed in this section, and after proposing a circuit it can generate a netlist so that a program such as SPICE can simulate the filter along with additional circuitry, if necessary.

The Filter Designer allows the user to specify a filter with either a passband/stopband description, center frequency/bandwidth description, or a combination of filter order and type (low-pass, high-pass, etc.). Then an approximation type is chosen, with Butterworth, Chebyshev, inverse Chebyshev, Bessel, and elliptic types available. A Bode plot, pole-zero plot, step or impulse response plot of the transfer function can be inspected. The designer can then select a specific circuit that will be used to realize the filter. The Sallen and Key low-pass and high-pass stages and the biquad multiloop feedback (Fig. 79.16) stages are included. The *s*-coefficients of the filter can also be displayed.

The Filter Designer allows modifications to the specifications, *s*-coefficients, or actual components of the circuit in order to examine their effect on the transfer function. There is also a rounding function that will round components to 1, 5, or 10 percent values for resistors and 5 percent for capacitors and then recompute the transfer function based on these new component values. Finally, the package offers a resize function that will rescale components without changing the transfer function.

Example 6

A Fifth-Order Low-Pass Filter. Design a low-pass filter using the Chebyshev approximation with a 1-dB equiripple passband, a 500 Hz passband, 45 dB attenuation at 1 kHz, and a gain of 10. Using a nomograph for Chebyshev magnitude functions, the order of this function is found to be five [5]. Using this information and a chart of quadratic factors of 1.0-dB equal-ripple magnitude low-pass functions, the transfer function is found to be

© 2003 by CRC Press LLC

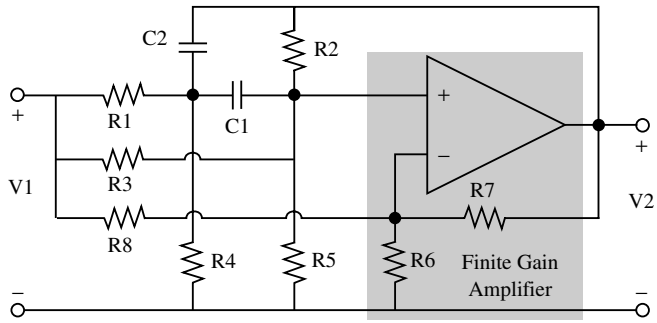

FIGURE 79.16 Biquad multiloop feedback stage.

$$T(s_n) = \frac{0.9883K_1}{s_n^2 + 0.1789s_n + 0.9883} \cdot \frac{0.4293K_2}{s_n^2 + 0.4684s_n + 0.4293} \cdot \frac{0.2895K_3}{s_n + 0.2895}$$

Denormalizing the frequency with $s_n = s/500(2\pi)$ gives

$$T_1(s) = \frac{9{,}751{,}000K_1}{\left(s^2 + 562s + 9{,}751{,}000\right)}$$

$$T_2(s) = \frac{4{,}240{,}000K_2}{\left(s^2 + 1470s + 4{,}240{,}000\right)}$$

and

$$T_3(s) = \frac{909K_3}{s + 909}$$

Stages 1 and 2 will be Sallen and Key low-pass filters with R = 10 kΩ. Following the guidelines given above, stage 1 will have the gain of 10 and successive stages will have unity gain. Using (79.23) for stage 1 ($R_2 = R_4 = R$),

$$\frac{1}{Q} = 2\sqrt{\frac{C_4}{C_2}} + (1 - K)\sqrt{\frac{C_2}{C_4}} = 0.1800$$

So $C_4 = 4.696C_2$. Substituting this into (79.22),

$$\omega_n = \frac{1}{2.167RC_2} = 3123 \ \text{rad/s}$$

Thus, C_2 = 14.8 nF and C_4 = 69.4 μF. Analysis for stage 2 with K_2 = 1 yields C_2 = 0.135 μF and C_4 = 17.4 nF. Stage 3 is simply an RC low-pass section with R = 10 kΩ and C = 0.110 μF. The schematic for this filter is shown in Fig. 79.17.

Example 7

A Fourth-Order Bandpass Filter. Design a bandpass filter centered at 4 kHz with a 1-kHz bandwidth. The time delay of the filter should be 0.5 ms (with less than 5 percent error at the center frequency).

The group of filters with constant time delays are called Thomson filters. For this design, begin with a low-pass filter with the normalized bandwidth of 1 kHz/4 kHz, or 0.25. Consulting a table for delay error in Thomson filter [5] shows that a fourth-order filter is needed. From tables for Thomson filters, the quadratic factors for the fourth-order low-pass filter give the overall transfer function

© 2003 by CRC Press LLC

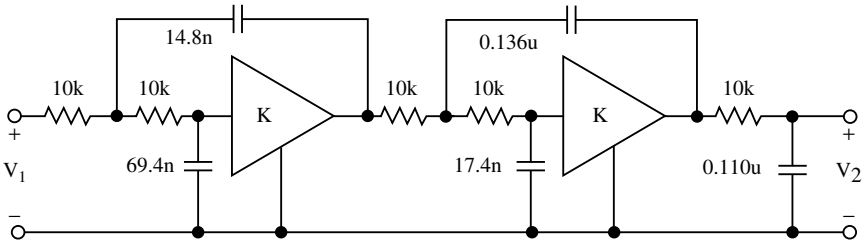

FIGURE 79.17 A fifth-order low-pass filter.

$$T_{\mathrm{LP}}(s_n) = \frac{1}{\left(s_n^2 + 4.208s_n + 11.488\right)\left(s_n^2 + 5.792s_n + 9.140\right)}$$

To convert $T_{\mathrm{LP}}(s_{\mathrm{n}})$ to a bandpass function $T_{\mathrm{BP}}(s_{\mathrm{n}})$, the transformation

$$s_n = \frac{\omega_R}{\mathrm{BW}} \frac{s_{bn}^2 + 1}{s_{bn}} = 4\frac{s_{bn}^2 + 1}{s_{bn}}$$

is used, giving

$$T_{\mathrm{BP}n}(s) = \frac{s^4/256}{\left(s^4 + 1.05s^3 + 2.72s^2 + 1.05s + 1\right)\left(s^4 + 1.45s^3 + 2.57s^2 + 1.45s + 1\right)}$$

ω_{R} and BW are the geometric center frequency and bandwidth of the bandpass filter. The polynomials in the denominator of the expression are difficult to factor, so an alternate method can be used to find the poles of the normalized bandpass function. Each pole p_{In} of the normalized low-pass transfer function generates two poles in the normalized bandpass transfer function [5], [10] given by

$$p_{bn} = \frac{\mathrm{BW}\, p_{1n}}{2\omega_R} \pm \sqrt{\left(\frac{BW\, p_{1n}}{2\omega_R}\right)^2 - 1} \tag{79.69}$$

Using (79.69) with each of the poles of $T_{\mathrm{LP}}(s_{\mathrm{n}})$ gives the following pairs of poles (which are also given in tables for Thomson filters):

$$p_{b1n} = -0.1777 \pm j0.6919 \qquad p_{b2n} = -0.3483 \pm j1.356$$

$$p_{b3n} = -0.3202 \pm j0.8310 \qquad p_{b4n} = -0.4038 \pm j1.0478$$

Note that each low-pass pole does not generate a conjugate pair, but when taken together, the bandpass poles generated by the low-pass poles will be conjugates. The unnormalized transfer functions generated by the normalized bandpass poles are

$$T_{\mathrm{BP1}}(s) = \frac{6283s}{\left(s^2 + 8932s + 322.3 \cdot 10^6\right)}$$

$$T_{\mathrm{BP2}}(s) = \frac{6283s}{\left(s^2 + 1751s + 1238 \cdot 10^6\right)}$$

$$T_{\mathrm{BP3}}(s) = \frac{6283s}{\left(s^2 + 16100s + 501.0 \cdot 10^6\right)}$$

© 2003 by CRC Press LLC

and

$$T_{BP4}(s) = \frac{6283s}{\left(s^2 + 20300s + 796.5 \cdot 10^6\right)}$$

The overall transfer function realized by these four intermediate transfer functions could also be grouped into two low-pass stages followed by two high-pass stages, however, this example will use four bandpass filters. Using the equal-capacitance gain of two-design strategy for the Sallen and Key bandpass stage,

$$\omega_n^2 = \left(1 + \frac{R_1}{R_2}\right)\frac{1}{R_1 R_4 C^2} \tag{79.70}$$

$$\frac{1}{Q} = \left(\left(1 - \frac{R_1}{R_2}\right)\sqrt{\frac{R_4}{R_1}} + 2\sqrt{\frac{R_1}{R_4}}\right)\sqrt{\frac{R_2}{R_1 + R_2}} \tag{79.71}$$

and

$$H_o = \left(\frac{\frac{K}{R_1}}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{2}{R_4} - \frac{K}{R_2}}\right) \tag{79.72}$$

Making the further assignment $R_2 = R_1$ simplifies the equations to

$$\omega_n^2 = \frac{2}{R_1 R_4 C^2} \qquad \frac{1}{Q} = 2\sqrt{\frac{R_1}{R_4}} \qquad \text{and } H_o = 2Q^2$$

Selecting C = 1 nF gives the component values shown in Fig. 79.18, the schematic diagram for the fourth-order bandpass filter. While the gain of the filter is greater than unity, the output can be attenuated if unity gain is desired.

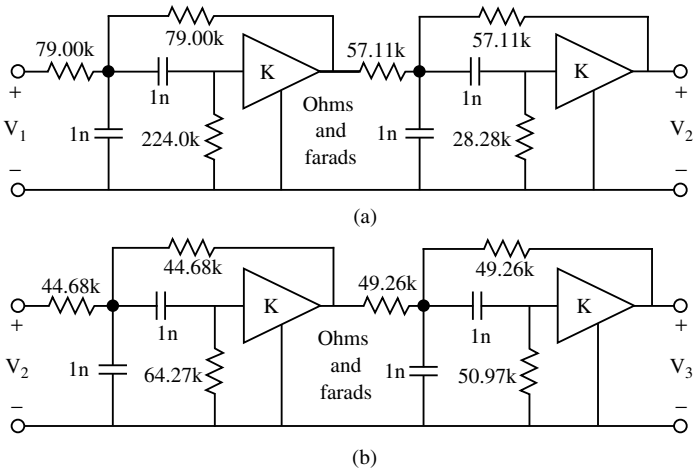

FIGURE 79.18 Fourth-order bandpass filter. (a) Stages 1 and 2. (b) Stages 3 and 4.

© 2003 by CRC Press LLC

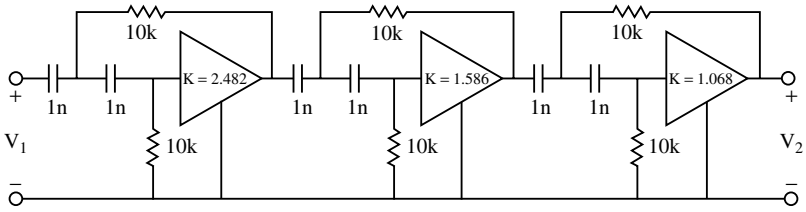

FIGURE 79.19 A sixth-order high-pass filter (all component values are Ω or F)

Example 8

A Sixth-Order High-Pass Filter. Design a Butterworth high-pass filter with a –3-dB frequency of 100 kHz and a stopband attenuation of 30 dB at 55 kHz. A nomograph for Butterworth (maximally flat) functions indicates that this filter must have an order of at least six. A table for quadratic factors of Butterworth functions [5] gives

$$T(s_n) = \frac{K_1}{(s_n^2 + 0.518 s_n + 1)} \frac{K_2}{(s_n^2 + 1.414 s_n + 1)} \frac{K_3}{(s_n^2 + 1.932 s_n + 1)}$$

Using $s_{nH} = 1/s_n$ for low-pass to high-pass transformation and $s_n = s/2\pi \cdot 10^5$ to denormalize the frequency,

$$T_1(s) = \frac{s^2 K_1}{s^2 + 325{,}500 s + 394.8 \cdot 10^9}$$

$$T_2(s) = \frac{s^2 K_2}{s^2 + 888{,}600 s + 394.8 \cdot 10^9}$$

and

$$T_3(s) = \frac{s^2 K_3}{s^2 + 1{,}214{,}000 s + 394.8 \cdot 10^9}$$

The Sallen and Key high-pass filter can be used to implement all three of these stages. Picking a constant R, constant C design style with $\omega_n = 10^5$ rad/s gives $R = 10$ kΩ and $C = 1$ nF for each stage. Equation (79.23) then simplifies to

$$\frac{1}{Q} = 3 - K$$

for each stage. Thus $K_1 = 2.482$, $K_2 = 1.586$, and $K_3 = 1.068$, and the resulting high-pass filter is shown in Fig. 79.19.

Example 9

A Fifth-Order Low-Pass Filter. Design a low-pass filter with an elliptic characteristic such that it has a 1-dB ripple in the passband (which is 500 Hz) and 65 dB attenuation at 1 kHz. From a nomograph for elliptic magnitude functions, the required order of this filter is five. A chart for a fifth-order elliptic filter with 1-dB passband ripple gives

$$T(s_n) = \frac{H(s_n^2 + 4.365)(s_n^2 + 10.568)}{(s_n + 0.3126)(s_n^2 + 0.4647 s_n + 0.4719)(s_n^2 + 0.1552 s_n + 0.9919)}$$

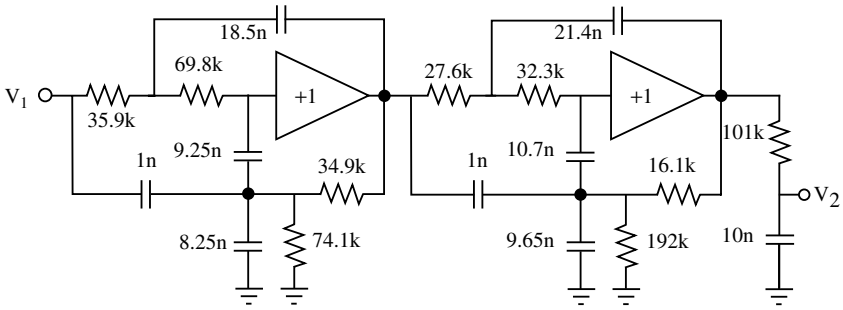

FIGURE 79.20 Fifth-order low-pass filter (all component values are Ω or F).

This transfer function can be realized with two notch filters like Fig. 79.9(a) and a first-order low-pass section. Denormalizing the frequency with $s_n = s/1000\pi$ gives

$$T_1(s) = \frac{H_1\left(s^2 + 43{,}080{,}000\right)}{s^2 + 1{,}460s + 4{,}657{,}000}$$

$$T_2(s) = \frac{H_2\left(s^2 + 104{,}300{,}000\right)}{s^2 + 487.6s + 9{,}790{,}000}$$

and

$$T_3(s) = \frac{982.1}{s + 982.1}$$

For the first stage, use (79.40) and (79.44) $H_1 = 0.1081$ and $a = 0.9429$. Setting $C_1 = 1$ nF and applying (79.40) and (79.41),

$$C_1 = 1 \text{ nF} \qquad C_4 = 9.25 \text{ nF} \qquad C_2 = 8.25 \text{ nF} \qquad C_5 = 18.5 \text{ nF}$$

$$R_2 = 69.8 \text{ k}\Omega \qquad R_1 = 35.9 \text{ k}\Omega \qquad R_3 = 34.9 \text{ k}\Omega \qquad R_1 = 74.1 \text{ k}\Omega$$

Similarly, in the second stage $H_2 = 0.0939$, $a = 0.1684$, and

$$C_1 = 1 \text{ nF} \qquad C_4 = 10.7 \text{ nF} \qquad C_2 = 9.65 \text{ nF} \qquad C_5 = 21.4 \text{ nF}$$

$$R_2 = 32.3 \text{ k}\Omega \qquad R_1 = 27.6 \text{ k}\Omega \qquad R_3 = 16.1 \text{ k}\Omega \qquad R_4 = 192 \text{ k}\Omega$$

The third stage can be a simple *RC* low-pass with $C = 10$ nF and $R = 101$ kΩ. The resulting cascade filter is shown in Fig. 79.20.

These examples illustrate both the use of the Filter Designer and the method of cascading first- and second-order stages to achieve higher order filters.

79.7 Influence of Nonidealities

Effective filter design requires an understanding of how circuit nonidealities influence performance. Important nonidealities to consider include passive component tolerance (i.e., resistor and capacitor accuracy), amplifier gain accuracy, finite amplifier gain-bandwidth, amplifier slew rate, and noise.

TABLE 79.1 Properties of Sensitivity Function [5]

$S_x^{ky} = S_{kx}^{y} = S_x^y$	$S_x^{y_1/y_2} = S_x^{y_1} - S_x^{y_2}$
$S_x^x = S_x^{kx} = S_{kx}^{kx} = 1$	$S_{x_1}^{y} = S_{x_2}^{y} S_{x_1}^{y_2}$
$S_{1/x}^{y} = S_x^{1/y} = -S_x^y$	$S_x^y = S_x^{\lvert y\rvert} + j\arg y S_x^{\arg y}$
$S_x^{y_1 y_2} = S_x^{y_1} + S_x^{y_2}$	$S_x^{\arg y} = \dfrac{1}{\arg y}\operatorname{Im} S_x^y \quad (*)$
$S_x^{\prod_{i=1}^{n} y_i} = \sum_{i=1}^{n} S_x^{y_i}$	$S_x^{\lvert y\rvert} = \operatorname{Re} S_x^y \quad (*)$
$S_x^{y^n} = nS_x^y$	$S_x^{y+x} = \dfrac{1}{y+z}\left(yS_x^y + zS_x^z\right)$
$S_x^{x^n} = S_x^{kx^n} = n$	$S_x^{\sum_{i=1}^{n} y_i} = \dfrac{\sum_{i=1}^{n} y_i S_x^{y_i}}{\sum_{i=1}^{n} y_i}$
$S_{x^n}^{y} = \dfrac{1}{n} S_x^y$	$S_x^{\ln y} = \dfrac{1}{\ln y} S_x^y$
$S_{x^n}^{x} = S_{kx^n}^{x} = \dfrac{1}{n}$	

Relations denoted by "(*)" use y to indicate a complex quantity and x to indicate a real quantity.

Sensitivity Analysis

Classical sensitivity functions [5] are valuable tools for analyzing the influence of nonidealities on filter performance. The sensitivity function, S_x^y [2], by definition, describes the change in a performance characteristic of interest, say y, due to the change in nominal value of some element x,

$$S_x^y = \left(\frac{\partial y}{\partial x}\right)\frac{x}{y} = \frac{\partial y/y}{\partial y/x} = \frac{\partial(\ln y)}{\partial(\ln x)} \tag{79.73}$$

The mathematical properties of the sensitivity function are given in Table 79.1 [5] for convenient reference.

A valuable result of the sensitivity function is that it enables us to estimate the percentage change in a performance characteristic due to variation in passive circuit elements from their nominal values. Consider for example a low-pass filter's cutoff frequency ω_o, which is a function of R_1, R_2, C_1, and C_2. Using sensitivity functions, the percentage change in ω_o is estimated as [3]

$$\frac{\Delta\omega_o}{\omega_o} \approx S_{R_1}^{\omega_o}\left(\frac{\Delta R_1}{R_1}\right) + S_{R_2}^{\omega_o}\left(\frac{\Delta R_2}{R_2}\right) + S_{C_1}^{\omega_o}\left(\frac{\Delta C_1}{C_1}\right) + S_{C_2}^{\omega_o}\left(\frac{\Delta C_2}{C_2}\right) \tag{79.74}$$

Not that the quantity $\Delta\omega_o/\omega_o$ represents a small differential change in the cutoff frequency ω_o. When considering the root locus of a filter design, the change in pole location due to a change in gain K, for example, could be described by [3]

$$S_K^{p_1} = \left(\frac{\partial\sigma_o}{\partial K}\right) + j\frac{\partial\omega_o}{\partial K}\left(\frac{K}{\omega_o}\right) \tag{79.75}$$

© 2003 by CRC Press LLC

where the pole $p_1 = \sigma_o + j\omega_o$. Furthermore, the filter transfer function's magnitude and phase sensitivity is defined by [3]

$$S_x^{T(j\omega)} = S_x^{|T(j\omega)|} + S_x^{\theta(j\omega)} = \mathrm{Re}\, S_x^{T(j\omega)} + \frac{1}{\theta(\omega)} \mathrm{Im}\, S_x^{T(j\omega)} \tag{79.76}$$

and

$$S_x^{T(j\omega)} = \frac{x}{|T(j\omega)|} \frac{\partial}{\partial x} |T(j\omega)| + jx \frac{\partial \theta(\omega)}{\partial x} \tag{79.77}$$

where $T(j\omega) = |T(j\omega)| \exp[j\theta(\omega)]$. The interested reader is directed to [5, ch. 3] for a detailed discussion of sensitivity.

Gain-Bandwidth

Now let us consider some of the amplifier nonidealities that influence the performance of our low-gain amplifier filter realizations. There are two amplifier implementations of interest each using an operational amplifier. They are the noninverting configuration and the inverting configuration shown in Fig. 79.21.

The noninverting amplifier is described by

$$K = \frac{V_2}{V_1} = \frac{A_d(s)}{1 + A_d(s)/K_o} \tag{79.78}$$

where $K_o = 1 + R_B/R_A$ is the ideal gain, and $A_d(s)$ is the operational amplifier's differential gain. Using the dominant-pole model for the op-amp,

$$A_d(s) = \frac{\mathrm{GB}}{s + \omega_a} = \frac{A_o \omega_a}{s + \omega_a} \tag{79.79}$$

where A_o is the dc gain, ω_a is the dominant pole, and GB is the gain-bandwidth product of the op-amp. Inserting (79.79) into (79.78) gives

$$K = \frac{\mathrm{GB}}{s + \omega_a(1 + A_o/K_o)} \approx \frac{\mathrm{GB}}{s + \mathrm{GB}/K_o} \tag{79.80}$$

The approximation of the K expression is valid provided $A_o \gg K_o$. The magnitude and phase of (79.80) are

$$|K(j\omega)| = \frac{\mathrm{GB}}{\sqrt{\omega^2 + (\mathrm{GB}/K_o)^2}} \tag{79.81}$$

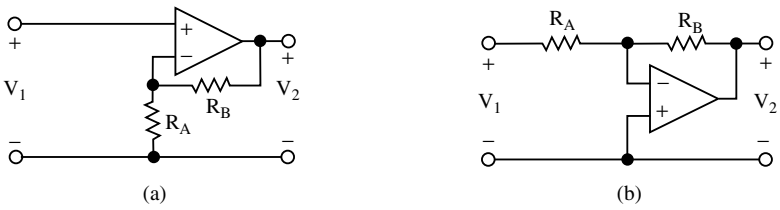

FIGURE 79.21 (a) Noninverting amplifier and (b) inverting amplifier.

© 2003 by CRC Press LLC

and

$$\arg\left[K(j\omega)\right] = -\tan^{-1}\left(\frac{\omega}{\mathrm{GB}}K_o\right) \tag{79.82}$$

Note that for $\omega > \mathrm{GB}/K_o$, (79.81) and (79.82) may be approximated by

$$\left|K(j\omega)\right| \approx K_o \tag{79.83}$$

and

$$\arg\left[K(j\omega)\right] \approx -\frac{\omega}{\mathrm{GB}}K_o \tag{79.84}$$

The phase expression (79.84) describes the phase lag introduced to an active filter realization by the op-amp's finite gain-bandwidth product. To illustrate the importance of taking this into account, consider a positive-gain filter with $K_o = 3$ and operation frequency $\omega = \mathrm{GB}/30$ [5]. According to (79.84), a phase lag of 5.73° is introduced to the filter by the op-amp. Such phase lag might significantly impair the performance of some filter realizations.

The inverting amplifier of Fig. 79.21(b) is described by

$$K = \frac{V_2}{V_1} = \frac{-A_d(s)\left[R_B/\left(R_A + R_B\right)\right]}{1 + A_d(s)\left[R_A/\left(R_A + R_B\right)\right]} \tag{79.85}$$

Inserting (79.79) into (79.85) gives

$$K = \frac{-\left[R_B/\left(R_A + R_B\right)\right]\mathrm{GB}}{s + \omega_a\left[1 + A_o R_A/\left(R_A + R_B\right)\right]} \approx \frac{-\left[R_B/\left(R_A + R_B\right)\right]\mathrm{GB}}{s + \mathrm{GB}\left[R_A/\left(R_A + R_B\right)\right]} \tag{79.86}$$

where as before the approximation is valid if $A_o \gg (R_A + R_B)/R_A$. The magnitude and phase expressions for (79.86) are

$$\left|K(j\omega)\right| = \frac{\mathrm{GB}\,R_B/\left(R_A + R_B\right)}{\sqrt{\omega^2 + \left[\mathrm{GB}\,R_A/\left(R_A + R_B\right)\right]^2}} \tag{79.87}$$

and

$$\arg\left[K(j\omega)\right] = \pi - \tan^{-1}\left[\frac{\omega}{\mathrm{GB}}\left(1 + \frac{R_B}{R_A}\right)\right] \tag{79.88}$$

If $\omega < \mathrm{GB}\,R_A/(R_A + R_B)$, then (79.87) and (79.88) are approximated by

$$\left|K(j\omega)\right| \approx \frac{R_B}{R_A} \tag{79.89}$$

and

$$\arg\left[K(j\omega)\right] \approx \pi - \left[\frac{\omega}{\mathrm{GB}}\left(1 + \frac{R_B}{R_A}\right)\right] \tag{79.90}$$

© 2003 by CRC Press LLC

An important limitation of the inverting configuration is its bandwidth [5], compared to that of the noninverting configuration, when small values of gain K are desired. Take for example the case where a unity-gain amplifier is needed. Using the amplifier of Fig. 79.21(a), the resistor values would be $R_B = 0$ and $R_A = \infty$. From (79.80) we see that this places a pole at $s = -\text{GB}$. Using the amplifier of Fig. 79.21(b), the resistors would be selected such that $R_B = R_A$. From (79.86) we see that a pole located at $s = -\text{GB}/2$ results. Hence, for unity-gain realizations, the inverting configuration has half the bandwidth of the noninverting case. However, for higher gains, as the ratio R_B/R_A becomes large, both configurations yield a pole location that approaches $s = -(\text{GB})R_A/R_B$.

When using the inverting configuration described above to implement a negative-gain realization, the input impedance to the amplifier is approximately R_A. R_A must then be carefully selected to avoid loading the RC network. Another problem is related to maintaining low phase lag when a high Q is desired [5]. A Q of 10 requires that the ratio R_B/R_A be approximately 900. However, to avoid a phase lag of 6° (79.90) indicates that for $Q = 10$ the maximum filter design frequency cannot exceed approximately GB/8500. If GB = 1 MHz, say if the 741 op-amp is being used, then the filter cannot function properly above a frequency of about 100 Hz.

We have seen that a practical amplifier implementation contributes a pole to the gain K of a filter due to the op-amp's finite gain-bandwidth product GB. This means that an active filter's transfer function will have an additional pole that is attributed to the amplifier. The poles then of an active filter will be influenced by this additional pole. Consider the positive-gain amplifier used in the Sallen-Key low-pass filter (Fig. 79.6). The filter's ideal transfer function is expressed in (79.21). For the equal R, equal C case ($R_1 = R_3$, $C_2 = C_4$) we have $R_B = R_A[2 - (1/Q)]$. By inserting (79.80) into (79.21), the transfer function becomes [3]

$$T(s_n) = \frac{V_2}{V_1} = \frac{\text{GB}_n}{s_n^3 + s_n^2\left(3 + \dfrac{\text{GB}_n}{1 - \dfrac{1}{Q}}\right) + s_n\left(1 + \dfrac{\text{GB}_n}{3Q - 1}\right) + \dfrac{\text{GB}_n}{3 - \dfrac{1}{Q}}} \tag{79.91}$$

where the normalized terms are defined by $s_n = s/\omega_o$ and GB_n/ω_o. The manner in which the poles of (79.91) are influenced by the amplifier's finite gain-bandwidth product is illustrated in Fig. 79.22(a). This plot is the upper left-half s_n plane. The solid lines correspond to constant values of Q and the circles correspond to discrete values of GB_n, which were the same for each Q. For $Q = 0.5$ the GB_n values are labeled. Note that the $\text{GB}_n = \infty$ case shown is the ideal case where amplifier GB is infinite. The poles shift toward the origin as ω_o approaches a value near GB. Furthermore, for large design values of Q, i.e., greater than 3, the actual Q value will decrease as ω_o approaches GB.

As another example, consider the Sallen-Key low-pass again but for the case where positive unity-gain and equal resistance ($R_1 = R_3$) are desired. When the amplifier's gain-bandwidth product is taken into account the filter's transfer function becomes [3]

$$T(s) = \frac{V_2}{V_1} = \frac{\text{GB}_n}{s_n^3 + s_n^2\left(2Q + \dfrac{1}{Q} + \text{GB}_n\right) + s_n\left(1 + \dfrac{\text{GB}_n}{Q}\right) + \text{GB}_n} \tag{79.92}$$

where again $s_n = s/\omega_o$ and $\text{GB}_n = \text{GB}/\omega_o$. The poles of (79.92) are shown in Fig. 79.22(b). The plots are similar but the (b) plot constant GB_n values for the range of Q shown are closer together than the (a) plot. This means that the poles of the unity-gain, equal R design are less sensitive to amplifier gain-bandwidth product than the equal R, equal C case. The influence GB has on Sallen-Key low-pass filter parameters is summarized in Table 79.2.

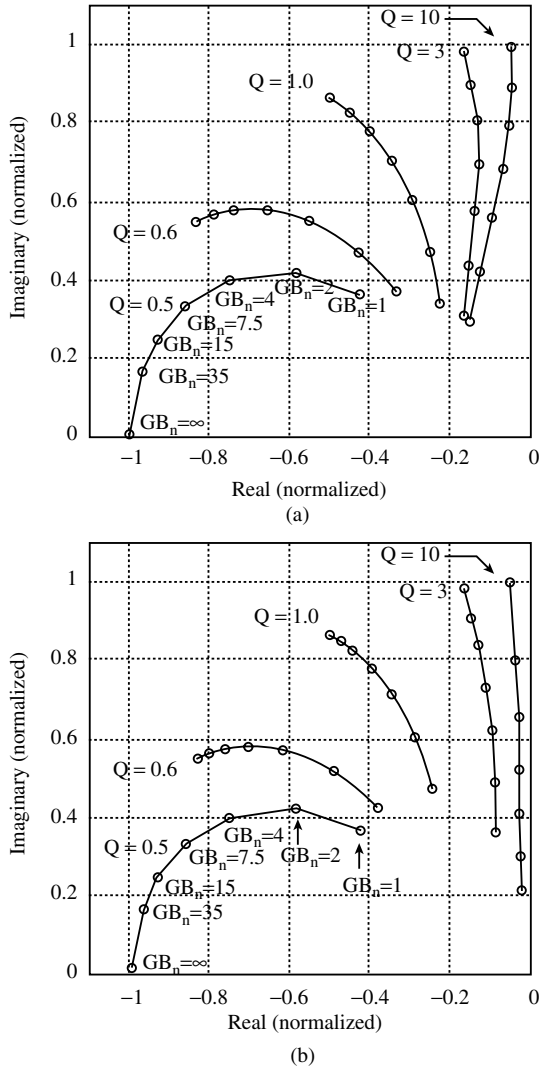

FIGURE 79.22 Effect of GB on the poles of the Sallen-Key second-order low-pass case. (a) Equal R, equal C case, (b) unity gain, equal R case.

Slew Rate

Slew rate is another operational amplifier parameter that warrants consideration in active filter design. When a filter signal level is large and/or the frequency is high, op-amp slew rate (SR) limitations can affect the small-signal behavior of amplifiers used in low-gain filter realizations. The amplifier's amplitude and phase response can be distorted by large-signal amplitudes. An analysis of slew rate induced distortion is presented in [1]. For the inverting amplifier [Fig. 79.21(b)], slewing increases the small-signal phase lag. This distortion is described by [5]

$$\arg\left[K(j\omega)\right] = \pi - \tan^{-1}\left(\frac{\left(\omega/\mathrm{GB}\left(1+R_B/R_A\right)\right)}{N(A)}\right) \tag{79.93}$$

TABLE 79.2 Summary of Finite GB on Filter Parameters

Sallen–Key Low-Pass Realizations	
Equal R, equal C	$\omega_0\,(\text{actual}) \approx \omega_o\,(\text{design})\left(1-\frac{1}{2}\left(3-\frac{1}{Q}\right)^2\frac{\omega_o}{\text{GB}}\right)$
	$Q\,(\text{actual}) \approx Q\,(\text{design})\left(1-\frac{1}{2}\left(3-\frac{1}{Q}\right)^2\frac{\omega_o}{\text{GB}}\right)$
	$\text{GB} \geq 45\left(1-\frac{1}{3Q}\right)^2\omega_0^*$
Unity-gain, equal R	$\omega_0\,(\text{actual}) \approx \omega_o\,(\text{design})\left(1-\frac{\omega_o Q}{\text{GB}}\right)$
	$Q\,(\text{actual}) \approx Q\,(\text{design})\left(1+\frac{\omega_o Q}{\text{GB}}\right)$
	$\text{GB} \geq 10\,Q\omega_0^*$

The "*" denotes the condition for $\Delta\omega_o/\omega_o = \Delta Q/Q \leq 10\%$, i.e., for ω_o and Q to change less than 10% [3].

where $N(A)$ is a describing function and A is the peak amplitude of the sinusoidal voltage input to the amplifier. $N(A) = 1$ while the op-amp is not slewing, yielding the same phase lag described by (79.88). However, for conditions where slewing is present, $N(A)$ becomes less than 1. Under such conditions the filter may become unstable. Refer to [1] and [5, ch. 4, sect. 6] for a detailed discussion of slew rate distortion.

Selecting an operational amplifier with higher slew rate can reduce large-signal distortion. Given the choice of FET input or BJT input op-amps, FET input op-amps tend to have higher slew rates and higher input signal thresholds before slewing occurs. When selecting an amplifier for a filter it is important to remember that slewing occurs when the magnitude of the output signal slope exceeds SR and when the input level exceeds a given voltage threshold. Often the slew rate of a filter's amplifier sets the final limit of performance that can be attained in a given active filter realization at high frequencies.

Noise [7]

The noise performance of a given filter design will ultimately determine the circuit's signal-to-noise ratio and dynamic range. For these reasons a strong understanding of noise analysis is required for effective filter design. In this section noise analysis of the noninverting and inverting op-amp configurations are discussed for the implementation of the gain block K. An example noise analysis is illustrated for a simple filter design.

Proceeding with noise analysis, consider the four noise sources associated with operational amplifier. Shown in Fig. 79.23, E_{n1} and E_{n2} represent the op-amp's voltage noise referred to the negative and positive

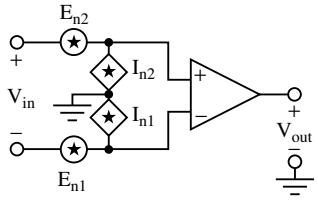

FIGURE 79.23 Operational amplifier noise model with four noise sources.

© 2003 by CRC Press LLC

inputs, respectively, and I_{n1} and I_{n2} represent the op-amp's current noise referred to the negative and positive inputs, respectively. E_{n1} and E_{n2} are related to E_n, from an op-amp manufacture's data sheet, through the relationship

$$E_n = \sqrt{E_{n1}^2 + E_{n2}^2} \quad \left[V/\sqrt{\text{Hz}}\right] \tag{79.94}$$

I_n is also usually reported in an op-amp manufacturer's data sheet. The value given for I_n is used for I_{n1} and I_{n2}.

$$I_n = I_{n1} = I_{n2} \quad \left[A/\sqrt{\text{Hz}}\right] \tag{79.95}$$

The analysis of the filter noise performance begins with the identification of all noise sources, which include the op-amp noise sources and all resistor thermal noise ($E_t = \sqrt{4\ \text{kT}\ R\Delta f}$ where 4 kT is approximately 1.65×10^{-20} V²/Ω; Hz at room temperature and Δf is the noise bandwidth). To begin the analysis, uncorrelated independent signal generators can be substituted for each noise source, voltage sources for noise voltage sources, and current sources for current noise sources. By applying superposition and using the rms value of the result, the noise contribution of each element to the total output noise E_{no} can be determined. Only squared rms values can be summed to determine E_{no}^2. The resultant expression then for E_{no}^2 should never involve subtraction of noise sources, only addition. Sources of noise in a circuit always add to the total noise at the circuit's output. The total noise referred to the input E_{ni} is simply E_{no} divided by the circuit's transfer function gain. Capacitors ideally only influence noise performance through their effect on the circuit's transfer function. That is, the transfer gain seen by a noise source to the circuit's output can be influenced by capacitors depending on the circuit. As a result, of course, a circuit's noise performance can be a strong function of frequency.

Consider again the noninverting op-amp configuration, which can be used to implement positive K. The circuit is shown in Fig. 79.24(a) with appropriate noise sources included. Resistor R_s has been included to represent the driving source's (V_1) output resistance. The simplified circuit lumps together the amplifier's noise sources into E_{na}, shown in Fig. 79.24(b). E_{na} is described by (79.96). The circuit in Fig. 79.24(b) can be used in place of the positive gain block K to simplify the noise analysis of a larger circuit. R_s obviously will be determined by the circuit seen looking back from the amplifier's input:

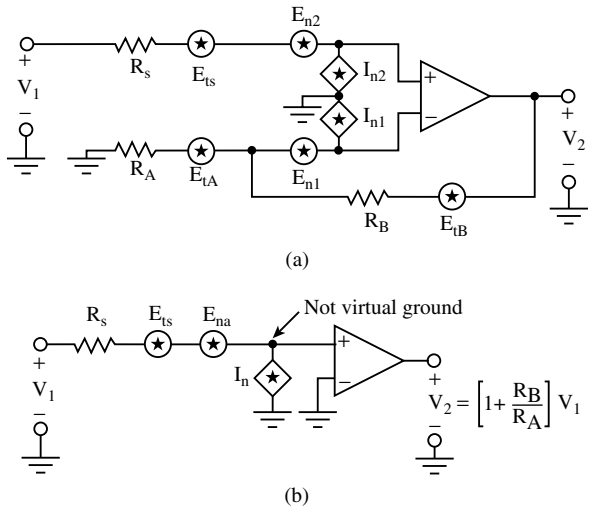

FIGURE 79.24 (a) Noninverting op-amp configuration with noise sources. (b) Simplified noninverting amplifier circuit with noise sources.

© 2003 by CRC Press LLC

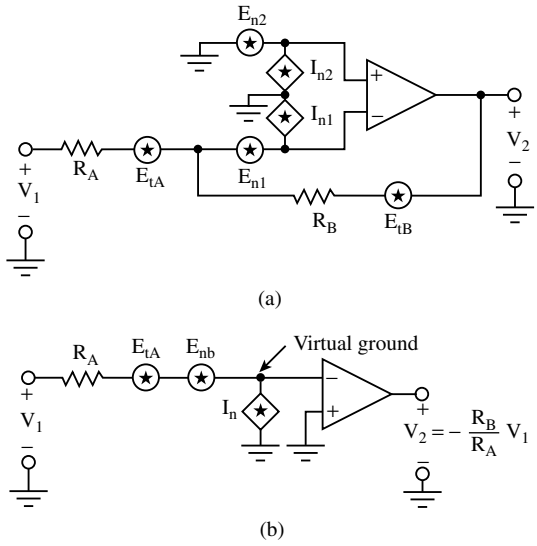

FIGURE 79.25 (a) Inverting op-amp configuration with noise sources. (b) Simplified inverting amplifier circuit with noise sources.

$$E_{na}^2 = E_n^2 + \left(\frac{R_A}{R_A + R_B}\right)^2 \left(E_{tB}^2\right) + \left(\frac{R_B}{R_A + R_B}\right)^2 \left(E_{tA}^2\right) + I_{n1}^2 \left(R_A \| R_B\right)^2 \tag{79.96}$$

The inverting op amp configuration for implementing a negative gain is shown in Fig. 79.25(a) with noise sources included. Here again, the op-amp's noise sources can be lumped together and referred to the input as noise source E_{nb} shown in Fig. 79.25(b). For simplicity, R_s has been lumped together with R_A.

E_{nb} is described by (79.97). The simplified circuit in Fig. 79.25(b) is convenient for simplifying the noise analysis of larger circuit that uses a negative gain block.

$$E_{nb}^2 = \left(1 + \frac{R_A}{R_B}\right)^2 \left(E_n^2\right) + \left(\frac{R_A}{R_B}\right)^2 \left(E_{tB}^2\right) \tag{79.97}$$

Example 10

First-Order Low-Pass Filter Noise Analysis. Noise analysis of a low-pass filter with noninverting midband gain of 6 dB and –20 dB/decade gain roll-off after a 20-kHz cutoff frequency is desired. Recall from Section 79.3 that $\omega_o = RC$. Let us designate R_1 for R and C_2 for C. To obtain $\omega_o = 2\pi(20\text{ kHz})$, commercially available component values $R_1 = 16.9\text{ k}\Omega$ and $C_2 = 470$ pF (such as a 1 percent metal-film resistor for R_1 and a ceramic capacitor for C_2) can be used. Implement K with the noninverting op-amp configuration and use Fig. 79.24(b) as a starting point of the noise analysis. The midband gain of 6 dB can be achieved by selecting $R_A = R_B$. For this example let $R_A = R_B = 10.0\text{ k}\Omega$, also available in 1 percent metal film. Including the thermal noise source for R_1, the circuit shown in Fig. 79.26 results.

From this circuit we can easily derive the output noise of the low-pass filter.

$$E_{\text{no}}^2 = K^2 \left[E_{na}^2 + \left| \frac{Z_2}{R_1 + Z_2} \right|^2 \left(E_{t1}^2\right) + \left|R_1 \| Z_2\right|^2 \left(I_n^2\right) \right] \tag{79.98}$$

where $Z_2 = 1/sC_2$, the impedance of the capacitor and E_{na} is defined by (79.96). The commercial op-amp OP-27 can be used to implement K and thus determines the values of E_n and I_n. For OP-27, $E_n = 3\text{ nV}/\sqrt{\text{Hz}}$

and $I_n = 0.4$ pA/$\sqrt{\text{Hz}}$. A comparison of the hand analysis to a PSpice simulation of this low-pass filter is shown in Fig. 79.27. The frequency dependence of K was not included in the hand analysis since the filter required a low midband gain of two and low cutoff frequency relative to the OP-27's 8 MHz gain-bandwidth product. The simulated frequency response is shown in Fig. 79.28. The computer simulation did include a complete model for the OP-27.

R_1	$16.4\ \text{nV}/\sqrt{\text{Hz}}$	1.998	$32.8\ \text{nV}/\sqrt{\text{Hz}}$	$16.4\ \text{nV}/\sqrt{\text{Hz}}$
	Total Noise Contributions		$\overline{40.4\ \text{nV}/\sqrt{\text{Hz}}}$	$\overline{20.2\ \text{nV}/\sqrt{\text{Hz}}}$

As indicated by Fig. 79.27, the output noise predicted by (79.98) agrees well with the simulation. Analyzing the noise contribution of each circuit element to the filter's total output noise can provide insight for improving the design. To this end, Table 79.3 was generated for this filter.

Note that at 1 kHz R_1 is the dominant source of noise. A smaller value of R_1 could be chosen at the expense of increasing C_2. Care must be taken in doing so because changing C_2 also changes the gain multiplier for I_n and R_1's noise source, as described in (79.98). The noise bandwidth, using a single-pole response approximation, is 20 kHz(π/2) = 31.4 kHz. Hence, $E_{\text{ni}} = (20.2\ \text{nV}/\sqrt{\text{Hz}}).(31.4\ \text{kHz})^{1/2} = 3.58\ \mu\text{V}$. To achieve then a signal-to-noise ratio of 10, the input signal level must be 35.8 μV. This would be more difficult to attain if 741 op-amp has been used, with its $E_n = 20\ \text{nV}/\sqrt{\text{Hz}}$, rather than the OP-27.

Often in signal processing circuits several stages are cascaded to shape the response of the system. In doing so, the noise contributed by each stage is an important consideration. Placement of each stage within the cascade ultimately determines the E_{ni} of the entire cascade. The minimum E_{ni} is achieved by placing the highest gain first. By doing so the noise of all the following stages is divided by the single largest gain stage of the entire cascade. This comes however at the sacrifice of dynamic range. With the highest gain first in the cascade, each following stage has a larger input signal than in the case where the highest gain stage is last or somewhere between first and last in the cascade. Dynamic range is lost since there is a finite limit in the input signal level to any circuit before distortion results.

79.8 Summary

This chapter has examined active filters using low-gain amplifiers. These filters are capable of realizing any second-order transfer function. Higher order transfer functions are realized using cascaded first-order and second-order stages. The nonideal behavior of finite gain-bandwidth, slew rate, and noise was examined. More information on this category of filters can be found in the references.

80.1 Introduction

In this section we will consider the design of second-order sections that incorporate a single operational amplifier. Such designs are based upon one of the earliest approaches to *RC* active filter synthesis, which has proven to be a fundamentally sound technique for over 30 years. Furthermore, this basic topology has formed the basis for designs as technology has evolved from discrete component assemblies to monolithic realizations. Hence, the circuits presented here truly represent reliable well-tested building blocks for sections of modest selectivity.

80.2 General Structure for Single-Amplifier Filters

The general structure of Fig. 80.1 forms the basis for the development of infinite-gain single-amplifier configurations. Simple circuit analysis may be invoked to obtain the open-circuit voltage transfer function. For the passive network:

$$I_1 = y_{11}V_1 + y_{12}V_2 + y_{13}V_3 \tag{80.1}$$

$$I_2 = y_{21}V_1 + y_{22}V_2 + y_{23}V_3 \tag{80.2}$$

$$I_3 = y_{31}V_1 + y_{32}V_2 + y_{33}V_3 \tag{80.3}$$

© 2003 by CRC Press LLC

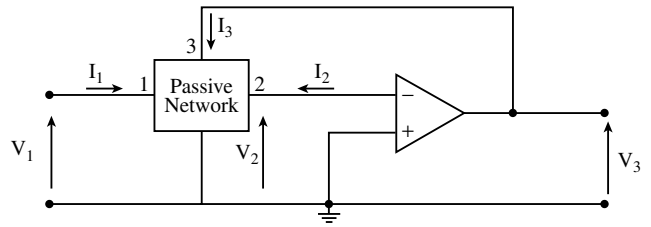

FIGURE 80.1 General infinite-gain single-amplifier structure.

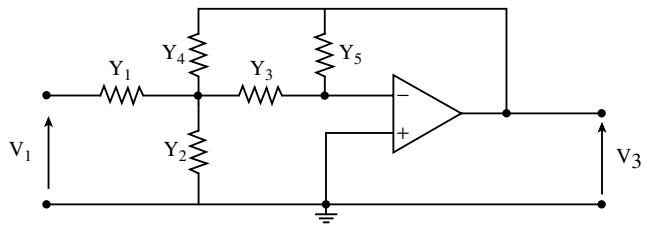

FIGURE 80.2 General double ladder multiple-feedback network.

For the amplifier, ideal except for finite gain A:

$$V_3 = -AV_2 \tag{80.4}$$

Noting that $I_2 = 0$, the above equations reduce to the following expression for the voltage transfer function:

$$\frac{V_3}{V_1} = \frac{-y_{31}}{y_{32} + \dfrac{y_{33}}{A}} \tag{80.5}$$

As $A \to \infty$, which we can expect at low frequencies, the above expression reduces to the more familiar

$$\frac{V_3}{V_1} = -\frac{y_{31}}{y_{32}} \tag{80.6}$$

Theoretically, a wide range of transfer characteristics can be realized by appropriate synthesis of the passive network [1]. However, it is not advisable to extend synthesis beyond second-order functions for structures containing only one operational amplifier due to the ensuing problems of sensitivity and tuning. Furthermore, notch functions require double-element replacements [2] or parallel ladder arrangements [3], which are nontrivial to design, and whose performance is inferior to that resulting from other topologies such as those discussed in Chapters 81 and 82.

While formal synthesis techniques could be used to meet particular requirements, the most common approach is to use a double-ladder realization of the passive network, as shown in Figure 80.2. This arrangement, commonly referred to as the multiple-loop feedback (MFB) structure, is described by the following voltage transfer ratio:

$$\frac{V_3}{V_1} = \frac{-Y_1 Y_3}{Y_5(Y_1 + Y_2 + Y_3 + Y_4) + Y_3 Y_4} \tag{80.7}$$

This negative feedback arrangement yields highly stable realizations. The basic all-pole (low-pass, band-pass, high-pass) functions can be realized by single-element replacements for the admittances $Y_1, \ldots, Y_5$, as described in the following subsection.

© 2003 by CRC Press LLC

80.3 All-Pole Realizations of the MFB Structure

Low-Pass Structure

The general form of the second-order all-pole low-pass structure is described by the following transfer ratio:

$$\frac{V_3}{V_1} = \frac{H}{s^2 + \frac{\omega_p s}{Q_p} + \omega_p^2} \tag{80.8}$$

By comparing the above requirement with (80.7) it is clear that both Y_1 *and* Y_3 must represent conductances. Furthermore, by reviewing the requirements for the denominator, Y_5 *and* Y_2 must be capacitors, while Y_4 is a conductance.

High-Pass Structure

The general form of the second-order all-pole high-pass transfer function is

$$\frac{V_3}{V_1} = \frac{Hs^2}{s^2 + \frac{\omega_p s}{Q_p} + \omega_p^2} \tag{80.9}$$

With reference to Eq. (80.7), it is seen that both Y_1 *and* Y_3 must represent capacitors. There is a need for a third capacitor ($Y_4 = sC_4$) to yield the s^2 term in the denominator function. The remaining two elements, Y_2 *and* Y_5, represent conductances.

Bandpass Structure

The general form of the second-order all-pole bandpass transfer function is

$$\frac{V_3}{V_1} = \frac{Hs}{s^2 + \frac{\omega_p s}{Q_p} + \omega_p^2} \tag{80.10}$$

Two solutions exist since Y_1 *and* Y_3 can be either capacitive or conductive. Choosing $Y_1 = G_1$ and $Y_3 = sC_3$ yields $Y_4 = sC_4$ and Y_2, Y_5 are both conductances.

The general forms of the above realizations are summarized in Table 80.1 [4].

80.4 MFB All-Pole Designs

MFB designs are typically reserved for sections having a pole-Q of 10 or less. One of the reasons for this constraint is the reliance upon component ratios for achieving Q. This can be illustrated by consideration of the low-pass structure for which

$$\frac{V_3}{V_1} = \frac{-G_1 G_3}{s^2 C_2 C_5 + sC_5(G_1 + G_3 + G_4) + G_3 G_4} \tag{80.11}$$

By comparison with (80.8),

$$Q_p = \frac{\sqrt{C_2 C_5 G_3 G_4}}{C_5\left(G_1 + G_3 + G_4\right)}$$

© 2003 by CRC Press LLC

TABLE 80.1 MFB All-Pole Realizations

Filter Type	Network	Voltage Transfer Function
Low-pass		$\frac{-G_1G_3}{s^2C_2C_5 + sC_5(G_1 + G_3 + G_4) + G_3G_4}$
High-pass		$\frac{-s^2C_1C_3}{s^2C_3C_4 + sG_5(C_1 + C_3 + C_4) + G_2G_5}$
Bandpass		$\frac{-sG_1C_3}{s^2C_3C_4 + sG_5(C_3 + C_4) + G_5(G_1 + G_2)}$

or, in terms of component ratios:

$$Q_p = \frac{\sqrt{C_2}}{\sqrt{C_5}} \left\{ \frac{1}{\frac{G_1}{\sqrt{G_3G_4}} + \sqrt{\frac{G_3}{G_4}} + \sqrt{\frac{G_4}{G_3}}} \right\} \tag{80.12}$$

Hence, high Q_p can only be achieved by means of high component spreads. In general terms, a Q_p of value n requires a component spread proportional to n^2.

Filter design is effected by means of coefficient matching. Thus, for the low-pass case, comparison of like coefficients in (80.8) and the transfer ratio in Table 80.1 yields

$$G_1G_3 = H \tag{80.13}$$

$$C_2C_5 = 1 \tag{80.14}$$

$$C_5(G_1 + G_3 + G_4) = \frac{\omega_p}{Q_p} \tag{80.15}$$

$$G_3G_4 = \omega_p^2 \tag{80.16}$$

These equations do not yield an equal-capacitor solution but can be solved for equal-resistor pairs. Hence, if $G_1 = G_3$,

© 2003 by CRC Press LLC

TABLE 80.2 Element Values for the MFB All-Pole Realizations

Element (Table 80.1)	Low-pass	Bandpass	High-Pass
Y_1	$G_1 = \dfrac{H}{\omega_p}$	$G_1 = H$	$C_1 = H$
Y_2	$C_2 = \dfrac{Q_p\left(2\omega_p^2 + H\right)}{\omega_p^2}$	$G_2 = 2\omega_p Q_p - H$	$G_2 = \omega_p(2+H)Q_p$
Y_3	$G_3 = \omega_p$	$C_3 = 1$	$C_3 = 1$
Y_4	$G_4 = G_3$	$C_4 = C_3$	$C_4 = C_3$
Y_5	$C_5 = \dfrac{\omega_p^2}{Q_p\left(2\omega_p^2 + H\right)}$	$G_5 = \dfrac{\omega_p}{2Q_p}$	$G_5 = \dfrac{\omega_p}{Q_p(2+H)}$

$$G_1 = G_3 = \sqrt{H} \qquad \left[\text{from } (80.13)\right]$$

$$G_4 = \frac{\omega_p^2}{\sqrt{H}} \qquad \left[\text{from } (80.16)\right]$$

Then,

$$C_5 = \frac{\omega_p\sqrt{H}}{Q_p\left(2H + \omega_p^2\right)} = \frac{1}{C_2}$$

An alternative solution for which $G_3 = G_4$ is shown in Table 80.2, together with equal-capacitor designs for the bandpass and high-pass cases.

The conditions [4] for maximum Q_p in the bandpass realization require $C_3 = C_4$ and $G_1 = G_2 = nG_5$, where n is a real number. This yields a maximum Q_p of $\sqrt{n/2}$, and requires that $H = \omega_p Q_p$.

Example 1. Using the cascade approach, design a four-pole Butterworth bandpass filter having a Q of 5, a center frequency of 1.5 kHz, and midband gain of 20 dB. Assume that only 6800 pF capacitors are available.

Solution. The low-pass prototype is the second-order Butterworth characteristic having a dc gain of 10 (i.e., 20 dB). Thus,

$$T(s) = \frac{10}{s^2 + \sqrt{2}s + 1} \qquad \text{(i)}$$

The low-pass-to-bandpass frequency transformation for a Q of 5 entails replacing s in (i) by $5(s + 1/s)$. This yields the following bandpass function for realization:

$$\frac{V_o}{V_i} = \frac{0.4s^2}{s^4 + 0.28284s^3 + 2.04s^2 + 0.28284s + 1}$$

$$= \frac{-sH_1}{\left(s^2 + .15142s + 1.15218\right)} \cdot \frac{-sH_2}{\left(s^2 + .13142s + .86792\right)} \qquad \text{(ii)}$$

$$\text{(section 1)} \qquad \text{(section 2)}$$

© 2003 by CRC Press LLC

$$Q_1 = Q_2 = 7.089$$

$$\omega_{p1} = 1.0734 \qquad \omega_{p2} = 0.9316$$

As expected, the Q-factors of the cascaded sections are equal in the transformed bandpass characteristic. However, the order of cascade is still important. So as to reduce the noise output of the filter, it is necessary to apportion most of the gain to section 1 of the cascade. Section 2 then filters out the noise without introducing excessive passband gain. In the calculation that follows, it is important to note that the peak gain of a bandpass section is given by HQ/ω_p.

Since the overall peak gain of the cascade is to be 10, let this also be the peak gain of section 1. Hence,

$$\frac{H_1 Q_1}{\omega_{p1}} = 6.6041 H_1 = 10$$

giving $H_1 = 1.514$.

Furthermore, from (ii):

$$H_1 H_2 = 0.4$$

so that $H_2 = 0.264$.

The design of each bandpass section proceeds by coefficient matching, conveniently simplified by Table 80.2. Setting $C_3 = C_4 = 1$ F, the normalized resistor values for section 1 may be determined as

$$R_1 = 0.661\ \Omega; \qquad R_2 = 0.073\ \Omega; \qquad R_5 = 13.208\ \Omega$$

The impedance denormalization factor is determined as

$$z_n = \frac{10^{12}}{2\pi \times 1500 \times 6800} = 15{,}603$$

Thus, the final component values for section 1 are

$$C_1 = C_2 = 6800 \text{ pF}$$

$$\left.\begin{aligned} R_1 &= 10.2\ \text{k}\Omega \\ R_2 &= 1.13\ \text{k}\Omega \\ R_5 &= 205\ \text{k}\Omega \end{aligned}\right\} \quad \text{Standard 1 percent values}$$

Note the large spread in resistance values ($R_5/R_2 \simeq 4Q^2$) and the fact that this circuit is only suitable for low-Q realizations. It should also be noted that the amplifier open-loop gain at ω_p must be much greater than $4Q^2$ if it is not to cause significant differences between the design and measured values of Q.

The component values for Section 2 are determined in an identical fashion.

Example 2. Design the MFB bandpass filter characterized in Example 1 as a high-pass/low-pass cascade of second-order sections. Use the design equations of Table 80.2 and, where possible, set capacitors equal to 5600 pF. It is suggested that you use the same impedance denormalization factor in each stage. Select the nearest preferred 1 percent resistor values.

Solution. Since the peak gain of the overall cascade is to be 10, let this also be the gain of stage 1 (this solution yields the best noise performance). The peak gain of the low-pass section is given by

© 2003 by CRC Press LLC

$$\frac{H_1 Q}{\sqrt{1-1/2Q^2}} = 7.16H_1 = 10 \quad \therefore H_1 = 1.397$$

The overall transfer function (from Example 1) is

$$\frac{V_o}{V_i} = \frac{0.4s^2}{s^4 + 0.2824s^3 + 2.04s^2 + 0.2824s + 1}$$

$$\therefore H_1 H_2 = 0.4 \text{ so that } H_2 = 0.286$$

Thus, assuming a low-pass/high-pass cascade, we have

$$\frac{V_o}{V_i} = \underbrace{\frac{1.397}{s^2 + 0.15145 + 1.1522}}_{\text{section 1}} \cdot \underbrace{\frac{0.286s^2}{s^2 + 0.1314s + 0.8679}}_{\text{section 2}}$$

Design the low-pass section (section 1) using Table 80.2 to yield

$$G_1 = \frac{H_1}{\sqrt{1.15218}} = 1.301, \text{ so that } R_1 = 0.7684\ \Omega$$

$$C_2 = \frac{\left(2\omega_p^2 + H_1\right)}{\omega_p^2} \mathrm{Q}_p = 22.77\ \mathrm{F}$$

$$G_3 = \omega_p = 1.0733, \text{ so that } R_3 = 0.9316\ \Omega = R_4$$

$$C_5 = 1/C_2 = 0.0439\ \mathrm{F}$$

Now, design the high-pass section (Section 2) to yield

$$C_1' = 0.286\ \mathrm{F}$$

$$G_2' = \omega_p\left(2 + H_2\right)\mathrm{Q} = 15.099, \text{ so that } R_2' = 0.0662\ \Omega$$

$$C_3' = C_4' = 1\ \mathrm{F}$$

$$G_5' = \frac{\omega_p}{\mathrm{Q}_p\left(2 + H\right)} = 0.0574, \text{ so that } R_5' = 17.397\ \Omega$$

To obtain as many 5600 pF capacitors as possible, the two sections should be denormalized separately. However, in this example, a single impedance denormalization will be used. Setting $C_3' = C_4' = 5600$ pF yields $z_n = 18947$.

This leads to the following component values:

Low-Pass Stage	High-Pass Stage
R_1 = 2.204 kΩ (2.21 kΩ)	C_1' = 1602 pF
C_2 = 0.128 μF	R_2' = 1.254 kΩ (1.24 kΩ)
R_3 = 17.651 kΩ (17.8 kΩ) = R_4	$C_3' = C_4'$ = 5600 pF
C_5 = 246 pF	R_5' = 329.62 kΩ (332 kΩ)
1% values in parentheses.	

© 2003 by CRC Press LLC

80.5 Practical Considerations in the Design of MFB Filters

Sensitivity, the effects of finite amplifier gain, and tuning are all of importance in practical designs. The following discussion is based upon the bandpass case.

Sensitivity

Taking account of finite amplifier gain A, but assuming $R_{in} = \infty$ and $R_o = 0$ for the amplifier, the bandpass transfer function becomes

$$\frac{V_3}{V_1} = \frac{-sG_1/C_4\left(1+\dfrac{1}{A}\right)}{s^2 + s\left\{\dfrac{G_5(C_3+C_4)}{C_3C_4} + \dfrac{G_1+G_2}{C_4(1+A)}\right\} + \left\{\dfrac{G_5(G_1+G_2)}{C_3C_4}\right\}} \tag{80.17}$$

which is identical to the expression in Table 80.1 if $A = \infty$.

Assuming a maximum Q design,

$$Q = \frac{Q_p}{1+\dfrac{2Q_p^2}{(1+A)}} \tag{80.18}$$

where Q_p is the desired selectively and Q is the actual Q-factor in the presence of finite amplifier gain.

If $A \gg 2Q - 1$, the classical Q-sensitivity may be derived as

$$S_A^Q = \frac{2Q^2}{A} \tag{80.19}$$

which is uncomfortably high. By contrast, the passive sensitivities are relatively low:

$$S^Q_{C_3,C_4} = 0 \quad S^Q_{G_5} = -0.5 \quad S^Q_{G_1,G_2} = 0.25$$

while the ω_p sensitivities are all ±0.5.

Effect of Finite Amplifer Gain

The effect of finite amplifier gain can be further illustrated by plotting (80.18) for various Q-factors, and for two commercial operational amplifiers. Assuming a single-pole roll-off model, the frequency dependence of open-loop gain for μ*A*741 and *LF*351 amplifiers is as follows.

Frequency (Hz)	Gain	
	μ*A*741	*LF*351
10	1.3×10^5	3.16×10^5
100	10^4	3.16×10^4
1000	10^3	3.16×10^3
10,000	10^2	3.16×10^2

Figure 80.3 shows the rather dramatic fall-off in actual Q as frequency increases (and hence gain decreases). Thus, for designs of modest Q (note that $A \gg 2\,Q - 1$), a very high quality amplifier is needed if the center frequency is more than a few kilohertz. For example, the *LF*351 with a unity gain frequency of 4 MHz will yield 6 percent error in Q at a frequency of only 1 kHz.

© 2003 by CRC Press LLC

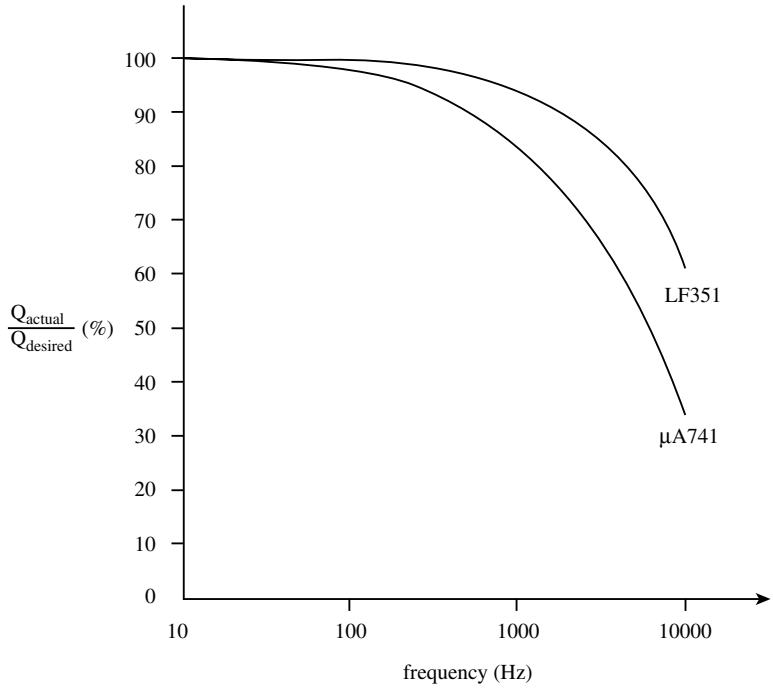

FIGURE 80.3 Effect of finite amplifier gain on the design Q for MFB bandpass realizations using two commercial operational amplifiers.

Tuning

Limited functional tuning of the bandpass section is possible. For example, the midband (peak) gain

$$K_o = \frac{G_1 C_3}{G_5(C_3 + G_4)} \tag{80.20}$$

may be adjusted by means of either G_1 or G_5.

Subsequent adjustment of either Q_p or ω_p is possible via G_2. In view of the discussion above, it is most likely that adjustment of Q_p will be desired. However, since the expressions for Q_p and ω_p are so similar, any adjustment of Q_p is likely to require an iterative procedure to ensure that ω_p does not change undesirably.

A more desirable functional tuning result is obtained in circumstances where it is necessary to preserve a constant bandwidth, i.e., in a spectrum analyzer. Since

$$\omega_p = \sqrt{G_5(G_1 + G_2)/C_3 C_4} \tag{80.21}$$

and bandwidth, B, is

$$B = \frac{\omega_p}{Q_p} = G_5(C_3 + C_4) \tag{80.22}$$

adjustment of G_2 will allow for a frequency sweep without affecting K_o or B.

An alternative to functional tuning may be found by adopting deterministic [5] or automatic [6] tuning procedures. These are particularly applicable to hybrid microelectronic or monolithic realizations.

© 2003 by CRC Press LLC

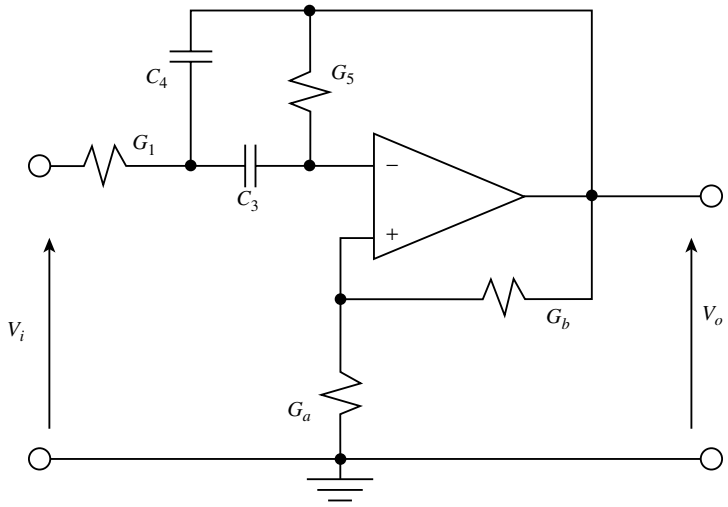

FIGURE 80.4 Modified multiple-loop feedback (MMFB) structure.

80.6 Modified Multiple-Loop Feedback (MMFB) Structure

In negative feedback topologies such as the MFB, "high" values of Q_p are obtained at the expense of large spreads in element values. By contrast, in positive feedback topologies such as those attributed to Sallen and Key, Q_p is enhanced by subtracting a term from the s^1 (damping) coefficient in the denominator. The two techniques are combined in the MMFB (Deliyannis) arrangement [7] of Fig. 80.4.

Analysis of the circuit yields the bandpass transfer function as

$$\frac{V_o}{V_i} = \frac{-sC_3G_1(1+k)}{s^2C_3C_4 + s\{G_5(C_3+C_4) - kC_3G_1\} + G_1G_5} \tag{80.23}$$

where $k = G_b/G_a$, and the Q-enhancement term "$-kC_3G_1$" signifies the presence of positive feedback. This latter term is also evident in the expression for Q_p:

$$Q_p = \frac{\sqrt{G_1/G_5}}{\left\{\sqrt{\frac{C_4}{C_3}} + \sqrt{\frac{C_3}{C_4}} - k\frac{G_1}{G_5}\sqrt{\frac{C_1}{C_2}}\right\}} \tag{80.24}$$

The design process consists of matching coefficients in (80.23) with those of the standard bandpass expression of (80.10). The design steps have been conveniently summarized by Huelsman [8] for the equal-capacitor solution and the following procedure is essentially the same as that described by him.

Example 3. Design a second-order bandpass filter with a center frequency of 1 kHz, a pole-Q of 8, and a maximum resistance spread of 50. Assume that the only available capacitors are of value 6800 pF.

1. The above constraint suggests an equal-valued capacitor solution. Thus, set $C_3 = C_4 = C$.
2. Determine the resistance ratio parameter n_o that would be required if there were no positive feedback. From Section 80.4, $n_o = 4Q_p^2 = 256$.
3. Select the desired ratio n (where n is greater than 1 but less than 256) and use it to determine the amount of positive feedback k. From (80.24),

© 2003 by CRC Press LLC

$$Q_p = \frac{\sqrt{n}}{2 - kn}$$

so that

$$k = \frac{1}{\sqrt{n}} \left\{ \frac{2}{\sqrt{n}} - \frac{1}{Q_p} \right\}$$

Since $n = 50$ and $Q_p = 8$, $k = 0.0316$.

4. A convenient value may now be selected for R_B. If $R_B = 110$ kΩ, then $R_A = R_B\,(0.0316) = 3.48$ kΩ.
5. Since, from (80.23),

$$\omega_p = \sqrt{\frac{G_1 G_5}{C_3 C_4}}$$

and $G_1/G_5 = n$, we may determine G_5 as

$$G_5 = \frac{\omega_p C}{\sqrt{n}}$$

Since $C = 6800$ pF, $n = 50$, and $G_5 = 1/R_5$:

$$R_5 = \frac{\sqrt{50}}{2\pi 10^3 \times 6.8 \times 10^{-9}} = 165.5 \text{ k}\Omega$$

Hence $R_1 = R_5/n = 3.31$ kΩ.

6. Using 1 percent preferred resistor values we have

$$R_B = 110 \text{ k}\Omega \qquad R_A = 3.16 \text{ k}\Omega$$
$$R_5 = 165 \text{ k}\Omega \qquad R_1 = 3.48 \text{ k}\Omega$$

Judicious use of positive feedback in the Deliyannis circuit can yield bandpass filters with Q values as high as 15–20 at modest center frequencies. A more detailed discussion of the optimization of this structure may be found elsewhere [9].

80.7 Biquadratic MMFB Structure

A generalization of the MMFB arrangement, yielding a fully biquadratic transfer ratio is shown in Fig. 80.5. If the gain functions K_1, K_2, K_3 are realized by resistive potential dividers, the circuit reduces to the more familiar Friend biquad of Fig. 80.6, for which

$$\frac{V_o}{V_i} = \frac{cs^2 + ds + e}{s^2 + as + b} \tag{80.25}$$

where

$$K_1 = \frac{R_5}{R_4 + R_5}; \qquad K_2 = \frac{R_D}{R_c + R_D}; \qquad K_3 = \frac{R_7}{R_6 + R_7}$$
$$R_1 = \frac{R_4 R_5}{R_4 + R_5}; \qquad R_A = \frac{R_c R_D}{R_c + R_D}; \qquad R_3 = \frac{R_6 R_7}{R_6 + R_7} \tag{80.26}$$

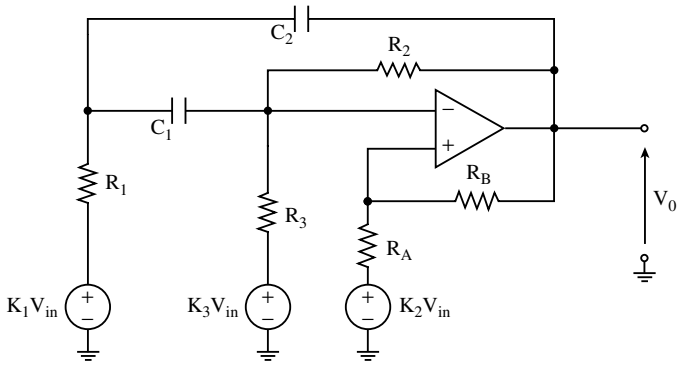

FIGURE 80.5 A generalization of the MMFB circuit.

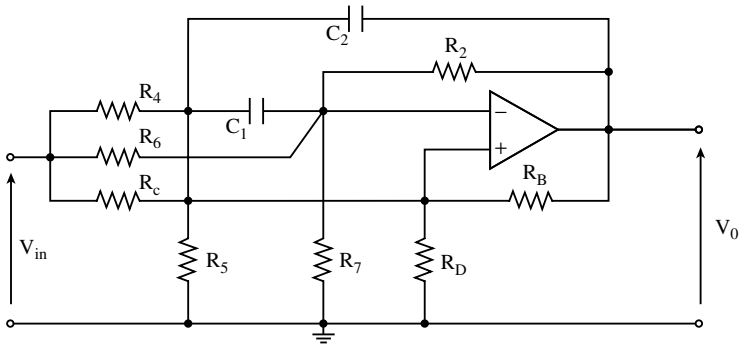

FIGURE 80.6 The Friend biquad.

This structure is capable of yielding a full range of biquads of modest pole Q, including notch functions derived as elliptic characteristics of low modular angle. It was used extensively in the Bell System, where the benefits of large-scale manufacture were possible. Using the standard tantalum thin film process, and deterministic tuning by means of laser trimming, quite exacting realizations were possible [10]. The structure is less suited to discrete component realizations. However, design is possible by coefficient matching. The reader is referred to an excellent step-by-step procedure developed by Huelsman [11].

80.8 Conclusions

The multiple-feedback structure is one of the most basic active filter building blocks. It is extremely reliable when used to realize low-Q (<10), low frequency (up to 15 kHz) second-order sections of the low-pass, bandpass, and high-pass forms. Stability is ensured by the negative feedback topology, though component spreads are proportional to Q^2.

The disadvantage of larger component spread may be reduced by the judicious use of positive feedback. This approach may be extended to yield the widely used Friend biquad, which allows the realization of notch and other approximations requiring a pair of imaginary zeros.

All networks described in this section readily lend themselves to the cascade method for realizing higher-order filters.

81.1 Introduction

The step from single-amplifier to multiple-amplifier biquadratic filter sections provides several benefits. The most important benefits are as follows.

- Reduced passive element spread, i.e., the ratio between the largest and the smallest values of resistors and/or capacitors can be reduced compared to the single-amplifier case.
- The required amplifier gains in some circuits grow linearly or less with the *Q*-factor of the complex pole pairs.
- Multiple-amplifier biquads often provide lower sensitivities to both passive and active components.
- Most of the multiple-amplifier biquads are more universal filter structures realizing the general biquadratic transfer function.
- Most of the filter parameters such as pole and zero *Q*-factors, pole and zero frequencies, and the gain factor of the transfer function can be tuned independently.
- Designing multiple-amplifier filters, often the values of the capacitors can be chosen freely. The filter parameters are then determined by resistors, which is less costly than by capacitors.

On the other hand, these benefits must be paid for by increased space requirements and increased power dissipation. However, today there are low-cost and low-power integrated-circuit op-amps available with up to four op-amps on one chip. Therefore, size and power dissipation are often no longer the main problem.

In the following, we will first consider biquadratic filter sections and dual-amplifier twin-*T* biquads. Both circuit families are directly derived from single-amplifier circuits. Next we will derive filter circuits having a quite different origin: filters that are derived from the generalized impedance converter (GIC) and filters derived from state-variable representation of linear systems on the analog computer. Finally, we will briefly consider filter circuits based on first-order all-pass sections.

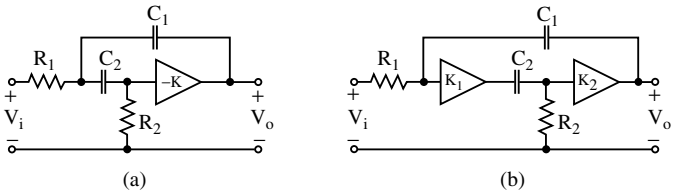

FIGURE 81.1 (a) Sallen and Key bandpass filter and (b) dual-amplifier bandpass filter with decoupled time constants.

81.2 Biquads with Decoupled Time Constants

One of the simplest methods for improving the performance of a biquad is demonstrated in Fig. 81.1.

Figure 81.1(a) shows a well-known Sallen and Key bandpass circuit [12], which offers moderate pole sensitivities with respect to the passive elements. It can easily be shown that this circuit has the following transfer voltage ratio:

$$H(s)=\frac{V_o}{V_i}=\frac{-K\cdot sT_2}{s^2T_1T_2(1+K)+s(T_{12}+T_1+T_2)+1} \tag{81.1}$$

with the amplifier gain K and the time constants $T_1 = R_1C_1$, $T_2 = R_2C_2$, and $T_{12} = R_1C_2$. The gain requirement is more than $4Q_p^2 - 1$ with Q_p being the Q-factor of the pole pair. This relationship limits the circuit to low- or medium-Q applications.

If we insert another amplifier between the two RC networks R_1C_1 and R_2C_2, we obtain the biquad in Fig. 81.1(b) [5], [14], which possesses a transfer voltage ratio

$$H(s)=\frac{V_o}{V_i}=\frac{K_1K_2\cdot sT_2}{s^2T_1T_2(1-K_1K_2)+s(T_1+T_2)+1} \tag{81.2}$$

Here the product K_1K_2 of the gain factors plays the role of the gain $–K$ in Fig. 81.1(a). One of the gain factors must be positive, the other negative. A comparison of (81.1) and (81.2) shows that after isolating both RC networks the "cross time constant" T_{12} disappears. The two time constants T_1 and T_2 are decoupled. From this change we can derive two benefits. Both factors K_1 and K_2 require only a gain of approximately $2Q_p$ and, as will be shown later, this circuit can be designed with zero Q-sensitivity.

Next, we generalize the structure in Figure 81.1(b) by replacing the passive elements by general admittances; see Fig. 81.2. In this circuit, the two subnetworks Y_{1a},Y_{1b} and Y_{2a}, Y_{2b} are decoupled.

By a simple analysis we obtain the transfer voltage ratio of the general circuit in Fig. 81.2:

$$H(s)=\frac{V_o}{V_i}=\frac{K_1K_2Y_{1a}Y_{2a}}{(Y_{2a}+Y_{2b})(Y_{1a}+Y_{1b})-K_1K_2Y_{1b}Y_{2a}} \tag{81.3}$$

By prespecifying the types of passive elements in Fig. 81.2 and (81.3), respectively, we next will derive a low-pass, a bandpass, and high-pass filter section.

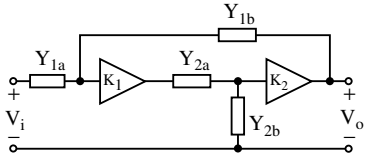

FIGURE 81.2 General biquad with decoupled networks.

© 2003 by CRC Press LLC

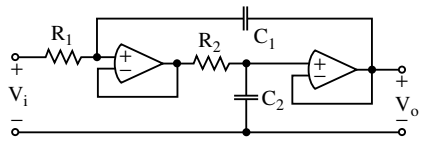

FIGURE 81.3 Dual op-amp low-pass filter section.

With the prespecified elements $Y_{1a} = G_1$, $Y_{1b} = sC_1$, $Y_{2a} = G_2$, and $Y_{2b} = sC_2$ we obtain from (81.3) the low-pass transfer function

$$\begin{aligned} H_{\mathrm{LP}}(s) &= \frac{V_o}{V_i} = \frac{K_1K_2G_1G_2}{s^2C_1C_2 + s\left[G_1C_2 + G_2C_1\left(1 - K_1K_2\right)\right] + G_1G_2} \\ &= \frac{K_1K_2}{s^2T_1T_2 + s\left[T_2 + T_1\left(1 - K_1K_2\right)\right] + 1} \end{aligned} \tag{81.4}$$

If we predefine $K_1 = K_2 = 1$ we simply get voltage followers in the filter circuit and additionally a simple design procedure resulting in a low-sensitivity filter section. Figure 81.3 shows the low-pass filter section with two op-amps and four passive elements.

For $K_1 = K_2 = 1$ we will have dc gain $H_0 = 1$, a pole frequency

$$\omega_p = 1/\sqrt{T_1T_2} \tag{81.5}$$

and a Q-factor

$$Q_p = \sqrt{T_2/T_1} \tag{81.6}$$

Thus, designing the filter section, from the predefined parameters ω_p and Q_p we determine the time constants

$$T_2 = \frac{Q_p}{\omega_p} \quad T_1 = \frac{1}{Q_p\omega_p} \tag{81.7}$$

Finally, we choose the values of the capacitors and calculate the resistors from the time constants.

From (81.5) and (81.6) we can immediately read the pole sensitivities:

$$S_{R_1}^{\omega_p} = S_{C_1}^{\omega_p} = S_{R_2}^{\omega_p} = S_{C_2}^{\omega_p} = -\frac{1}{2} \tag{81.8}$$

$$S_{R_1}^{Q_p} = S_{C_1}^{Q_p} = -S_{R_2}^{Q_p} = -S_{C_2}^{Q_p} = -\frac{1}{2} \tag{81.9}$$

This result is comparable with the pole sensitivities of passive second-order *RLC* networks.

Next we will develop a high-pass filter section by prespecifying $Y_{1a} = sC_1$, $Y_{1b} = G_1$, $Y_{2a} = sC_2$, and $Y_{2b} = G_2$ resulting in a transfer voltage ratio

$$\begin{aligned} H_{\mathrm{HP}}(s) &= \frac{V_o}{V_i} = \frac{s^2K_1K_2C_1C_2}{s^2C_1C_2 + s\left[G_2C_1 + G_1C_2\left(1 - K_1K_2\right)\right] + G_1G_2} \\ &= \frac{s^2K_1K_2T_1T_2}{s^2T_1T_2 + s\left[T_1 + T_2\left(1 - K_1K_2\right)\right] + 1} \end{aligned} \tag{81.10}$$

© 2003 by CRC Press LLC

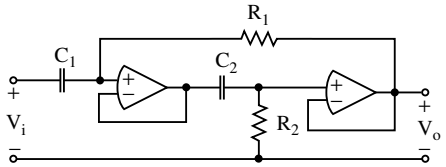

FIGURE 81.4 Dual op-amp high-pass filter section.

The only difference of this transfer function compared with the low-pass transfer function in (81.4) is the high-pass term (with s^2) in the numerator and the fact that the time constants T_1 and T_2 are interchanged in the denominator polynomial. Thus we can transfer the results in (81.5)–(81.9) to the high-pass filter by only replacing the index 1 by 2 and vice versa. Figure 81.4 shows the high-pass filter section.

The bandpass filter circuit mentioned at the beginning of this section is defined by the following types of elements: $Y_{1a} = G_1$, $Y_{1b} = sC_1$, $Y_{2a} = sC_2$, and $Y_{2b} = G_2$. Its transfer function is written in (81.2). The bandpass design is somewhat different from that of the low-pass and the high-pass filters described above. If we set the design values

$$G_1 = G_2 = 1 \quad C_1 = C_2 = \frac{1}{2Q_p} \tag{81.11}$$

and

$$-K_1K_2 = 4Q_p^2 - 1 \tag{81.12}$$

we obtain a special design where all passive Q-sensitivities are zero and all other sensitivities are very low [5], [14]:

$$S_{R_1}^{Q_p} = S_{C_1}^{Q_p} = S_{R_2}^{Q_p} = S_{C_2}^{Q_p} = 0 \tag{81.13}$$

$$S_{R_1}^{\omega_p} = S_{C_1}^{\omega_p} = S_{R_2}^{\omega_p} = S_{C_2}^{\omega_p} = -\frac{1}{2} \tag{81.14}$$

$$S_{K_1}^{Q_p} = S_{K_2}^{Q_p} = \frac{-K_1K_2}{2\left(1-K_1K_2\right)} < \frac{1}{2} \tag{81.15}$$

$$S_{K_1}^{\omega_p} = S_{K_2}^{\omega_p} = -\frac{1}{2}\left(1 - \frac{1}{4Q_p^2}\right) \tag{81.16}$$

Figure 81.5 shows the bandpass filter section realized with two op-amps. In this circuit K_1 is a noninverting and K_2 an inverting amplifier. The resistor R_2 of the passive network R_2, C_2 is realized by the input resistor of the inverting amplifier.

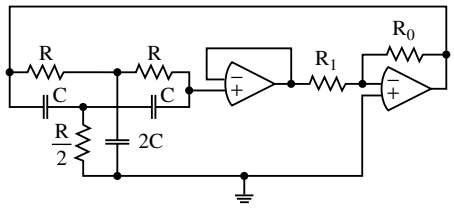

FIGURE 81.6 Dual-amp twin-*T* resonator.

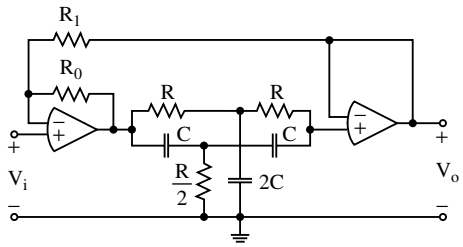

FIGURE 81.7 Dual-amp twin-*T* band-rejection filter.

81.3 Dual-Amplifier Twin-*T* Biquads

Twin-*T* feedback networks are easily tunable and provide relatively favorable sensitivity properties. In active filters, a twin-*T* network is connected between the input and the output of an inverting amplifier. It has been shown [6] that the sensitivity to the active element can be substantially reduced when a symmetrical feedback network is used, i.e., when the dc gain of the feedback network is equal to the high-frequency gain.

In a single-amplifier twin-*T* biquad, the output port of the feedback network is loaded by the input resistance of the inverting amplifier. As a consequence, the feedback network is no longer symmetrical. Here again we can significantly improve the behavior of the twin-*T* biquad by introducing a second amplifier: inserting a voltage follower between the twin-*T* network and the inverting amplifier maintains the symmetry of the feedback network. Figure 81.6 shows the corresponding dual-amp twin-*T* resonator[1] with the usually chosen passive element relations.

From the resonator in Fig. 81.6 several filter circuits can be derived by inserting the input voltage source in one of the grounded branches and by taking one of the two amplifier outputs as output terminal of the filter section. The voltage transfer ratios of all these circuits will have different numerator polynomials but the same denominator polynomial. As an example, Fig. 81.7 shows a band-rejection filter derived from the dual-amp twin-*T* resonator in Fig. 81.6.

The voltage transfer ratio of the band-rejection filter in Fig. 81.7 can be calculated to be

$$H_{BR}(s) = \frac{V_o}{V_i} = \frac{s^2T^2 + 1}{s^2T^2 + s4T/K + 1} \tag{81.17}$$

with the time constant $T = RC$ and the gain $K = (R_0 + R_1)/R_1$ of the series connection of the two op-amp circuits. Designing this filter, we determine the time constant T from the notch frequency ω_z or pole frequency ω_p, respectively,

$$T = 1/\omega_z = 1/\omega_p \tag{81.18}$$

[1]A resonator is a circuit without input and output terminals that only serves to show the feedback mechanism.

© 2003 by CRC Press LLC

and the amplifier gain from the Q-factor:

$$K = 4 \cdot Q_p \tag{81.19}$$

In [6], it is shown that the filter has favorably low gain-sensitivity products.

In order to obtain further filter variants, in [6] a complementary circuit is derived from the resonator in Fig. 81.6; see Fig. 81.8.

This resonator is especially useful for deriving filter sections with frequently applied transfer functions. In Figs. 81.9 through 81.13 some of these filter sections are depicted. Their voltage transfer ratios are given by

$$H(s) = \frac{V_o}{V_i} = \frac{N(s)}{s^2T^2 + s4T/K + 1} \tag{81.20}$$

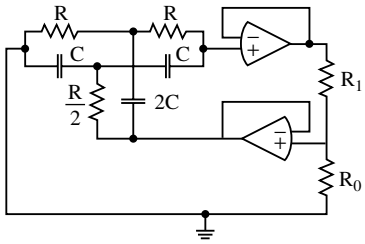

FIGURE 81.8 Complementary circuit of the resonator in Fig. 81.6.

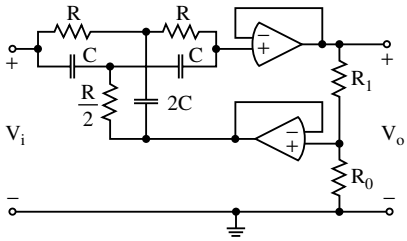

FIGURE 81.9 Twin-T band-rejection filter.

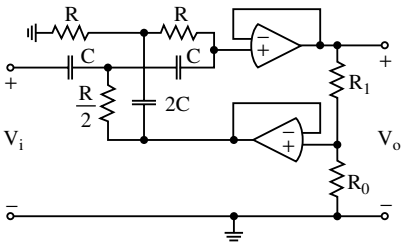

FIGURE 81.10 Twin-T low-pass filter.

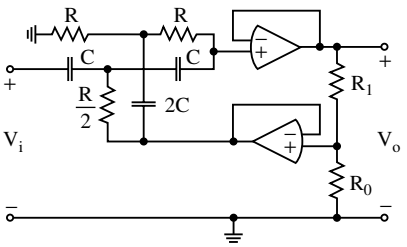

FIGURE 81.11 Twin-T high-pass filter.

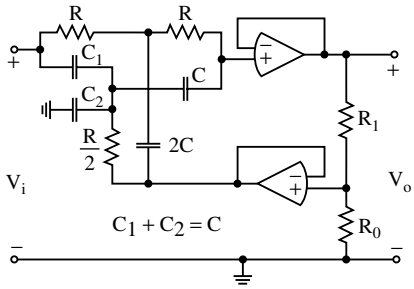

FIGURE 81.12 Twin-*T* Cauer low-pass filter section.

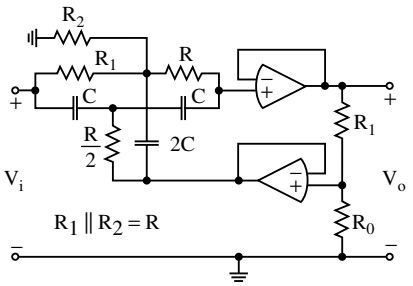

FIGURE 81.13 Twin-*T* Cauer high-pass filter section.

The band-rejection filter in Fig. 81.9 has a numerator polynomial $N(S) = s^2T^2 + 1$. The filter section in Fig. 81.10 is low-pass with a numerator $N(s) = 1$, the filter section in Fig. 81.11 is high-pass with $N(s) = s^2T^2$. The design of these sections is exactly the same as that of the filter in Fig. 81.7. It also provides the same pole sensitivities.

The two structures in Fig. 81.12 and 81.13 are particularly suitable for realizing elliptical filter sections (also called Cauer filters). The Cauer low-pass filter section in Fig. 81.12 has a numerator polynomial

$$N(s) = s^2R^2CC_1 + 1, \quad C_1 + C_2 = C \tag{81.21}$$

In this circuit, the first capacitor C is split into a parallel connection of two capacitors C_1 and C_2, where C_2 is grounded. The zeros are on the $j\omega$ axis at positions $\pm j\omega_z$ with $\omega_z = 1/\sqrt{R^2CC_1}$. The notch frequency ω_z is greater than the pole frequency ω_p. Designing the filter section, we determine the parameters T and K as described above. The splitting ratio of the input capacitor is determined by the poles and zeros:

$$\frac{C_2}{C_1} = \frac{\omega_z^2}{\omega_p^2} - 1 \tag{81.22}$$

Finally, in Fig. 81.13 we have a Cauer high-pass filter section with a numerator polynomial

$$N(s) = s^2RR_1C^2 + 1 \quad R_1 \| R_2 = R \tag{81.23}$$

Here the zero frequency ω_z is less than the pole frequency ω_p. As in the low-pass case, the splitting ratio of the input resistors is determined by these two frequencies:

$$\frac{R_1}{R_2} = \frac{\omega_p^2}{\omega_z^2} - 1 \tag{81.24}$$

The circuit in Fig. 81.6 is actually of third order. By matching the passive components, as shown in Fig. 81.6, we obtain a second-order transfer function. The question may arise as to what happens if we have a small mismatch due to the tolerances of practical components. In this case, a third pole and a third zero appear on the negative real axis of the s-plane. They do not cancel each other exactly, but

© 2003 by CRC Press LLC

approximately. In general, the existance of the third pole and the third zero does not affect the frequency response of the filter significantly. However, there is a second effect due to a small mismatch of passive components that is more severe: the position of the pole pair desired by design is changed. This change can be estimated by the pole sensitivities with respect to the passive elements [6].

81.4 GIC-Derived Dual-Amplifier Biquads

In this section, we consider a class of biquadratic building blocks with two op-amps that are derived from the generalized impedance converter (GIC). A catalog of such building blocks realizing a wide variety of network functions, including elliptic and all-pass ones, was published by Fliege [4].

Figure 81.14(b) shows the general filter structure, which is based on the resonator with two nullors in Fig. 81.14(a). Each nullor consists of one nullator and one norator and constitutes a model for the ideal op-amp. Combining the norator between the node between the admittances Y_2 and Y_3 and ground and the nullator across Y_4 and Y_6 yields the op-amp μ_1 in Fig. 81.14(b). It can readily be verified that the voltage transfer ratio of the circuit in Fig. 81.14(b) with $\mu_i = \infty$, $i = 1, 2$ is given by

$$H(s) = \frac{V_o}{V_i} = \frac{Y_{6b}\left(Y_2Y_4 + Y_{1a}Y_4\right) + Y_{1b}\left(Y_3Y_5 - Y_{6a}Y_4\right)}{Y_1Y_3Y_5 + Y_2Y_4Y_6} \tag{81.25}$$

with

$$Y_1 = Y_{1a} + Y_{1b} \quad Y_6 = Y_{6a} + Y_{6b} \tag{81.26}$$

If we choose the node between Y_4 and Y_5 as the output of the building block we will obtain a similar transfer function. We only have to interchange the admittances Y_1 by Y_6, Y_2 by Y_5, and Y_3 by Y_4.

First, we will derive a second-order low-pass building block from the general structure and we will take this low-pass filter as a prototype for the whole circuit family to explain their advantageous characteristics. If we choose the passive elements of the building block as $Y_{1a} = G_1$, $Y_{1b} = 0$, $Y_2 = G_2$, $Y_3 = sC_3$, $Y_4 = G_4$, $Y_5 = G_5 + sC_5$, $Y_{6a} = 0$, and $Y_{6b} = G_6$ we obtain the low-pass building block in Fig. 81.15. Its voltage transfer ratio reads

$$\begin{aligned} H_{\mathrm{LP}}(s) = \frac{V_o}{V_i} &= \frac{G_6G_4\left(G_2 + G_1\right)}{s^2C_3C_5G_1 + sC_3G_5G_1 + G_2G_4G_6} \\ &= H_0 \cdot \frac{\omega_p^2}{s^2 + s\omega_p/Q_p + \omega_p^2} \end{aligned} \tag{81.27}$$

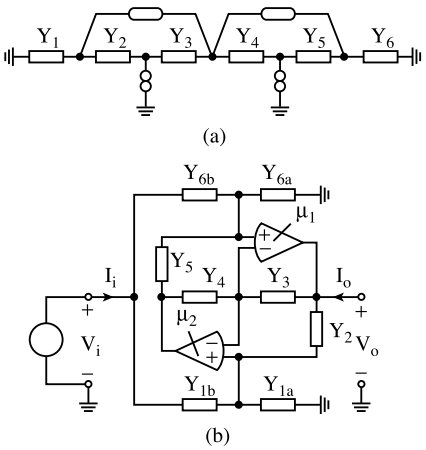

FIGURE 81.14 Resonator with (a) two nullors and (b) the corresponding general dual-amplifier filter structure.

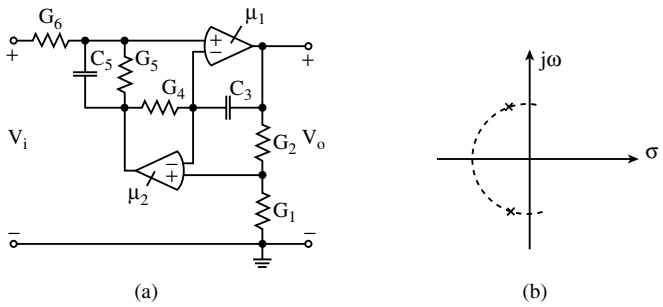

FIGURE 81.15 Second-order low-pass building block.

with dc gain

$$H_0 = \left(1+\alpha_{21}\right)/\alpha_{21} \tag{81.28}$$

pole frequency

$$\omega_p = \sqrt{\alpha_{21}/\left(T_{34}T_{56}\right)} \tag{81.29}$$

and Q-factor

$$Q_p = \omega_p \cdot T_{55} \tag{81.30}$$

Here, the time constants are defined as

$$T_{\mu\nu} = C_\mu / G_\nu \tag{81.31}$$

and the conductance ratios as

$$\alpha_{\mu\nu} = G_\mu / G_\nu \tag{81.32}$$

Figure 81.15(b) shows the location of the finite poles and zeros in the s-plane.

In the following, we predefine $G_1 = G_2$, i.e., $\alpha_{21} = 1$, and $T_{34} = T_{56} = T$. This provides optimum pole sensitivities with respect to the passive elements and with respect to the gain-bandwidth products of the operational amplifiers. Hence, the gain factor H_0 always has the value 2.

Based on these parameter restrictions, we can establish an easy design procedure. First, we can choose the capacitors $C_3 = C_5 = C$. Then, given the pole parameters ω_p and Q_p, we determine the two resistors

$$R_4 = R_6 = R = \frac{1}{\omega_p \cdot C} \tag{81.33}$$

and from (81.30) the resistor

$$R_5 = Q_p \cdot R \tag{81.34}$$

There are three key features that make these dual-amplifier biquads particularly favorable for practical applications.

© 2003 by CRC Press LLC

- The biquad building blocks have a low spread of elements. The resistors $R_1 = R_2$ can be chosen freely. The same holds for the two capacitors $C_3 = C_5$. The frequency-determining resistors $R_4 = R_6$ have equal values, too. There is only the Q-determining resistor R_5, which differs by a factor of Q_p.
- The relative sensitivities of the gain and the pole parameters with respect to the passive elements are of the same order of magnitude as in case of a second-order passive *RLC* network; see (81.35).
- The impact of the op-amp gain and gain-bandwidth product on the pole parameter is extremely low.

A sensitivity analysis of the biquad circuit in Fig. 81.15 gives the following results:

$$\begin{aligned}
S_{R_1}^{H_0} &= -S_{R_2}^{H_0} = -\frac{1}{2}s \\
S_{R_1}^{\omega_p} &= -S_{R_2}^{\omega_p} = -S_{C_3}^{\omega_p} = -S_{R_4}^{\omega_p} = -S_{C_5}^{\omega_p} = -S_{R_6}^{\omega_p} = \frac{1}{2} \\
S_{R_1}^{Q_p} &= -S_{R_2}^{Q_p} = -S_{C_3}^{Q_p} = -S_{R_4}^{Q_p} = +S_{C_5}^{Q_p} = -S_{R_6}^{Q_p} = \frac{1}{2} \\
S_{R_5}^{Q_p} &= 1.
\end{aligned} \tag{81.35}$$

In most practical applications, we can describe the op-amp dynamics by a one-pole model:

$$\mu(s) = \frac{\mu_0}{1 + (s/\omega_c)} = \frac{1}{(1/\mu_0) + (s/\omega_T)} \tag{81.36}$$

with the dc gain μ_0, the 3-dB cutoff frequency ω_c, and the gain-bandwidth product $\omega_T = \mu_0\omega_c = 1/T_T$.

If the circuit elements are chosen properly, e.g., choosing network parameters $\alpha_{21} = 1$ and $T_{34} = T_{56} = T = 1/\omega_p$, an analysis of the impact of the parameters μ_{0i} and $T_{Ti} = 1/\omega_{Ti}$ of the two op-amps μ_i, $i = 1, 2$, on the pole parameters of the transfer function yields

$$\frac{\Delta\omega_p}{\omega_p} \approx \frac{1}{\mu_{01}} - \frac{1}{\mu_{02}} - \frac{T_{T1} + T_{T2}}{T} \tag{81.37}$$

$$\frac{\Delta Q_p}{Q_p} \approx -2Q_p\left(\frac{1}{\mu_{01}} + \frac{1}{\mu_{02}} + \frac{T_{T1} - T_{T2}}{T}\right) \tag{81.38}$$

In case of high pole frequencies the impact of the dc gains μ_{01} and μ_{02} can be neglected against that of the gain-bandwidth products. From (81.37), after some intermediate steps, we obtain

$$\omega_p + \Delta\omega_p \approx \frac{1}{T + T_{T1} + T_{T2}} \tag{81.39}$$

In case of an ideal op-amp we have $\omega_p = 1/T$. The nonideal op-amp causes a pole frequency change $\Delta\omega_p$ due to the time constants T_{Ti}. The frequency determining time constant T of the passive network is increased by the two time constants T_{Ti} of the op-amps, which are reciprocals of the gain-bandwidth products ω_{Ti}.

The most interesting result is the Q-factor change in (81.38). If the frequency responses of the two op-amps are matched, as is usually the case with dual packages, the impact of the two gain-bandwidth products cancel out. Thus, we have nearly no Q enhancement at higher pole frequencies.

© 2003 by CRC Press LLC

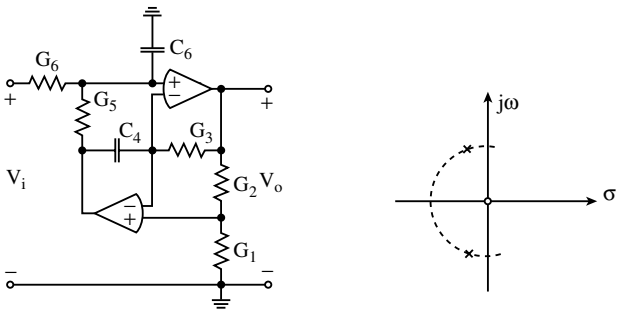

FIGURE 81.16 Second-order bandpass building block.

To make the GIC-derived biquad almost independent of op-amp parameters, the above-mentioned conditions ($\alpha_{21} = 1$, $T_{34} = T_{56}$) must be met by the passive elements. In a more general view, this result holds for the whole family of GIC-derived building blocks. Each of these building blocks has two frequency-determining time constants and one resistive voltage divider (G_1 and G_2 or G_3 and G_4). In any case, to obtain independence of op-amp parameters we have to choose equal time constants and a voltage divider with equal resistors. If the time constants or the resistors, respectively, do not match exactly, the independance of op-amp parameters remains nearly unchanged.

Next we will derive a bandpass building block from the general biquad in Fig. 81.14(b). If we choose the passive elements as $Y_{1a} = G_1$, $Y_{1b} = 0$, $Y_2 = G_2$, $Y_3 = G_3$, $Y_4 = sC_4$, $Y_5 = G_5$, $Y_{6a} = sC_6$, and $Y_{6b} = G_6$, we obtain the bandpass building block in Fig. 81.16, which has a voltage transfer ratio

$$H_{BP}(s) = \frac{V_o}{V_i} = \frac{G_6\left(sC_4G_2 + sC_4G_1\right)}{s^2C_4C_6G_2 + sC_4G_2G_6 + G_1G_3G_5} = H_0 \cdot \frac{s}{s^2 + s\omega_p/Q_p + \omega_p^2} \tag{81.40}$$

with pole frequency

$$\omega_p = \sqrt{\alpha_{12}/\left(T_{43}T_{65}\right)} \tag{81.41}$$

Q-factor

$$Q_p = \omega_p \cdot T_{66} \tag{81.42}$$

and midband gain

$$H_0Q_p = \left(1 + \alpha_{12}\right) \tag{81.43}$$

The filter design is similar to that of the low-pass building block. First we choose the two resistors $R_1 = R_2$ and the two capacitors $C_4 = C_6 = C$. Then, from the pole frequency ω_p we determine the two resistors

$$R_3 = R_5 = R = \frac{1}{\omega_p \cdot C} \tag{81.44}$$

and from the Q-factor Q_p the resistor

$$R_6 = Q_p \cdot R \tag{81.45}$$

© 2003 by CRC Press LLC

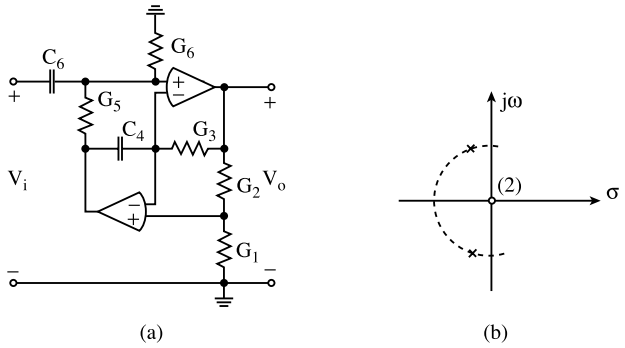

FIGURE 81.17 Second-order high-pass building block.

The pole sensitivities with respect to the passive elements and the relationship between the gain and the gain-bandwidth product of the op-amps are the same as in case of the low-pass filters. It should be mentioned that the maximum of the magnitude response $|H(j\omega)|$ occurs at $\omega = \omega_p$ and has exactly the value 2, independent of the Q-factor and the time constants of the circuit;[2] see (81.43).

We can derive a high-pass building block by choosing the following elements: $Y_{1a} = G_1$, $Y_{1b} = 0$, $Y_2 = G_2$, $Y_3 = G_3$, $Y_4 = sC_4$, $Y_5 = G_5$, $Y_{6a} = G_6$, and $Y_{6b} = sC_6$; see Fig. 81.17.

This filter circuit has a voltage transfer ratio

$$H_{\mathrm{HP}}(s) = \frac{V_o}{V_i} = \frac{sC_6\left(sC_4G_2 + sC_4G_1\right)}{s^2C_4C_6G_2 + sC_4G_2G_6 + G_1G_3G_5} = \left(1+\alpha_{12}\right)\cdot\frac{s^2}{s^2 + s\omega_p/Q_p + \omega_p^2} \tag{81.46}$$

with ω_p as in (81.41) and Q_p as in (81.42).

The design of the high-pass building block in Fig. 81.17 is identical to that of the bandpass described above. Both building blocks also have the same pole sensitivities and the same impact of the op-amps on the pole parameters.

If we feed the input signal not only through the capacitor C_6, but additionally through the element G_1, and if we set again $\alpha_{12} = 1$ we obtain the all-pass building block in Fig. 81.18.

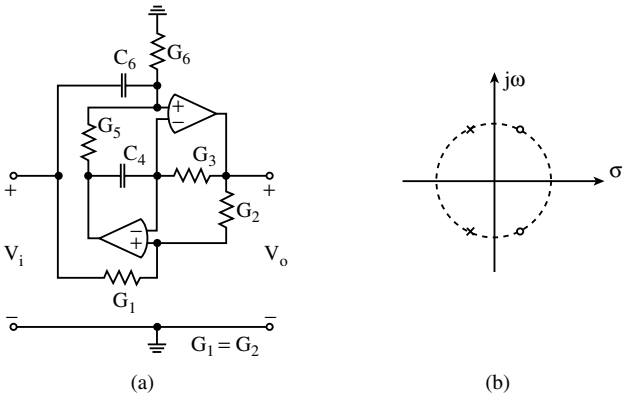

FIGURE 81.18 Second-order all-pass building block.

[2]Only assuming $\alpha_{12} = 1$.

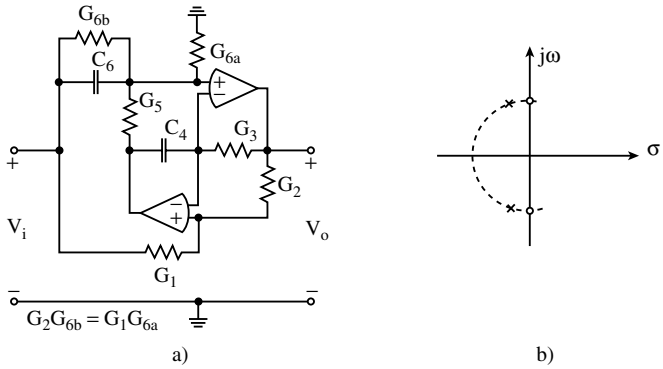

FIGURE 81.19 Notch filter building block.

Its voltage transfer ratio reads

$$H_{\mathrm{AP}}(s)=\frac{V_o}{V_i}=\frac{s^2C_6C_4G_2-sC_4G_1G_6+G_1G_3G_5}{s^2C_4C_6G_2+sC_4G_2G_6+G_1G_3G_5}$$
$$=\frac{s^2-\dfrac{s}{T_{66}}+\dfrac{1}{T_{43}T_{65}}}{s^2+\dfrac{s}{T_{66}}+\dfrac{1}{T_{43}T_{65}}} \tag{81.47}$$

The all-pass building block is designed exactly as the high-pass or bandpass circuit.

From the all-pass building block, we can derive a second-order notch filter by adding a conductor G_{6b} in parallel with the capacitor G_6; see Fig. 81.19.

The circuit in Fig. 81.19 has the general voltage transfer ratio

$$H(s)=\frac{V_o}{V_i}=\frac{sC_6C_4G_2+sC_4\left(G_2G_{6b}-G_1G_{6a}\right)+G_1G_3G_5}{s^2C_4C_6G_2+sC_4G_2G_6+G_1G_3G_5} \tag{81.48}$$

with $G_6 = G_{6a} + G_{6b}$. By setting $G_2G_{6b} = G_1G_{6a}$ (normally $G_1 = G_2$ and $G_{6a} = G_{6b}$) we obtain a second-order notch filter with a voltage transfer ratio

$$H(s)=\frac{s^2+\dfrac{\alpha_{12}}{T_{43}T_{65}}}{s^2+\dfrac{s}{T_{66}}+\dfrac{\alpha_{12}}{T_{43}T_{65}}} \tag{81.49}$$

where $\alpha_{12} = 1$ if $G_1 = G_2$.

Finally we will derive two second-order elliptic or Cauer-type building blocks from the general dual-amplifier structure in Fig. 81.14(b). To get a Cauer low-pass building block we take $Y_{1a} = G_1$, $Y_{1b} = C_1$, $Y_2 = G_2$, $Y_3 = G_3$, $Y_4 = G_4$, $Y_5 = sC_5$, $Y_{6a} = 0$, and $Y_{6b} = G_6$; see Fig. 81.20.

This filter circuit has a voltage transfer ratio

$$H(s)=\frac{V_o}{V_i}=\frac{s^2C_1G_3C_5+G_6\left(G_2G_4+G_1G_4\right)}{s^2C_1G_3C_5+sG_1G_3C_5+G_2G_4G_6} \tag{81.50}$$

© 2003 by CRC Press LLC

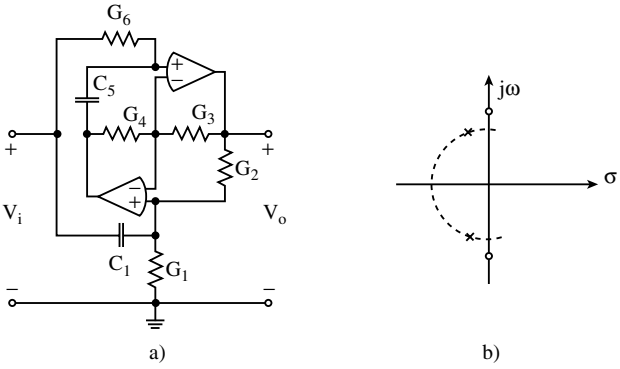

FIGURE 81.20 Second-order Cauer low-pass building block.

$$= \frac{s^2 + \dfrac{\alpha_{43}\left(1+\alpha_{12}\right)}{T_{12}T_{56}}}{s^2 + \dfrac{s}{T_{11}} + \dfrac{\alpha_{43}}{T_{12}T_{56}}}$$

$$= \frac{s^2 + \omega_z^2}{s^2 + s\omega_p/Q_p + \omega_p^2}$$

The magnitude ω_z of the zeros is always greater than the magnitude ω_p of the poles. Additionally, without any matching of elements, the real part of the zeros is always zero.

The design can proceed in the following steps. First we predefine $\alpha_{43} = 1$ and choose due to practical considerations the values of the resistors $R_3 = R_4$. We also select the two capacitors C_1 and C_5. Then, comparing the first coefficient in the denominator of $H(s)$ in (81.50), namely, $T_{11} = Q_p/\omega_p$ with $T_{11} = C_1R_1$, we determine the resistor

$$R_1 = \frac{Q_p}{\omega_p C_1} \tag{81.51}$$

Further, comparing the last coefficients in the numerator and denominator yields

$$\frac{\omega_z^2}{\omega_p^2} = 1 + \alpha_{12} \tag{81.52}$$

With $\alpha_{12} = R_2/R_1$ we can solve (81.52) for

$$R_2 = R_1 \cdot \left(\frac{\omega_z^2}{\omega_p^2} - 1\right) \tag{81.53}$$

Finally, from $\omega_p^2 = 1/(T_{12}T_{56})$ we can determine the resistor

$$R_6 = \frac{1}{\omega_p^2 C_1 C_5 R_2} \tag{81.54}$$

In order to get the three resistors R_1, R_2, and R_6 in the same order of magnitude it might be advisable to predefine different values for the capacitors C_1 and C_5.

© 2003 by CRC Press LLC

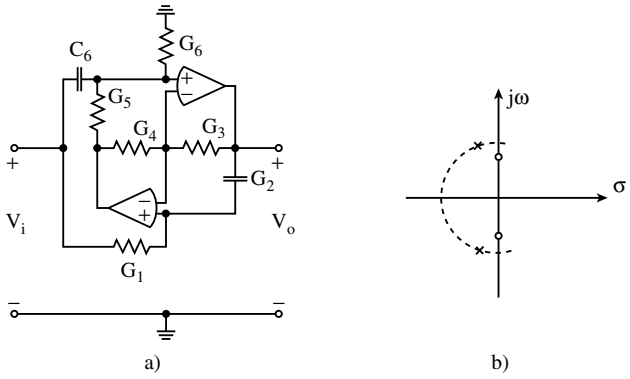

FIGURE 81.21 Second-order Cauer high-pass building block.

A Cauer high-pass building block is depicted in Fig. 81.21. Its voltage transfer ratio reads

$$H(s)=\frac{V_o}{V_i}=\frac{s^2C_2G_4C_6+G_1\left(G_3G_5-G_6G_4\right)}{s^2C_2G_4C_6+sG_6G_4C_2+G_1G_3G_5}$$

$$=\frac{s^2+\dfrac{\alpha_{34}-\alpha_{65}}{T_{21}T_{65}}}{s^2+s\dfrac{1}{T_{11}}+\dfrac{\alpha_{43}}{T_{12}T_{56}}} \tag{81.55}$$

$$=\frac{s^2+\omega_z^2}{s^2+s\omega_p/Q_p+\omega_p^2}$$

The design of this building block is similar to that of the low-pass circuit. First we choose the resistors $R_3 = R_4$ and the capacitors C_2 and C_6 and then, with predefined parameters Q_p, ω_p, and ω_z, we determine the remaining three resistors:

$$R_6=\frac{Q_p}{\omega_pC_6} \tag{81.56}$$

$$R_5=R_6\cdot\left(1-\frac{\omega_z^2}{\omega_p^2}\right) \tag{81.57}$$

$$R_1=\frac{1}{\omega_p^2C_6C_2R_5} \tag{81.58}$$

81.5 GIC-Derived Three-Amplifier Biquads

In order to get more flexibility for realizing arbitrary second-order transfer functions and to obtain less resistor spread for realizing a given pole-Q, we can extend the resonator in Fig. 81.14(a) to a resonator with three nullors; see Fig. 81.22.

There are two different biquads known from the literature that are based on the resonator in Fig. 81.22. The first one is proposed by Mikhael and Bhattacharyya [9] and is shown in Fig. 81.23.

This filter circuit requires a small resistor spread to realize high pole-Q. The zeros of the transfer function are formed with a resistive feed-forward network providing a flexible design with arbitrary numerator coefficients. The voltage transfer ratio V_3/V_i is

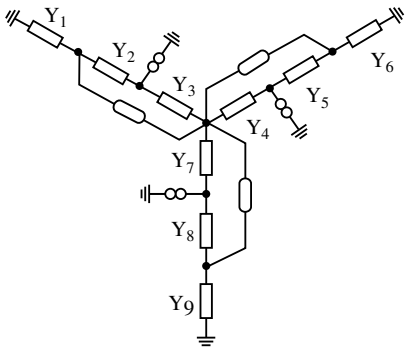

FIGURE 81.22 Resonator with three nullors.

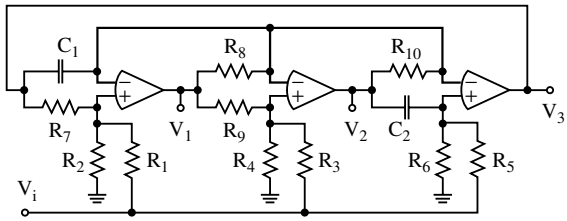

FIGURE 81.23 Mikhael–Bhattacharyya biquad.

$$H_3(s) = \frac{V_3}{V_i} = \frac{N_3(s)}{D(s)} \tag{81.59}$$

with

$$\begin{aligned} N_3(s) = {} & s^2 C_1 C_2 G_1 G_9 + sC_2\left(G_7 G_8 G_3 + G_8 G_2 G_3 - G_8 G_1 G_4\right) \\ & + \left(G_9 G_7 G_{10} G_5 + G_9 G_{10} G_2 G_5 - G_9 G_{10} G_4 G_6\right) \end{aligned} \tag{81.60}$$

and

$$\begin{aligned} D(s) = {} & s^2 C_1 C_2\left(G_1 G_9 + G_2 G_9\right) + sC_2\left(G_7 G_8 G_3 + G_7 G_8 G_4\right) \\ & + \left(G_9 G_7 G_{10} G_5 + G_9 G_{10} G_7 G_6\right) \end{aligned} \tag{81.61}$$

The two other output nodes lead to similar transfer expressions.

The second biquad, which is based on the resonator in Fig. 81.22, was proposed by Padukone, Mulawka, and Ghausi [11] and is depicted in Fig. 81.24. Assuming ideal op-amps and choosing V_3 as output voltage, we obtain the following transfer function:

$$H_3(s) = \frac{V_3}{V_i} = \frac{N_3(s)}{D(s)} \tag{81.62}$$

with

$$\begin{aligned} N_3(s) = {} & s^2\left[C_2 C_3\left(G_2 G_6 - G_1 G_3\right) + C_1 C_2 G_1 G_8\right] \\ & + s\left[C_1 G_2 G_5 G_9 - C_3 G_2 G_5 G_7 + C_2 G_1 G_4 G_8\right] + \left(G_2 G_4 G_5 G_9\right) \end{aligned} \tag{81.63}$$

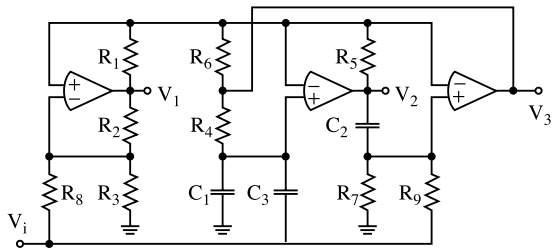

FIGURE 81.24 Padukone–Mulawka–Ghausi biquad.

and

$$D(s) = s^2(C_1 + C_3)C_2G_2G_6 + sC_2G_1G_4(G_3 + G_8) + G_2G_4G_5(G_7 + G_9) \tag{81.64}$$

It has been shown [11] that the pole sensitivities to all passive components are not greater than unity. The filter section has the main advantage of being particularly insensitive to gain-bandwidth variations even when the op-amps are mismatched.

81.6 State-Variable-Based Biquads

A frequently-used multiple-amplifier biquad is the circuit proposed by Kerwin, Huelsman, and Newcomb [8]. This filter circuit has extreme flexibility, good performance, and low sensitivities to the passive components. The filter is based on analog computer structures [13], which are derived from the state-variable representation of linear continuous systems. Therefore, these filters are also referred to as *state-variable filters*.

Figure 81.25(a) shows the basic analog computer structure consisting of one summing amplifier and two integrators. We assume both integrators to have the same transfer function $-1/(sT)$, where T is called the integrator time constant. Analyzing this structure yields

$$V_1 = -K_1 \cdot V_3 + K_2 \cdot V_i + K_3 \cdot V_2 \tag{81.65}$$

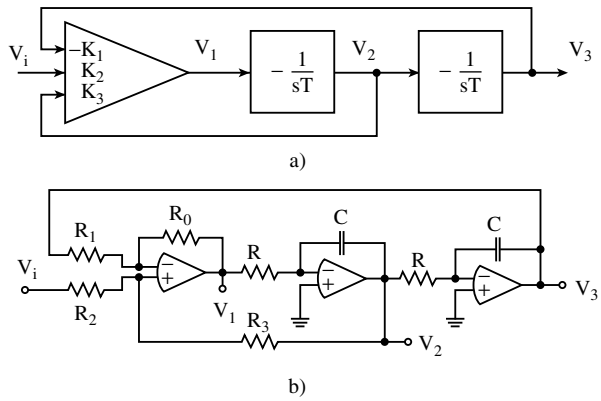

FIGURE 81.25 (a) Second-order analog computer structure and (b) state-variable filter section proposed by Kerwin, Huelsman, and Newcomb.

© 2003 by CRC Press LLC

$$V_2 = -\frac{1}{sT} \cdot V_1 \tag{81.66}$$

$$V_3 = -\frac{1}{sT} \cdot V_2 \tag{81.67}$$

which results in

$$H_{\mathrm{HP}}(s) = \frac{V_1}{V_i} = \frac{s^2T^2K_2}{s^2T^2 + sTK_3 + K_1} \tag{81.68}$$

Using (81.66), we can immediately derive the voltage transfer ratio V_2/V_i from (81.68):

$$H_{\mathrm{BP}}(s) = \frac{V_2}{V_i} = \frac{-sTK_2}{s^2T^2 + sTK_3 + K_1} \tag{81.69}$$

Finally, with (81.67) we obtain from (81.69)

$$H_{\mathrm{LP}}(s) = \frac{V_3}{V_i} = \frac{K_2}{s^2T^2 + sTK_3 + K_1} \tag{81.70}$$

Thus, the structure in Fig. 81.25(a) simultaneously realizes a high-pass filter, a bandpass filter, and a low-pass filter. The corresponding filter circuit proposed by Kerwin, Huelsman, and Newcomb is depicted in Fig. 81.25(b). The integrators consist of one op-amp, one resistor R, and one capacitor C. The time constant is given by $T = RC$. The three gain factors of the summing amplifier are determined by the four resistors $R_0 - R_3$:

$$K_1 = \frac{R_0}{R_1} \tag{81.71}$$

$$K_2 = \frac{R_3}{R_2 + R_3}\left(1 + \frac{R_0}{R_1}\right) \tag{81.72}$$

$$K_3 = \frac{R_2}{R_2 + R_3}\left(1 + \frac{R_0}{R_1}\right) \tag{81.73}$$

Obviously, the integrator time constant T plays the role of a reciprocal normalization frequency. Thus, if we refer the frequency variable s to $1/T$, we obtain from (81.70) the normalized low-pass transfer function

$$H_{\mathrm{LP}}(s) = \frac{V_3}{V_i} = \frac{K_2}{s^2 + sK_3 + K_1} \tag{81.74}$$

Given the normalized pole frequency ω_p and the pole Q-factor Q_p, we can design the filter section by equating

$$K_1 = \omega_p^2 \tag{81.75}$$

and

$$K_3 = \omega_p / Q_p \tag{81.76}$$

© 2003 by CRC Press LLC

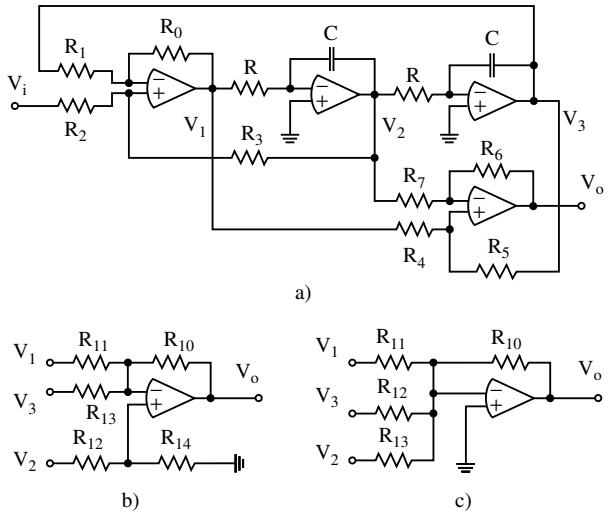

FIGURE 81.26 (a) State-variable filter with output amplifier, (b) output amplifier with inverting and noninverting inputs, and (c) output amplifier with three inverting inputs.

Then K_2 is fixed by the dc gain of the transfer function:

$$K_2 = H_0 \tag{81.77}$$

The state-variable filter circuit can be extended to a general biquad by adding an output amplifier that sums the three voltages V_1, V_2, and V_3. Figure 81.26(a) shows a state-variable filter with an output amplifier summing the voltages V_1, V_2, and V_3 of the circuit in Fig. 81.25(b). This biquad has been proposed also by Kerwin, Huelsman, and Newcomb [8]. As alternative circuits, the amplifiers in Fig. 81.26(b) and (c) can be used. Figure 81.26(b) shows an output amplifier that realizes the following sum:

$$V_o = \alpha_1 V_1 + \alpha_2 V_2 + \alpha_3 V_3 \tag{81.78}$$

with

$$\alpha_1 = -\frac{R_{10}}{R_{11}} \quad \alpha_2 = \frac{R_{14}}{R_{12}+R_{14}}\left(1+\frac{R_{10}}{R_{11}\|R_{13}}\right) \quad \alpha_3 = -\frac{R_{10}}{R_{13}} \tag{81.79}$$

If we solve (81.68)–(81.70) for the three output voltages and substitute them in (81.79) with normalized variables s we obtain

$$H(s) = \frac{V_o}{V_i} = -K_2 \frac{|\alpha_1| s^2 + |\alpha_2| s + |\alpha_3|}{D(s)} \tag{81.80}$$

All numerator coefficients have the same sign. Therefore, the zeros of the transfer function are in the left-s-half plane. If we set $\alpha_2 = 0$, i.e., if we delete the voltage divider R_{12}, R_{14} and ground the noninverting input terminal of the op-amp, we obtain zeros on the $j\omega$ axis.

When designing the biquad, R_{14} and R_{10} may be used to scale the impedance level of the two resistive subnetworks. Then from the three numerator coefficients or from the overall gain constant of the transfer function, the zero frequency ω_z, and the zero Q-factor Q_z we can easily determine the remaining resistors R_{11}, R_{12}, and R_{13}.

© 2003 by CRC Press LLC

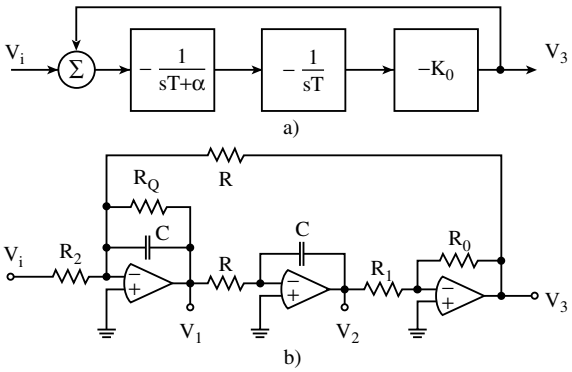

FIGURE 81.27 (a) Principle and (b) three op-amp realization of the Tow-Thomas filter.

The output amplifier in Fig. 81.26(c) has three inverting inputs. Summing the voltages V_1, V_2, and V_3 leads to a numerator polynomial where the sign of the middle coefficient is different from the sign of the other two. Thus, the zeros are in the right-s-half plane. Again, we can delete the resistor R_{12} to realize zero on the $j\omega$ axis.

A second state-variable biquad circuit proposed by Tow and Thomas [3], [16], [17] yields similar performance to that of the Kerwin–Huelsman–Newcomb circuit. It uses a feedback loop with one damped integrator, one integrator, and one inverting amplifier; see Fig. 81.27(a). Figure 81.27(b) shows the Tow–Thomas circuit with three op-amps.

The damped integrator has a transfer function

$$\frac{V_1}{V_3} = \frac{-1}{sT+\alpha}\bigg|_{V_i=0} \tag{81.81}$$

with $T = RC$ and $\alpha = R/R_Q$. The inverting amplifier has a gain

$$\frac{V_3}{V_2} = -\frac{R_0}{R_1} = -K_0 \tag{81.82}$$

An analysis of the circuit in Fig. 81.27(b) with V_i being the input voltage and V_3 the output voltage yields a transfer function

$$H_{LP}(s) = \frac{V_3}{V_i} = \frac{-K_0\alpha_2}{s^2T^2 + sTK_Q + K_0} \tag{81.83}$$

with

$$K_0 = \frac{R_0}{R_1} \quad \alpha_2 = \frac{R}{R_2} \quad K_Q = \frac{R}{R_Q} \tag{81.84}$$

For the design of the filter, the integrator time constant T serves as a reciprocal normalization frequency. Then, from the predefined normalized pole frequency we can determine the resistor ratio K_0, from the pole Q-factor the ratio K_Q, and from the dc gain of the filter section the ratio α_2. Choosing convenient values for C and R_0, we finally determine the resistors R, R_1, R_Q, and R_2 from the parameters T, K_0, K_Q, and α_2, respectively.

© 2003 by CRC Press LLC

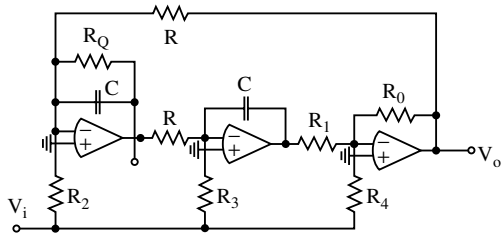

FIGURE 81.28 Generalized Tow-Thomas biquad.

The filter circuit in Fig. 81.26 requires an additional op-amp to realize a transfer function with a general second-degree numerator polynomial. An alternative method is to feed fractions of the input signal forward into the input of each op-amp. This is realized in the multiple-input Tow-Thomas biquad [3]; see Fig. 81.28. The transfer function of this circuit can be calculated to be

$$H(s)=\frac{V_o}{V_i}=-\frac{s^2T^2\alpha_4+sT\left[K_Q\alpha_4-K_0\alpha_3\right]+\left[K_0\left(\alpha_2-K_Q\alpha_3\right)\right]}{s^2T^2+sTK_Q+K_0} \tag{81.85}$$

with K_0, α_2, and K_Q as defined in (81.84) and

$$\alpha_3=\frac{R}{R_3}\quad \alpha_4=\frac{R_0}{R_4} \tag{81.86}$$

Thus, arbitrary numerator coefficients can be predescribed. In particular, if we choose $\alpha_3 = \alpha_4 = 0$ we obtain the low-pass filter circuit in Fig. 81.27(b) and the transfer function in (81.83).

When the state-variable filters described above are used to realize high-Q filter functions, the Q practically obtained is usually higher than that desired in the design. This effect is called Q enhancement and is caused by the phase lag introduced by the nonideal op-amps. One way to solve this problem is to use integrators with phase compensation.

Figure 81.29 shows a noninverting integrator with an additional op-amp for phase lag compensation. A detailed description of this circuit can be found in [7]. Putting this noninverting integrator together with an inverting integrator in a feedback loop results in a resonator with a Q-factor that is almost independent of the gain-bandwidth product of the op-amps. Thus, nearly no Q enhancement occurs.

Exactly this feedback loop is used in the Åkerberg–Mossberg biquad [1]; see Fig. 81.30. In this circuit, a noninverting integrator with phase lag compensation together with an inverting damped integrator is connected as a feedback loop. More details about this filter section can be found in [1], [6], [7].

Finally, let us consider the general biquad proposed by Berka and Herpy [2]; see Fig. 81.31. This biquad is also based on a state-variable representation and requires a second-order differentiator and a damped integrator. One of the main advantages of this circuit is extremely low sensitivities. A detailed description of the filter circuit and its design can be found in [6].

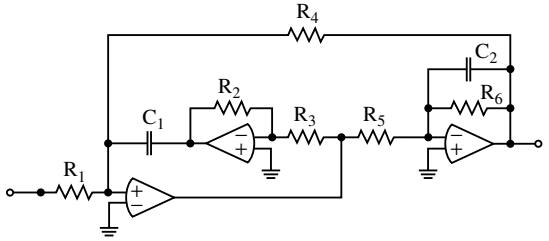

FIGURE 81.30 Åkerberg–Mossberg biquad.

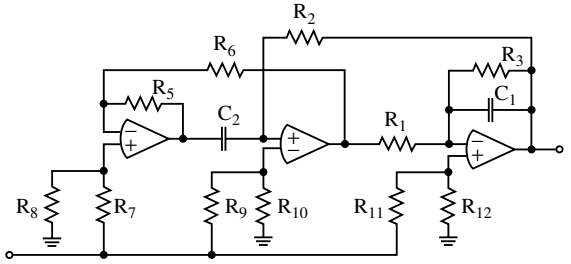

FIGURE 81.31 Berka–Herpy biquad.

81.7 All-Pass-Based Biquads

Finally, we will briefly consider two circuits that are based on first-order all-pass sections. Figure 81.32 shows the classical filter circuit introduced by Tarmy and Ghausi [15].

In this circuit amplifiers with differential inputs and differential outputs are used. In the feedback loop, two all-pass sections with voltage transfer ratios

$$H_i(s) = \frac{sT_i - 1}{sT_i + 1} \tag{81.87}$$

$T_i = R_iC_i$, $i = 1, 2$, and one inverting amplifier are cascaded. The overall transfer function is

$$H(s) = \frac{V_o}{V_i} = \alpha_1 \frac{s^2T_1T_2 - s(T_1 + T_2) + 1}{s^2T_1T_2 + s\alpha_2(T_1 + T_2) + 1} \tag{81.88}$$

with

$$\alpha_1 = \frac{K_1K_3K_4}{1 + K_2K_3K_4} \quad \alpha_2 = \frac{1 - K_2K_3K_4}{1 + K_2K_3K_4} \tag{81.89}$$

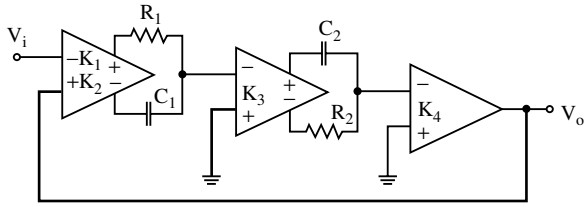

FIGURE 81.32 Tarmy–Ghausi circuit.

© 2003 by CRC Press LLC

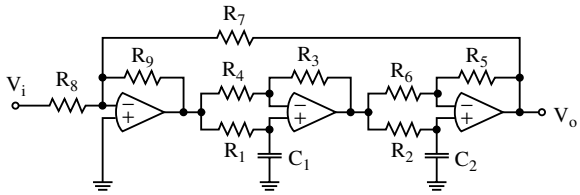

FIGURE 81.33 Tarmy-Ghausi circuit modified by Moschytz.

The main advantages of the Tarmy–Ghausi circuit are its low sensitivities to the gain-bandwidth products of the op-amps and thus its favorable performance at high pole frequencies and high pole *Q*-factors.

Most of the popular low-cost op-amps are not configured for differential output operations. This problem is bypassed by a circuit proposed by Moschytz [10]; see Fig. 81.33.

The circuit in Fig. 81.33 is also based on first-order all-pass sections. But the all-pass circuits are realized by means of only single-ended op-amps. Therefore, this circuit is more convenient for practical realizations.

81.8 Summary

In this chapter, we have shown that a lot of different multiple-amplifier biquads are known from the literature. Hence, a design engineer who aims to realize a high-performance active filter is in the favorable situation to find a rich variety of alternative circuits and design methods. On the other hand, this variety is also confusing and the design engineer may need assistance in deciding among all these circuits and methods. Unfortunately, the multiple-amplifier biquads mentioned in this chapter cannot be classified in a simple way. Therefore, only a rough guidance can be given. In a practical case, it is advisable to compare two or three solutions next to the predefined demands by a thorough analysis and then to find the final solution.

The biquads with decoupled time constants offer some of the benefits mentioned at the beginning of this section at low costs, namely, small passive element spread and low sensitivities. The dual-amplifier twin-*T* biquads and the GIC-derived dual-amplifier biquads offer a trade-off between costs and performance. The twin-*T* biquads are particularly suitable for the design of elliptic filters. The special merits of the GIC-derived biquads are the small number of passive components and the independence of the op-amp parameters. Thus, this biquad represents a robust filter solution for many different applications. Additionally, these filters can be easily designed.

The GIC-derived three-amplifier biquads and the state-variable-based filters offer additional flexibility with respect to an independent choice and an independent tuning of the filter parameters. Typically, these circuits are used in applications with switched parameters, e.g., filters with switched cutoff frequencies. This flexibility is paid for by a higher number of op-amps and passive components. It should be mentioned that the original state-variable circuits, i.e., two integrators in a loop, are rather sensitive to the phase lag introduced by the nonideal op-amps. This is always a problem when simultaneously high-frequency and high-*Q* performance shall be achieved. In such applications, biquads with compensated phase lag should be applied, e.g., the biquads proposed by Åkerberg and Mossberg, Berka and Herpy, or Tarmy and Ghausi.

82.1 Introduction

CGIC's have been used to realize high-performance active biquads with 2 OA's, 3 OA's, or n OA's per section [1] and [5].

In this chapter two- and three-amplifier biquads are presented that are based on CGIC's. Although several biquads have been reported, the ones presented here have proved to be clearly superior to single-amplifier biquads. This is because the design carried out [1] was constrained by stringent performance criteria satisfying important properties and features such as stability, versatility, insensitivity to component tolerances and drift, low dependence on the op-amp (OA) frequency limitations, finite gain, tunability, small spread in component values, and minimum total capacitance.

Wasfy B. Mikhael, "Chapter 9: Biquad II" in *RC Active Filter Design Handbook*, Stephenson, New York: Wiley, 1985.

© 2003 by CRC Press LLC

In addition, the performance of the CGIC-based biquads presented here are comparable to multiple OA biquads. On the other hand, the 3-OA CGIC biquad is shown to yield additional performance improvements over the 2-OA CGIC biquad. Also, the CGIC biquads use the OA's in the differential mode.

In the following discussion the generalized structure of the 2-OA and 3-OA CGIC biquads are presented. Illustrative examples of the element identification to realize the most commonly used biquads are tabulated. Stability and sensitivity properties are discussed. A design procedure for each biquad is described that minimizes the active sensitivities while maintaining the filter's stability. Several second-order design examples are given. A sixth-order Chebyshev LPF and a sixth-order elliptic BPF are designed using the design values and tuning procedure suggested. The excellent performance of the resulting realizations is experimentally verified. A universal 2-OA GIC hybrid implementation using thick film is also described. 2-OA CGIC biquadratic active filter realizations for extended high-frequency applications employing the composite operational amplifiers technique [6], [7] are given.

82.2 Biquadratic Structure Using the Antoniou CGIC (2-OA CGIC Biquad)

Consider the network of Fig. 82.1, which is simply Antoniou's CGIC [2], with two new ports created across 3-G and 4-G. This is represented symbolically in Fig. 82.2.

A new configuration is now obtained, as shown in Fig. 82.3. A synthesis procedure is now described that uses this configuration. The transfer functions between the input and output terminals 2, 3, and 4, assuming ideal OA's are readily obtained as

$$\frac{V_3}{V_1} = T_1 = \left[Y_5 + h(s)\left[Y_7\left(1 + Y_6/Y_2\right) - Y_5Y_8/Y_2\right]\right]\Big/ D(s) \tag{82.1a}$$

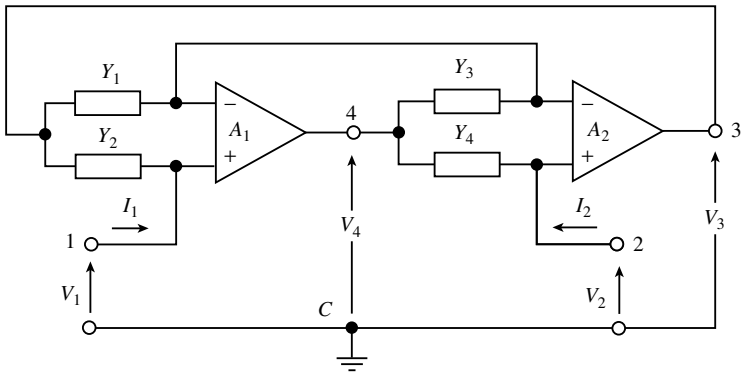

FIGURE 82.1 Antoniou's CGIC with additional ports 3*G* and 4*G*.

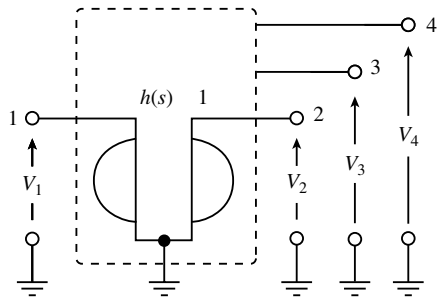

FIGURE 82.2 Symbolic representation of the CGIC in Fig. 82.1.

© 2003 by CRC Press LLC

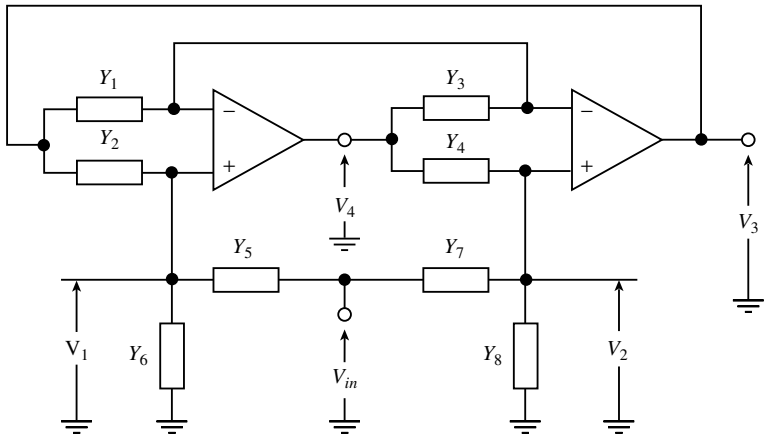

FIGURE 82.3 The basic configuration.

$$\frac{V_4}{V_i} = T_2 = \left[Y_5\left(1 + Y_8/Y_4\right) - Y_6Y_7/Y_4 + h(s)Y_7\right]/D(s) \tag{82.1b}$$

$$\frac{V_2}{V_i} = T_3 = \left[Y_5 + h(s)Y_7\right]/D(s) \tag{82.1c}$$

where

$$\begin{aligned} h(s) &= Y_2Y_3/Y_1Y_4 \\ D(s) &= \left(Y_5 + Y_6\right) + h(s)\left(Y_7 + Y_8\right) \end{aligned} \tag{82.1d}$$

The conversion function $h(s)$ and the admittances Y_5 to Y_8 can be selected in many different ways, and it is clear that any stable second-order transfer function with any desired zero and pole locations can be realized.

Letting

$$Y_i = sC_i + G_i \tag{82.2}$$

where $i = 1$ to 4, we have from (82.1)

$$h(s) = \left(sC_2 + G_2\right)\left(sC_3 + G_3\right)/\left[\left(sC_1 + G_1\right)\left(sC_4 + G_4\right)\right] \tag{82.3}$$

Clearly, by omitting one or more conductances and/or capacitances, a number of specific conversion functions can be generated.

82.3 Realization of the Most Commonly Used Biquad Functions Using the 2-OA CGIC

The most frequently used second-order transfer functions have already been described in Chapter 79. Realizations of these functions are given in Table 82.1. The LP, HP, BP, and BS sections are produced by choosing $h(s)$ in a simple manner such as K_1s, K_2s^2, $K_3s + K_4s^2$ or their reciprocals. Circuits 3, 4, and 7 can be regarded as realizations of simple RLC networks [2], [3]. Second-order AP sections can be obtained from circuits 11 and 12 of Table 82.1.

[a]These elements can be set equal to zero.

[b]A special case of Circuit 12 — namely, the all-pass case — has also been independently proposed by J. T. Lim, Bell Northern Research, Canada, as communicated privately by him to Dr. A. Antoniou.

© 2003 by CRC Press LLC

Figures 82.1 and 82.2 and Table 82.1 show that, with the exception of circuit 10, the response is obtained from the output of an OA. Owing to the low output resistance of the amplifier, any number of sections can be cascaded without using isolation amplifiers.

82.4 Stability During Activation and Sensitivity Using the 2-OA CGIC Biquad

Stability Properties

It has been shown [4] that some networks using CGIC's can be conditionally stable, that is, a circuit can lock in an unstable mode during activation (just after switching on the power supply). For amplifiers with a finite open loop gain A, the circuit of Fig. 82.3 gives

$$\frac{V_k}{V_i} = \frac{N_k(s)}{D(s)}$$

where $k = 2, 3, 4$ and

$$\begin{aligned} D(s) &= M_1 Y_1 + M_2 Y_3 \\ &\quad + (1 + M_1)(1 + M_2)\left[Y_1/A_1 + Y_3/A_2 + Y_1/A_1A_2 + Y_3/A_1A_2\right] \end{aligned} \tag{82.4}$$

$$M_1 = \frac{Y_5 + Y_6}{Y_2}$$

$$M_2 = \frac{Y_7 + Y_8}{Y_4}$$

It can be easily shown that for the circuit in Fig. 82.3 low-frequency unstable modes cannot arise during activation. This is due to the absence of differences and changes of sign in the denominator coefficients. Thus any combination of OA gains that occur during transients and power supply switching does not result in saturation or low-frequency instability before reaching the steady state [5].

Sensitivity Analysis

The pole Q-factor Q_p, the undamped frequency of oscillation ω_p, the notch frequency ω_n, and the multiplier constants H_{BS}, H_{LP}, H_{HP}, and H_{BP}, as well as Q_z, ω_z, and H_{AP}, have been previously defined in Chapter 75. The sensitivity of a quantity x with respect to variations in an element e is denoted by S_e^x. For ideal amplifiers, the use of Table 82.1 leads to

$$0 \le S_e^x \le 1 \tag{82.5}$$

where x represents any one of these H, ω, or Q qualities and e represents any capacitance or conductance.

82.5 Design and Tuning Procedure of the 2-OA CGIC Biquad

A design procedure is now described. Table 82.1 shows that there are several degrees of freedom in the choice of element values. These may be used to minimize $S_A^{Q_p}$ or the spread of element values. By using minimum sensitivity (to the OA parameters) constraints in circuits 1, 3, 7, 10, and 12, possible sets of element values for LP, HP, BP, BS, and AP sections have been obtained, as shown in Table 82.2. In addition,

© 2003 by CRC Press LLC

TABLE 82.2 Design Values and Tuning Procedure

Circuit Number (from Table 10.1)	Design Values	Transfer Function Realized	Tuning Sequence ω_o	Tuning Sequence ω_p	Tuning Sequence Q_p
1	$G_1 = G_4 = G_5 = G_8 = G,\ G_3 = G/Q_p,\ C_2 = C_3 = C,$ where $C = \dfrac{G}{\omega_p}$	$T_2 = \dfrac{2\omega_p^2}{D(s)}$	—	G_8	G_3
3	$G_1 = G_2 = G_4 = G_6 = G,\ G_8 = G/Q_p,\ C_8 = 0,\ C_3 = C_7 = C,$ where $C = \dfrac{G}{\omega_p}$	$T_1 = \dfrac{2s^2}{D(s)}$	—	G_4	G_8
7	$G_1 = G_2 = G_4 = G_6 = G,\ G_7 = G/Q_p,\ G_8 = 0,\ C_3 = C_8 = C,$ where $C = \dfrac{G}{\omega_p}$	$T_1 = \dfrac{\left(\dfrac{2\omega_p}{Q_p}\right)s}{D(s)}$	—	G_2	G_7
10	$G_1 = G_2 = G_4 = G_5 + G_6 = G,\ G_8 = G/Q_p,\ C_3 = C_7 + C_8 = C,$ where $\omega_p = \dfrac{G}{C}$ and $\omega_n^2 = \omega_p \dfrac{G_5}{C_7}$	$T_3 = \dfrac{C_7}{C}\dfrac{\left(s^2 + \omega_n^2\right)}{D(s)}$	G_2	G_6	G_8
12	$G_1 = G_2 = G_4 = G_5 = G,\ G_6 = 0,\ C_3 = C_7 = C,\ C_8 = G/Q_p,$ where $\omega_p = \dfrac{G}{C}$	$T_1 = \dfrac{D(-s)}{D(s)}$	G_4		G_8

Note: $D(s) = s^2 + (\omega_p/Q_p)s + \omega_p^2$.

© 2003 by CRC Press LLC

this choice of elements guarantees stable operation with real OA's. It is seen that the notch frequency ω_n, the undamped frequency of oscillation ω_p, and Q-factor Q_p can be easily adjusted by sequentially trimming three distinct resistors. A tuning sequence is also given in Table 82.2.

It is to be noted from Table 82.2 for the design of the BS sections, that

$$\omega_n^2 = \frac{\omega_p G_s}{C_s} \tag{82.6}$$

where

$$G_5 + G_6 = G_1 \qquad C_7 + C_8 + C \qquad \text{and} \qquad \omega_p = \frac{G}{C}$$

Hence

$$\frac{w_n^2}{w_p^2} = \frac{G_5}{G} \cdot \frac{C}{C_7} \tag{82.7}$$

where

$$\frac{G_5}{G} \text{ is always } \le 1 \qquad \text{and} \qquad \frac{C}{C_7} \text{ is always } \ge 1$$

It is seen from (82.7) that for $\omega_n \le \omega_p$, C_8 can be set to zero ($C_7 = C$), and only two capacitors per section are used. For $\omega_n > \omega_p$, three capacitors are required. In all cases, regardless of the choice of C_7 and C_8, the total capacitance per section is equal to $2C$.

In most applications where notch sections are used, ω_n/ω_p is close to unity and care should be taken when choosing G_5 and C_7 in (82.7). A suitable choice of G_5, G_6, G_7, and C_8 values may be obtained by letting

$$\frac{G_5}{G} = \frac{1}{K} \quad \text{and} \quad \frac{C}{C_7} = 2$$

Thus K is approximately equal to 2 ($K < 2$ for $\omega_n > \omega_p$ and $K > 2$ for $\omega_n \le \omega_p$). The suggested choice yields a capacitor spread of 2 and both R_5 and R_6 are approximately equal to $2R$.

82.6 Design Examples Using the 2-OA CGIC Biquad

Example 1. Design a second-order Butterworth ($Q_p = 0.707$) LP filter having a cutoff frequency $f_p = 20{,}000/2\pi$ Hz.

Procedure

1. Circuit 1 in Table 82.2 realizes an LPF. The design equations are also given in Table 82.2.
2. First we choose an appropriate value for C, say 10 nF. Thus $C = C_2 = C_3 = 10$ nF.
3. Now,

$$R = \frac{1}{C\omega_p} = \frac{1}{20{,}000 \times 10^{-8}}$$

Therefore, $R = 5$ kΩ

© 2003 by CRC Press LLC

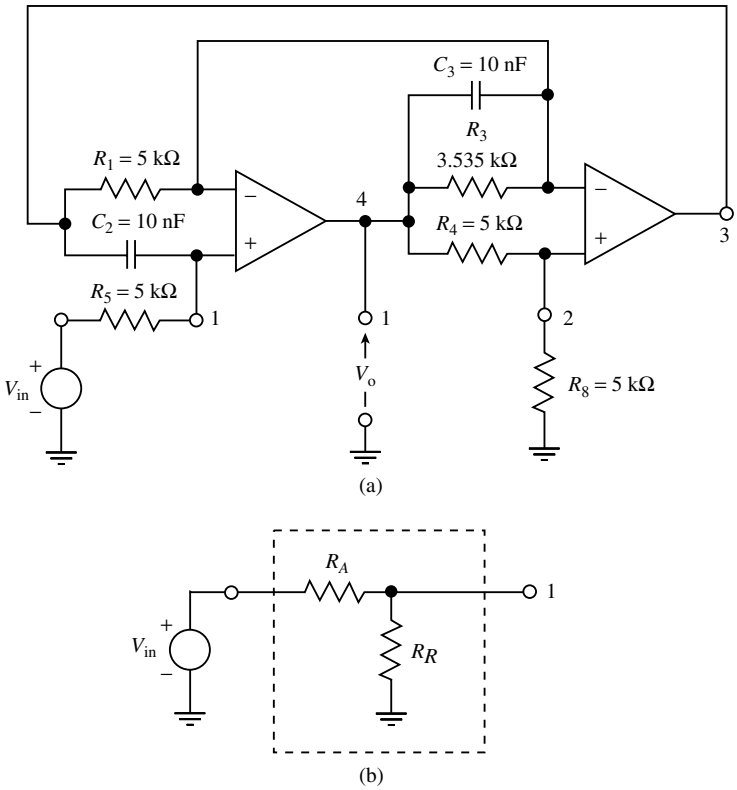

FIGURE 82.4 (a) Second-order Butterworth LPF design example; (b) controlling the gain factor of the LPF.

4. Consequently, $R = R_1 = R_4 = R_5 = R_8 = 5$ kω and $R_3 = RQ_p = 3.535$ kΩ.
5. The circuit is shown in Fig. 82.4(a). It is noted that the low-frequency gain of the LP filter H_{LP} is 2.

A simple procedure can be followed to scale H_{LP} by a factor x less than unity, that is, effectively multiplying the transfer function realized by x. This is done by replacing the resistance R_5 by two resistors R_A, and R_B (in series with the input V_{in}) in the manner shown in Fig. 82.4(b), where

$$R_5 = R = 5\ \text{k}\Omega$$

$$= R_A \| R_B$$

The desired gain and scale factor $x = R_B/(R_A + R_B)$. Thus for $x = \frac{1}{2}$, resulting in a dc gain of the LP filter of unity, the choice of resistors R_A and R_B is $R_A = R_B = 10$ kΩ.

If functional tuning of the filter is desired, the tuning sequence of circuit 1 in Table 82.2 can be followed. First, ω_p is adjusted by applying a sinusoidal input at the desired ω_p frequency. Then R_B is tuned until ω_p realized equals the desired value. This can be detected by monitoring the phase angle of the output relative to the input. When the proper ω_p is reached, the output lags the input by 90°. Next, to adjust the Q_p, the filter gain H_{dc} of the LPF at a frequency much lower than ω_p is determined. Then an input at ω_p is applied. R_3 is adjusted until the gain of the LPF at ω_P is Q_P desired H_{dc}.

Example 2. Design a second-order BP filter with $Q_p = 10$ and $f_p = 10{,}000/2\pi$ Hz.

Procedure

1. Circuit 7 in Table 82.2 realizes a BP filter. The design equations are also given in Table 82.2.
2. First we choose a suitable value for C, say 10 nF.

© 2003 by CRC Press LLC

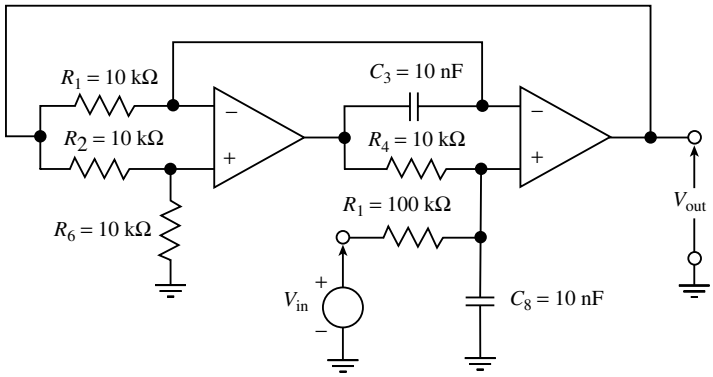

FIGURE 82.5 Design of a second-order BPF.

3. Thus $C_3 = C_8 = C = 10$ nF.
4. Hence $R = (1/C\omega_p) = 10$ kΩ. Consequently, $R = R_1 = R_2 = R_4$, $R_6 = 10$ kΩ, and $R_7 = RQ_p = 100$ kΩ.
5. The circuit is shown in Fig. 82.5. The gain at resonance, that is, at $\omega = \omega_p$, is equal to 2. To scale the gain by a factor x less than 2, the resistor R_7 is split into two resistors in a manner similar to that in Fig. 82.4(b) and explained in Example 1.

Again, if functional tuning is desired, the sequence in Table 82.2 can be followed.

Example 3. Design a second-order HP filter with $Q_p = 1$ and $f_p = 10{,}000/2\pi$ Hz.

Procedure

1. Circuit 3 in Table 82.2 realizes an HP filter.
2. Let us choose $C_3 = C_7 = C = 5$ nF. Hence R can be computed as

$$R = \frac{1}{\omega_p C} = \frac{1}{10000 \times 50 \times 10^{-9}}$$

   Therefore, $R = 20$ kΩ.
3. Consequently, $R_1 = R_2 = R_4 = R_6 = R = 20$ kΩ and $R_8 = RQ = 20$ kΩ.
4. The realization is shown in Fig. 82.6. The gain at high-frequency H_{HP} is equal to 2.

82.7 Practical High-Order Design Examples Using the 2-OA CGIC Biquad

Using Table 82.2, 1 percent metal-film resistors, 2 percent polystyrene capacitors and μA741 OA's, a sixth-order Chebyshev LP filter and a sixth-order elliptic BP filter were designed and constructed. The LP filter has a maximum passband attenuation of 1.0 dB; bandwidth = 3979 Hz. The BP filter has the following specifications:

Center frequency = 1500 Hz.
Passband = 60 Hz.
Maximum passband attenuation = 0.3 dB.
Minimum stopband attenuation outside the frequency range 1408 → 1595 Hz = 38 dB.

Low-Pass Filter

The realization uses cascaded section of type 1, in Table 82.2, as shown in Figure 82.7(a). The measured frequency response (input level = 50 mV), shown in Fig. 82.7(b) and (c), agrees with the theoretical response. The effect of dc-supply variations is illustrated in Fig. 82.7(d). The deviation in the passband ripple is about 0.1 dB for supply voltage in the range 5 to 15 V. The effect of temperature variations is illustrated in Fig. 82.7(e), which shows the frequency response at –10°C (right-hand curve), 20°C, and 70°C (left-hand curve). The last peak has been displaced horizontally by 42 Hz, which corresponds to a change of 133 ppm/°C. The frequency displacement is due to passive element variations and is within the predicted value.

Bandpass Filter

The realization uses cascaded sections of the types 7 and 10, in Table 82.2, and is shown in Fig. 82.8(a). The measured frequency response is shown in Fig. 82.8(b) and (c), and it is in agreement with the theoretical response. Fig. 82.8(d) shows the frequency response for supply voltages of 7.5 V (lower curve) and 15 V; the input is 0.3 V. The passband ripple remains less than 0.39 dB and the deviation in the stopband is negligible. Fig. 82.8(e) and (f) illustrate the effect of temperature variations. The passband ripple remains less than 0.35 dB in the temperature range –10 to 70°C. A center frequency displacement of 15 Hz has been measured that corresponds to a change of 125 ppm/°C.

82.8 Universal 2-OA CGIC Biquad

Study of Table 82.2 suggests that several circuits may be combined to form a universal biquad. This can be achieved on a single substrate using thick-film technology.

Upon examining the element identification and design values in Table 82.2 it is easy to see that one common thick-film substrate can be made to realize circuits 1, 3, 7, and 10 in Table 82.2 (other circuits from Table 82.1 can be included if desired) with no duplication in OA's and chip capacitors and minimal duplication in resistors. The superposition of circuits 1, 3, 7, and 10 is shown in Fig. 82.9. The following items should be noted.

1. Each resistor having the same subscript represents one resistor only and needs to appear once in a given biquad realization and thus once on the substrate. As an example, for $R_J = RQ_p$, only one R_J is needed with connection to several nodes. The unwanted connections may be opened during the trimming process according to the type of circuit required.
2. Three capacitor pads are needed; they are marked 1, 2, and 3 in Fig. 82.9. To obtain capacitor 4, either capacitor 2 or 3 connections are made common with capacitor 4 terminals. The capacitor

Frequency responses: (b) Logarithmic gain scale and linear frequency scale; (c) linear gain and frequency scales; (d) for supply voltages ±5 V (lower curve) and ±15 V, input level = 0.05 V; (e) at temperatures –10°C (right-hand curve), 20°C, and 70°C (left-hand curve).

pad terminals are available on the external terminals of the substrate.[1] The chip capacitors are reflow-soldered in the appropriate locations based on the circuit realized.

A dual CGIC universal biquad implemented using thick-film resistors, chip NPO capacitors, and one quad OA is shown in Fig. 82.10. Note that this hybrid array is capable of realizing gyrators and simulating inductors and super capacitors. Sample results are given in Fig. 82.11 for realizing different biquadratic functions using this implementation.

[1]This can readily be understood by examining the different realizations to be obtained from this layout.

82.9 The 3-OA CGIC Biquadratic Structure

Consider the circuit shown in Fig. 82.12 where the output can be taken to be either V_1, V_2, or V_3. Assuming ideal OA's, the transfer functions between the input and output terminals 1, 2, and 3 can be readily obtained as

$$V_1/V_i = T_1$$

$$= \left\{Y_{11}\, Y_{12}\left[Y_1\left(1 + Y_4/Y_9\right) - Y_2 Y_3/Y_9\right]\right. \tag{82.8a}$$

$$\left. + \left(Y_{12}\, Y_3\, Y_7\, Y_8\right)/Y_9 + \left[\left(1 + Y_4/Y_9\right)Y_5 - Y_3\, Y_6/Y_9\right]Y_7\, Y_{10}\right\}/D(s)$$

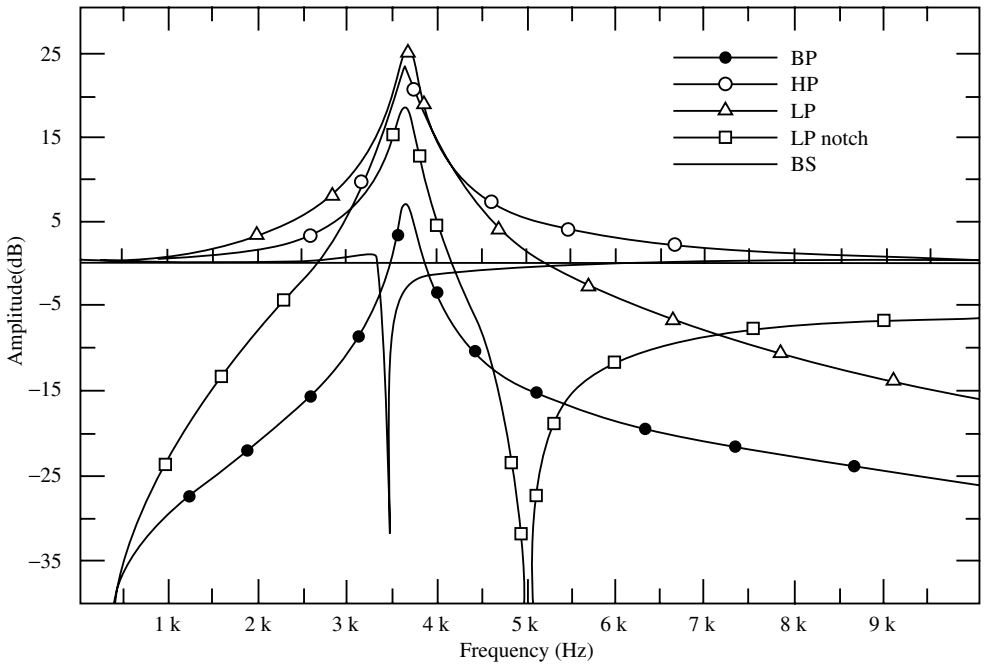

FIGURE 82.11 Different second-order realizations obtained from the universal CGIC biquad.

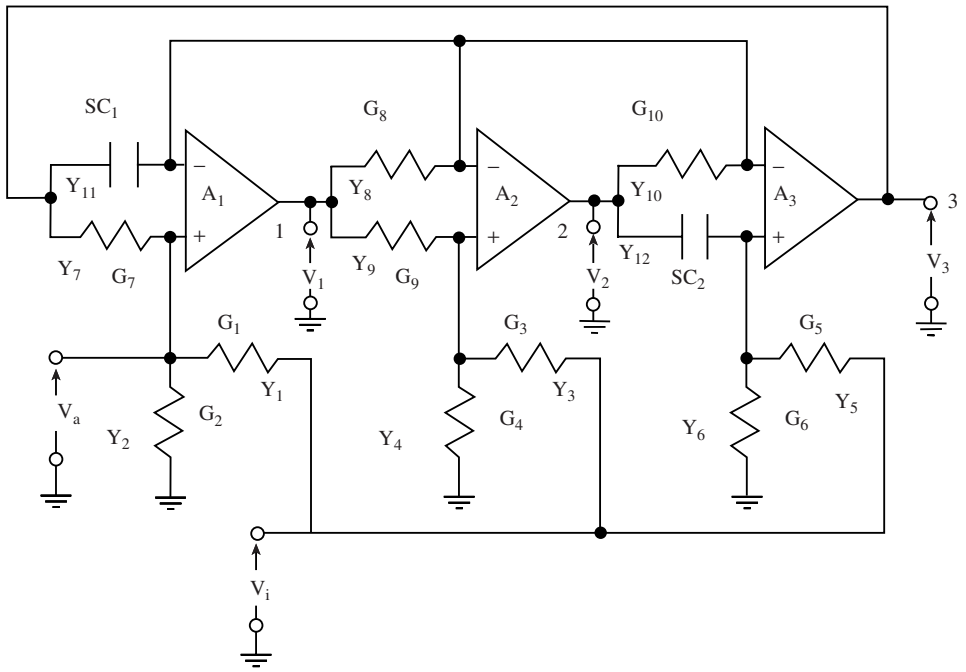

FIGURE 82.12 3-OA CGIC Biquad.

© 2003 by CRC Press LLC

$$V_2/V_i = T_2$$
$$= \left\{ Y_{11}\, Y_{12}\, Y_1 + Y_{12}\left[Y_1\, Y_6 + \left(Y_3\, Y_7\, Y_8 \right)/Y_9 - Y_5 Y_6 \right] \right.$$
$$\left. + \left[Y_3\, Y_6 - Y_4\, Y_5 \right]\left(Y_7\, Y_8\, Y_{12} \right)/Y_9 Y_{11} + Y_5 Y_7\, Y_{10} \right\}/D(s) \tag{82.8b}$$

$$V_3/V_i = T_3$$
$$= \left\{ Y_1\, Y_{11}\, Y_{12} + Y_{12}\left[\left(1 + Y_2/Y_7 \right) Y_3 - Y_1\, Y_4/Y_7 \right] Y_8/Y_9 \right.$$
$$\left. + \left[\left(1 + Y_2/Y_7 \right) Y_5 - Y_1\, Y_6/Y_7 \right] Y_7 Y_{10} \right\} D(s) \tag{82.8c}$$

where

$$D(s) = Y_{11}\, Y_{12}\left(Y_1 + Y_2 \right) + Y_{12}\left(Y_3 + Y_4 \right) Y_7\, Y_8/Y_9 + \left(Y_5 + Y_6 \right) Y_7 Y_{10} \tag{82.9}$$

The admittances Y_1 to Y_{12} can be selected in many ways and any stable second-order transfer function can be realized. For the purposes of this chapter, Y_1 to Y_{10} are taken to be purely conductive, while Y_{11} and Y_{12} are purely capacitive, that is,

$$\begin{aligned} Y_1 - Y_{10} &= G_1 - G_{10} \\ Y_{11} &= sC_1 \qquad\qquad Y_{12} = sC_2 \end{aligned} \tag{82.10}$$

Any rational and stable transfer function can be expressed as a product of second-order transfer functions of the form

$$T(s) = \left(a_2 s^2 + a_1 s + a_0 \right)/\left(b_2 s^2 + b_1 s + b_0 \right) \tag{82.11}$$

where $a_1 = a_2 = 0$, $a_0 = a_1 = 0$, $a_0 = a_2 = 0$, or $a_1 = 0$, for an LP, HP, BP, or N section, respectively. These section can be realized by choosing the G_i's ($i = 1 - 10$) properly in (82.8). By comparing (82.8) to (82.11), circuits 1–4 in Table 82.3 can be obtained.

All-pass transfer functions can be realized by setting $a_2 = b_2$, $a_1 = -b_1$, $a_0 = b_0$; these can be obtained from circuit 5 of Table 82.3.

It can be easily shown that this biquad possesses similar excellent low sensitivity properties and stability during activation as those of the 2-OA CGIC biquad, given in Section 82.4.

82.10 Design and Tuning Procedure of the 3-OA CGIC Biquad

Several degrees of freedom exist in choosing element values, as shown in Table 82.3. These are used to satisfy the constraints of the given design, namely, those of low sensitivity, reduced dependence on the OA finite gain and bandwidth, and low element-spread design, in circuits 1–5 in Table 82.3. Using these constraints, a possible design for LP, HP, BP, AP, and N sections is obtained, as indicated in Table 82.4. It is seen that Q_p, ω_p, ω_n, Q_z, and ω_z, can be independently adjusted by trimming at most three resistors. A trimming sequence is also given in Table 82.4.

82.11 A Practical Sixth-Order Elliptic BP Filter Design Using the 3-OA CGIC Biquad

The sixth-order elliptic bandpass filter specified in Section 82.7 was designed using the 3-OA CGIC biquad and similar components to those in Section 82.7.

4	$R_1 = R(1+\overline{Q}_p^{1/2})/H_N, R_2 = 1/(G - G_1),$ $R_4 = R\overline{Q}_p^{1/2}, R_6 = 1/(\alpha G - G_5),$ $R_5 = R\omega_p^2(1+\overline{Q}_p^{1/2})/(\alpha H_N \omega_n^2), H_N \le (1+\overline{Q}_p^{1/2}),$ $H_N = \le \omega_p^2(1+\overline{Q}_p^{1/2})/\omega_n^2$ for $\omega_n > \omega_p$	$T_1 = H_N\dfrac{(s^2+\omega_n^2)}{D(s)}$	R_5	R_6	R_4	—
5	For all-pass: $R_1 = R, R_4 = RQ_p^{1/2}$ $R_5 = R/\alpha, R_1 = R_7,$ $R_2 = \infty, H_{AP} = 1$	$T_1 = H_{AP}\dfrac{s^2 - \frac{\omega_z}{Q_z}s + \omega_z^2}{D(s)}$	R_5	R_4		

$D(s) = s^2 + (\omega_p/Q_p)s + \omega_p^2,\ \alpha = 2Q_p^{1/2}/(1+Q_p^{1/2}).$

$C_1 = C_2 = C = 1/(\omega_p R),\ R_{10} = \alpha R,\ R_8 = RQ_p^{1/2},\ R_7 = R_8 = R.$

The realization shown in Fig. 82.13(a) uses cascaded sections of the types 3 and 4 in Table 82.4. The element design values are also given in Fig. 82.13(a). The measured frequency response is shown in Fig. 82.13(b) and (c); it is in agreement with the theoretical response. Fig. 82.13(d) shows the frequency response for supply voltages of ±7.5 V (lower curve), and ±15 V (upper curve); the input voltage is 0.3 V. The passband ripple remains less than 0.34 dB and the deviation in the stopband is negligible. Fig. 82.13(e) and (f) illustrate the effect of temperature variations. The passband ripple remains less than 0.5 dB in the temperature range –10°C (right-hand curve) to 70°C (left-hand curve). A center frequency displacement of 9 Hz has been measured, which corresponds to a change of 75 ppm°/C.

These results illustrate the additional performance improvements compared with the results in Section 82.7 using the 2-OA CGIC biquad.

82.12 The Composite GIC Biquad: 2 C 2-OA CGIC

To obtain the composite CGIC biquad [7], each single OA in the original 2-OA CGIC biquad is replaced by a composite amplifier each constructed using two regular OA's [6] and denoted C2OA. All possible combinations of the four C2OA structures in [7] were used to replace the two OA's in the CIC network. Although several useful combinations were obtained, it was found that the best combination is shown in Fig. 82.14, where A_1 is replaced by C2OA-4 and A_2 is replaced by C2OA-3 in the CGIC of Fig. 82.1.

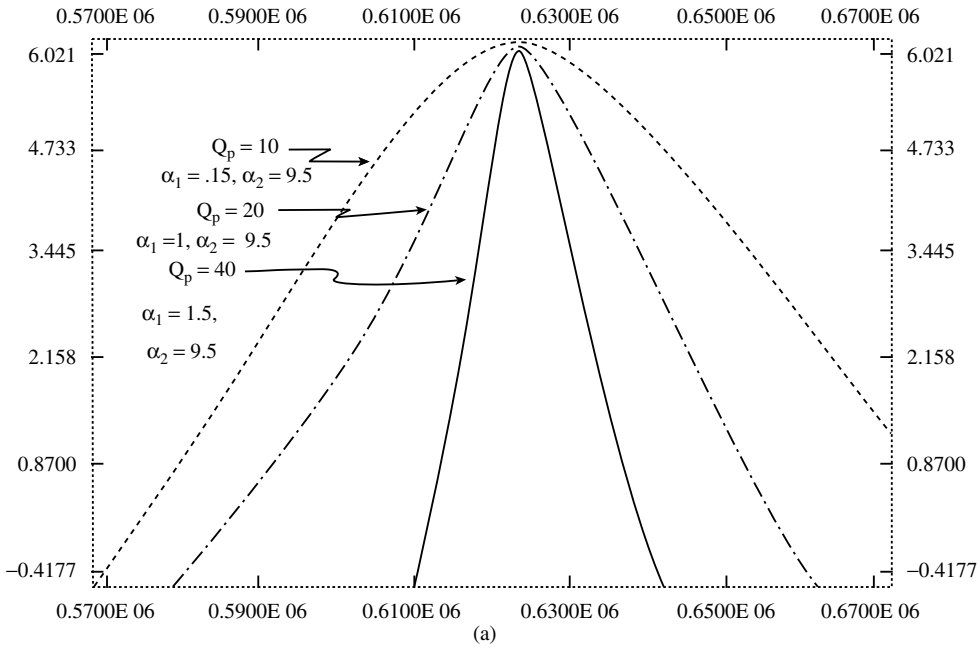

FIGURE 82.15 (a) Computer plots of the composite GIC BP filter frequency responses for f_0 = 100 kHz and Q_p = 10, 20,40. (Continued).

Computer simulation plots and experimental results of Fig. 82.15 show clearly the considerable improvements of the new CGIC filter responses over those of a 2-OA CGIC implemented using regular OA's.

Similar improvements in inductance simulation applications, employing the 2C2-OA CGIC, have been reported.

82.13 Summary

Two configurations have been presented for the synthesis of *RC*-active networks. These have been used to design a number of universal second-order sections such as low-pass, high-pass, bandpass, and bandstop sections. By using these sections, most of the practical filter specifications can be realized. Each section employs a CGIC, which can be implemented by using 2 OA's in the 2-OA CGIC biquad and 3 OA's

© 2003 by CRC Press LLC

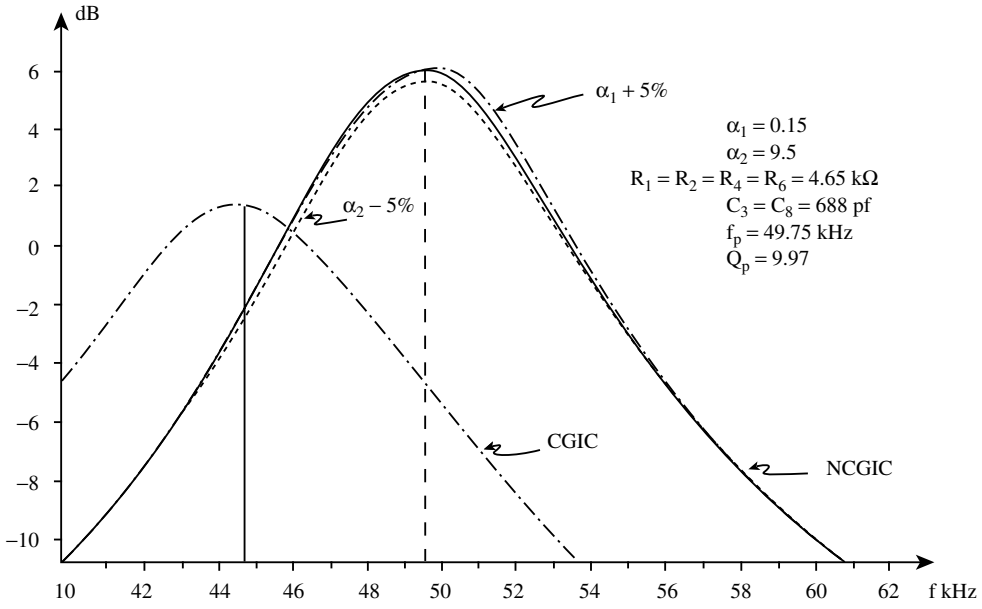

FIGURE 82.15 (Continued). (b) Experimental results of single and composite GIC BP filters of Fig. 6.3, and the response sensitivity for a_1 and a_2 variations (f_0 = 50 kHz, Q_p = 10).

in the 3-OA CGIC design. The sensitivities of Q_p, ω_p, Q_z, ω_z, and also the multiplier constant of the realization, have been found to be low with respect to the passive- and active-element variations. A simple functional tuning sequence in which only resistors are adjusted has been described. With the exception of one of the notch sections using the 2-OA CGIC, of all the circuits considered, the output can be located at an OA output. Consequently, these sections can be cascaded without the need for isolating amplifiers. Although exact matching of the gain bandwidth products of the OA's in the CGIC biquad is not essential, optimum results are obtained when they are matched within practical ranges. This is achieved easily by using dual or quad OA's. Also, the choice of the element values for optimum performance are also given. The additional performance improvements using the 3-OA CGICiquads are illustrated experimentally. Useful operating frequencies extension employing the composite operational amplifier technique in the 2-OA CGIC biquad is also given.

83.5 Summary

Rolf Schaumann
Portland State University

83.1 Introduction

With the realization of second-order filters discussed in the previous chapters of this section, we will now treat methods for practical filter implementations of order higher than two. Specifically, we will investigate how to realize efficiently, with low sensitivities to component tolerances, the input-to-output voltage transfer function

$$H(s)=\frac{V_{out}}{V_{in}}=\frac{N(s)}{D(s)}=\frac{a_m s^m+a_{m-1}s^{m-1}+\cdots+a_1 s+a_0}{s^n+b_{n-1}s^{n-1}+\cdots+b_1 s+b_0} \tag{83.1}$$

where $n \geq m$ and $n > 2$. The sensitivity behavior of high-order filter realizations shows that, in general, it is not advisable to realize the transfer function $H(s)$ in the so-called *direct form* [5, ch. 3] (see also Chapter 73 in this book). By *direct form* we mean an implementation of (83.1) that uses only one or maybe two active devices, such as operational amplifiers (op amps) or operational transconductance amplifiers (OTAs), embedded in a high-order passive *RC* network. Although it is possible in principle to realize (83.1) in direct form, the resulting circuits are normally so sensitive to component tolerances as to be impractical. Since the direct form for the realization of high-order functions is ruled out, in this section we present those methods that result in designs of practical manufacturable active filters with acceptably low sensitivity, the *cascade* approach, the *multiple-loop feedback topology,* and *ladder simulations*. Both cascade and multiple-loop feedback techniques are modular, with active biquads used as the fundamental building blocks. The ladder simulation method seeks active realizations that inherit the low passband sensitivity properties of passive doubly terminated *LC* ladder filters (see Chapter 77).

In the *cascade* approach, a high-order function $H(s)$ is factored into low- (first- or second-) order subnetworks, which are realized as discussed in the previous chapters of this section and connected in cascade such that their product implements the prescribed function $H(s)$. The method is widely employed in industry; it is well understood, very easy to design, and efficient in its use of active devices. It uses a modular approach and results in filters that, for the most part, show satisfactory performance in practice. The main advantage of cascade filters is their generality, i.e., any arbitrary stable transfer function can be realized as a cascade circuit, and tuning is very easy because each biquad is responsible for the realization of only *one* pole pair (and zero pair): the realizations of the individual critical frequencies of

© 2003 by CRC Press LLC

the filter are *decoupled* from each other. The disadvantage of this decoupling is that for filters of high order, say $n > 8$, with stringent requirements and tight tolerances, the passband sensitivity of cascade designs to component variations is often found to remain still too sensitive. In these cases, the following approaches lead to more reliable circuits.

The *multiple-loop feedback* or *coupled-biquad methods* also split the high-order transfer function into second-order subnetworks. These are interconnected in some type of feedback configuration that introduces *coupling* chosen to reduce the transfer function sensitivities. The multiple-loop feedback approach retains the modularity of cascade designs but at the same time yields high-order filter realizations with noticeably better passband sensitivities. Of the numerous topologies that have been proposed in the literature, see, e.g., [5, ch. 6], we discuss only the FLF (follow-the-leader feedback) and the LF (leapfrog) methods. Both are particularly well suited for all-pole characteristics but can be extended to realizations of general high-order transfer functions. Although based on coupling of biquads in a feedback configuration, the LF procedure is actually derived from an *LC* ladder simulation and will, therefore, be treated as part of that method.

As the name implies, the *ladder simulation approach* uses an active circuit to simulate the behavior of doubly terminated *LC* ladders in an attempt to inherit their excellent low passband-sensitivity properties. The methods fall into two groups. One is based on *element replacement* or *substitution*, where the inductors are simulated via electronic circuits whose input impedance is inductive over the necessary frequency range; the resulting active "components" are then inserted into the *LC* filter topology. The second group may be labeled *operational simulation* of the *LC* ladder, where the active circuit is configured to realize the *internal operation*, i.e., the equations, of the *LC* prototype. Active filters simulating the structure or the behavior of *LC* ladders have been found to have the lowest passband sensitivities among active filters and, consequently, to be the most appropriate if filter requirements are stringent. They can draw on the wealth of information available for lossless filters, e.g., [5, ch. 2], [9, ch. 13], [7] that can be used directly in the design of active ladder simulations. A disadvantage of this design method is that a passive *LC* prototype must, of course, exist[1] before an active simulation can be attempted.

83.2 Cascade Realizations

Without loss of generality we may assume in our discussion of *active* filters that the polynomials $N(s)$ and $D(s)$ of (83.1) are *even*, i.e., both n and m are even. An odd function can always be factored into the product of an even function and a first-order function, where the latter can easily be realized by a *passive RC* network and can be appended to the high-order active filter as an additional section. Thus, we can factor (83.1) into the product of second-order pole-zero pairs, so that the high-order transfer function $H(s)$ is factored into the product of the second-order functions

$$T_i(s) = k_i \frac{\alpha_{2i}s^2 + \alpha_{1i}s + \alpha_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = k_i\, t_i(s) \tag{83.2}$$

such that

$$H(s) = \prod_{i=1}^{n/2} T_i(s) = \prod_{i=1}^{n/2} k_i \frac{\alpha_{2i}s^2 + \alpha_{1i}s + \alpha_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = \prod_{i=1}^{n/2} k_i t_i(s) \tag{83.3}$$

In (83.2), ω_{0i} is the pole frequency and Q_i the pole quality factor; the coefficients α_{2i}, α_{1i}, and α_{0i} determine the type of second-order function $T_i(s)$ that can be realized by an appropriate choice of biquad from the literature, e.g., [5, ch. 5], [9, chs. 4, 5] (see also Chapters 80, 81, and 82). The transfer functions $T_i(s)$ of

[1]The realizability conditions for passive *LC* filters are more restrictive than those for active *RC* filters; specifically, the numerator $N(s)$ of (84.1) must be strictly even or odd so that only $j\omega$-axis transmission zeros can be realized.

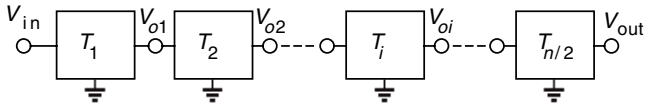

FIGURE 83.1 Cascade realization of an *n*th-order transfer function; *n* is assumed even.

the individual biquads are scaled by a suitably defined *gain constant* k_i, e.g., such that the leading coefficient in the numerator of the *gain-scaled* transfer function $t_i(s)$ is unity or such that $|t_i(j\omega)| = 1$ at some desired frequency. If we assume now that the output impedances of the biquads are small compared to their input impedances, all second-order blocks can be connected in cascade as in Fig. 83.1 without causing mutual interactions due to loading. The product of the biquadratic functions is then realized as required by (83.3).

The process is straightforward and leads to many possibilities for cascading the identified circuit blocks, but several questions must still be answered:

1. Which pair of zeros of (83.1) should be assigned to which pole-pair when the biquadratic functions $T_i(s)$ are formed? Since we have $n/2$ pole pairs and $n/2$ zero pairs (counting zeros at 0 and at ∞) we can select from $(n/2)!$ possible *pole-zero pairings*.
2. In which order should the biquads be cascaded? For $n/2$ biquads, we have $(n/2)!$ possible ways of *section ordering*.
3. How should the gain constants k_i in Eq. (83.2) be chosen to determine the signal level for each biquad? In other words, what is the optimum *gain assignment*?

Because the total prescribed transfer function $H(s)$ is simply the product of $T_i(s)$, the choices in 1, 2, and 3 are quite arbitrary as far as $H(s)$ is concerned. However, they determine significantly the dynamic range,[2] i.e., the distance between the maximum possible undistorted signal (limited by the active devices) and the noise floor, because the maximum and minimum signal levels throughout the cascade filter depend on the pole-zero pairings, cascading sequence, and gain assignment.

There exist well-developed techniques and algorithms for answering the questions of pole-zero pairing, section ordering, and gain assignment exactly [3, ch. 1], [5, ch. 6]; they rely heavily on computer routines and are too lengthy to be treated in this chapter. We will only give a few rules-of-thumb, which are based on the intuitive observation that in the passband the magnitude of each biquad should vary as little as possible. This keeps signal levels as equal as possible vs. frequency and avoids in-band attenuation and the need for subsequent amplification that will at the same time raise the noise floor and thereby further limit the dynamic range. Note also that in-band signal amplification may overdrive the amplifier stages and cause distortion. The simple rules below provide generally adequate designs.

1. Assign each zero or zero-pair to the closest pole-pair.
2. Sequence the sections in the order of increasing values of Q_i, i.e., $Q_1 < Q_2 < \ldots < Q_{n/2}$, so that the section with the flattest transfer function magnitude comes first, the next flattest one follows, and so on. If the position of any section is predetermined,[3] use the sequencing rule for the remaining sections.

After performing steps 1) and 2), assign the gain-scaling constants k_i such that the maximum output signals of all sections in the cascade are the same, i.e.,

$$\max\left|V_{oi}(j\omega)\right| = \max\left|V_{o,n/2}(j\omega)\right| = \max\left|V_{\text{out}}(j\omega)\right| \qquad i = 1, \ldots, n/2-1 \tag{83.4}$$

[2]Pole-zero pairing also affects to some extent the sensitivity performance, but the effect usually is not very strong and will not be discussed in this chapter. For a detailed treatment see [3].

[3]Such as, e.g., placing a lowpass at the input may be preferred to avoid unnecessary high-frequency signals from entering the filter.

© 2003 by CRC Press LLC

This can be done readily with the help of a network analysis routine or simulator, such as SPICE, by computing the output signals at each biquad: using the notation, from (83.3),

$$H(s)=\prod_{i=1}^{n/2}T_i(s)=\prod_{i=1}^{n/2}k_it_i(s)=\prod_{i=1}^{n/2}k_i\ \prod_{i=1}^{n/2}t_i(s) \tag{83.5}$$

and

$$H_i(s)=\prod_{j=1}^{i}T_j(s)=\prod_{j=1}^{i}k_jt_j(s)=\prod_{j=1}^{i}k_j\ \prod_{j=1}^{i}t_j(s) \tag{83.6}$$

we label the total prescribed gain constant

$$K=\prod_{i=1}^{n/2}k_i \tag{83.7}$$

such that

$$\max\left|\prod_{i=1}^{n/2}t_i(j\omega)\right|=M_{n/2} \tag{83.8a}$$

is some given value. Further, let us denote the maxima of the intermediate gain-scaled transfer functions by M_i, i.e.,

$$\max\left|\prod_{k=1}^{i}t_k(j\omega)\right|=M_i \qquad i=1,\ldots,n/2-1 \tag{83.8b}$$

then we obtain [5, ch. 6]

$$k_1=K\frac{M_{n/2}}{M_1} \quad \text{and} \quad k_j=\frac{M_{j-1}}{M_j} \qquad j=2,\ldots,n/2 \tag{83.9}$$

Choosing the gain constants as in (83.9) guarantees that the same maximum voltage appears at all biquad outputs to assure that the largest possible signal can be processed without distortion.

To illustrate the process, let us realize the sixth-order transfer function

$$H(s)=\frac{0.7560s^3}{\left(s^2+0.5704s+1\right)\left(s^2+0.4216s+2.9224\right)\left(s^2+0.1443s+0.3422\right)} \tag{83.10}$$

where the frequency parameter s is normalized with respect to $\omega_n = 130{,}590\ s^{-1}$. It defines a sixth-order bandpass filter with a 1-dB equiripple passband in 12 kHz $\le f \le$ 36 kHz and at least 25-dB attenuation in $f \le$ 4.8 kHz and $f \ge$ 72 kHz [5, ch. 1]. $H(s)$ can be factored into the product of

$$T_1(s)=k_1t_1(s)=\frac{k_1s}{s^2+0.5704s+1} \quad \text{with}$$
$$Q_1=\frac{\sqrt{1}}{0.5704}\approx 1.75 \tag{83.11a}$$

© 2003 by CRC Press LLC

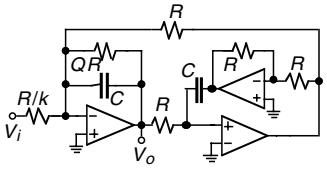

FIGURE 83.2 Åckerberg-Mossberg bandpass circuit.

$$T_2(s) = k_2 t_2(s) = \frac{k_2 s}{s^2 + 0.4216s + 2.9224} \quad \text{with}$$
$$Q_2 = \frac{\sqrt{2.9224}}{0.4216} \approx 4.06 \tag{83.11b}$$

$$T_3(s) = k_3 t_3(s) = \frac{k_3 s}{s^2 + 0.1443s + 0.3422} \quad \text{with}$$
$$Q_3 = \frac{\sqrt{0.3422}}{0.1443} \approx 4.06 \tag{83.11c}$$

which are cascaded in the order of increasing values of Q, i.e., $T_1T_2T_3$. We can compute readily the maximum values at the output of the sections in the cascade as $M_1 = |t_1|_{\max} \approx 1.75$, $M_2 = |t_1t_2|_{\max} \approx 1.92$ and $M_3 = |t_1t_2t_3|_{\max} \approx 1.32$ to yield by (83.9)

$$k_1 = 0.7560\,\frac{1.32}{1.75} \approx 0.57 \qquad k_2 = \frac{1.75}{1.92} \approx 0.91 \qquad k_3 = \frac{1.92}{1.32} \approx 1.45 \tag{83.12}$$

Let us build the sections with the Åckerberg-Mossberg circuit [9, ch. 4.4] shown in Fig. 83.2. It realizes

$$\frac{V_o}{V_i} = -\frac{k\omega_0^2}{s^2 + s\omega_0/Q + \omega_0^2} \quad \text{with} \quad \omega_0 = \frac{1}{RC} \tag{83.13}$$

We obtain readily from (83.11) through (83.13) the following (rounded) component values:

for T_1: R = 1.5 kΩ, QR = 2.7 kΩ, R/k = 2.7 kΩ

for T_2: R = 0.9 kΩ, QR = 3.6 kΩ, R/k = 1.7 kΩ

for T_3: R = 2.6 kΩ, QR = 10 kΩ, R/k = 1 kΩ

The three sections are then interconnected in cascade in the order $T_1T_2T_3$.

83.3 Multiple-Loop Feedback Realizations

These topologies are also based on biquad building blocks, which are then embedded, as the name implies, into multiple-loop resistive feedback configurations. The resulting coupling between sections is selected such that transfer function sensitivities are reduced below those of cascade circuits. It has been shown that the sensitivity behavior of the different available configurations is comparable. We shall, therefore, concentrate our discussion only on the follow-the-leader feedback (FLF) and, as part of the ladder simulation techniques, on the leapfrog (LF) topologies, which have the advantage of being relatively easy to derive without any sacrifice in performance. Our derivation will reflect the fact that both configurations[4] are particularly convenient for geometrically symmetrical bandpass functions and that the LF topology is obtained from a direct simulation of an *LC* lowpass ladder.

[4]As are all other multiple-loop feedback circuits.

© 2003 by CRC Press LLC

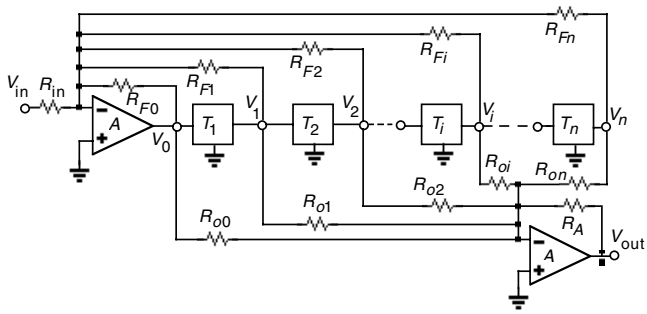

FIGURE 83.3 FLF circuit built from second-order sections $T_i(s)$ and a feedback network consisting of an op amp summer with resistors R_{Fi}. Also shown is an output summer with resistors R_{oi} to facilitate the realization of arbitrary transmission zeros.

The Follow-the-Leader Feedback Topology

The follow-the-leader feedback (FLF) topology consists of a cascade of biquads whose outputs are fed back into a summer at the filter's input. At the same time, the biquad outputs may be fed forward into a second summer at the filter's output to permit an easy realization of arbitrary transmission zeros. The actual implementation of the summers and the feedback factors is shown in Fig. 83.3; if there are n noninteracting biquads, the order of the realized transfer function $H(s)$ is $2n$. Assuming that the two summer op amps are ideal, routine analysis yields

$$-V_0 = \frac{R_{F0}}{R_{\text{in}}} V_{\text{in}} + \sum_{i=1}^{n} \frac{R_{F0}}{R_{Fi}} V_i = \alpha V_{\text{in}} + \sum_{i=1}^{n} F_i V_i \tag{83.14}$$

where we defined $\alpha = R_{F0}/R_{\text{in}}$ and the feedback factors $F_i = R_{F0}/R_{Fi}$. Similarly, we find for the output summer

$$V_{\text{out}} = -\sum_{i=0}^{n} K_i V_i = -\sum_{i=0}^{n} \frac{R_A}{R_{oi}} V_i \tag{83.15}$$

from which the definition of the resistor ratios K_i is apparent. Any of the parameters F_i and K_i may, of course, be reduced to zero by replacing the corresponding resistor, R_{Fi} or R_{oi}, respectively, by an open circuit. Finally, the internal voltages V_i can be computed from

$$V_i = V_0 \prod_{j=1}^{i} T_j(s) \qquad i = 1, \ldots, n \tag{83.16}$$

so that with (83.14)

$$H_0(s) = \frac{V_0}{V_{\text{in}}} = -\frac{\alpha}{1 + \sum_{k=1}^{n} \left[F_k \prod_{j=1}^{k} T_j(s) \right]} \tag{83.17}$$

which with (83.16) yields

© 2003 by CRC Press LLC

$$H_i(s) = \frac{V_i}{V_{\text{in}}} = -\frac{N_i(s)}{D(s)} = -\frac{\alpha \prod_{j=1}^{i} T_j(s)}{1 + \sum_{k=1}^{n} \left[F_k \prod_{j=1}^{k} T_j(s) \right]} \qquad i = 1, \ldots, n \tag{83.18}$$

Note that

$$H_n(s) = \frac{V_n}{V_{\text{in}}} = -\frac{N_n(s)}{D(s)} = -\frac{\alpha \prod_{j=1}^{n} T_j(s)}{1 + \sum_{k=1}^{n} \left[F_k \prod_{j=1}^{k} T_j(s) \right]} \tag{83.19}$$

is the transfer function of the FLF network *without* the output summer, i.e., with $R_{oi} = \infty$ for all i.

By (83.19), the transmission zeros of $H_n(s)$ are set by the zeros of $T_j(s)$, i.e., by the *feedforward* path, whereas the poles of $H_n(s)$ are determined by the *feedback* network and involve both the poles and zeros of the biquads $T_j(s)$ and the feedback factors F_k. Typically, an FLF network is designed with second-order bandpass biquads

$$T_i(s) = A_i \frac{s/Q_i}{s^2 + s/Q_i + 1} = A_i \; t_i(s) \tag{83.20}$$

so that $H_n(s)$ has all transmission zeros at the origin, i.e., it is an all-pole bandpass function. Note that in (83.20) the frequency parameter s is normalized to the pole frequency ω_0 ($\omega_{0i} = \omega_0$ for all i is assumed), and Q_i and A_i are the section's pole quality factor and midband gain, respectively. Designing an FLF network with arbitrary zeros requires second-order sections with finite transmission zeros, which leads to quite difficult design procedures. It is much simpler to use (83.15) with (83.18) to yield

$$H(s) = \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{N_{2n}(s)}{D_{2n}(s)} = \alpha \frac{K_0 + \sum_{k=1}^{n} \left[K_k \prod_{j=1}^{k} T_j(s) \right]}{1 + \sum_{k=1}^{n} \left[F_k \prod_{j=1}^{k} T_j(s) \right]} \tag{83.21}$$

which realizes the transfer function of the complete circuit in Fig. 83.3 with an arbitrary numerator polynomial $N_{2n}(s)$, even for second-order bandpass functions $T_i(s)$ as in (83.20). It is a ratio of two polynomials whose roots can be set by an appropriate choice of the functions $T_i(s)$, the parameters K_i for the transmission zeros, and the feedback factors F_i for the poles.

We illustrate the design procedure by considering a specific case. For $n = 3$, Eq. (83.21) becomes

$$H(s) = \alpha \frac{K_0 + K_1 T_1 + K_2 T_1 T_2 + K_3 T_1 T_2 T_3}{1 + F_1 T_1 + F_2 T_1 T_2 + F_3 T_1 T_2 T_3} \tag{83.22}$$

Next we transform the bandpass functions $T_i(s)$ in (83.20) into lowpass functions by the lowpass-to-bandpass transformation (see Chapter 71)

$$p = Q \frac{s^2 + 1}{s} \tag{83.23}$$

© 2003 by CRC Press LLC

where $Q = \omega_0/B$ is the "quality factor" of the high-order bandpass with bandcenter ω_0 and bandwidth B, and p is the normalized lowpass frequency. This step transforms the bandpass functions (83.20) with *all identical* pole frequencies ω_0 into the first-order lowpass functions

$$T_{i\mathrm{LP}}(p) = \frac{A_i Q/Q_i}{p + Q/Q_i} = \frac{q_i}{p + q_i} \tag{83.24}$$

where $q_i = Q/Q_i$ and A_i is the *dc* gain of the lowpass section. Applying (83.23) also to the prescribed function $H(s)$ of order $2n$ in (83.22) converts it into a prototype lowpass function $H_{\mathrm{LP}}(p)$ of order n. Substituting (83.24) into the numerator and denominator expressions of that function, of order $n = 3$ in our case, shows that the zeros and poles, respectively, are determined by

$$N_3(p) = \alpha K_0 \prod_{j=1}^{3}(p + q_j) + \sum_{j=1}^{2}\left[k_j \prod_{i=j+1}^{3}(p + q_i)\right] + k_3 \tag{83.25a}$$

and

$$D_3(p) = \prod_{j=1}^{3}(p + q_j) + \sum_{k=1}^{2}\left[f_k \prod_{i=k+1}^{3}(p + q_i)\right] + f_3 \tag{83.25b}$$

where we introduced the abbreviations

$$f_i = F_i \prod_{j=1}^{i} A_j q_j \quad \text{and} \quad k_i = \alpha K_i \prod_{j=1}^{i} A_j q_j \tag{83.26}$$

To realize the prescribed third-order function

$$H_{\mathrm{LP}}(p) = \frac{V_o}{V_i} = \frac{a_3 p^3 + a_2 p^2 + a_1 p + a_0}{p^3 + b_2 p^2 + b_1 p + b_0} \tag{83.27}$$

we compare coefficients between (83.25) and (83.27). For the denominator terms we obtain

$$b_2 = q_1 + q_2 + q_3 + f_1$$

$$b_1 = q_1 q_2 + q_1 q_3 + q_2 q_3 + f_1(q_2 + q_3) + f_2$$

$$b_0 = q_1 q_2 q_3 + f_1 q_2 q_3 + f_2 q_3 + f_3$$

These are three equations in six unknowns, f_i and q_i, $i = 1, \ldots, 3$, which can be written more conveniently in matrix form:

$$\begin{pmatrix} 1 & 0 & 0 \\ q_2 + q_3 & 1 & 0 \\ q_2 q_3 & q_3 & 1 \end{pmatrix} \begin{pmatrix} f_1 \\ f_2 \\ f_3 \end{pmatrix} = \begin{pmatrix} b_2 - (q_1 + q_2 + q_3) \\ b_1 - (q_1 q_2 + q_1 q_3 + q_2 q_3) \\ b_0 - q_1 q_2 q_3 \end{pmatrix} \tag{83.28}$$

The transmission zeros are found via an identical process: the unknown parameters k_i are computed from an equation of the form (83.28) with f_i replaced by $k_i/(\alpha K_0)$ and b_i replaced by a_i/a_3, $i = 1, \ldots, 3$. Also, $K_0 = a_3/\alpha$.

© 2003 by CRC Press LLC

The unknown parameters f_i can be solved from the matrix expression (83.28). It is a set of *linear* equations whose coefficients are functions of the prescribed coefficients b_i and of the numbers q_i which for given Q are determined by the quality factors Q_i of the second-order sections $T_i(s)$. Thus, the Q_i are *free* parameters that may be selected to satisfy any criteria that may lead to a better-working circuit. The free design parameters may be chosen, for example, to reduce a circuit's sensitivity to element variations. This leads to a multi-parameter (i.e., the n Q_i-values) optimization problem whose solution requires the availability of the appropriate computer algorithms. If such software is not available, specific values of Q_i can be chosen. The design becomes particularly simple if all the Q_i-factors are equal, a choice that has the additional practical advantage of resulting in *all identical* second-order building blocks, $T_i(s) = T(s)$. For this reason, this approach has been referred to as the "Primary Resonator Block" (PRB) technique. The passband sensitivity performance of PRB circuits is almost as good as that of fully optimized FLF structures. The relevant equations are derived in the following:

With $q_i = q$ for all i we find from (83.28)

$$\begin{pmatrix} 1 & 0 & 0 \\ 2q & 1 & 0 \\ q^2 & q & 1 \end{pmatrix} \begin{pmatrix} f_1 \\ f_2 \\ f_3 \end{pmatrix} = \begin{pmatrix} b_2 - 3q \\ b_1 - 3q^2 \\ b_0 - q^3 \end{pmatrix} \tag{83.29}$$

It shows that

$$\begin{aligned} F_1 A_1 q &= f_1 = b_2 - 3q \\ F_2 A_1 A_2 q^2 &= f_2 = b_1 - 3q^2 - 2qf_1 \\ F_3 A_1 A_2 A_3 q^3 &= f_3 = b_0 - q^3 - q^2 f_1 - q f_2 \end{aligned} \tag{83.30}$$

The system (83.30) represents three equations for the four unknowns, q, f_i, $i = 1, \ldots, 3$, (in general, one obtains n equations for $n + 1$ unknowns) so that one parameter, q, can still be used for optimization purposes. This single degree of freedom is often eliminated by choosing

$$q = \frac{b_{n-1}}{n b_n} \tag{83.31a}$$

i.e., $q = b_2/3$ in our example, which means $f_1 = 0$. The remaining feedback factors can then be computed recursively from (83.30). The systematic nature of the equations makes it apparent how to proceed for $n > 3$. As a matter of fact, it is not difficult to show that, with $f_1 = 0$, in general

$$f_2 = b_{n-2} - \frac{n(n-1)}{2!} q^2 b_n \tag{83.31b}$$

$$f_i = b_{n-i} - \frac{q^i}{(n-i)!}\left[\frac{n!}{i!} b_n + \sum_{j=1}^{i-1} \frac{f_j}{q^j} \frac{(n-j)!}{(i-j)!}\right] \qquad i = 3, \ldots, n \tag{83.31c}$$

Note that b_n usually equals unity. As mentioned earlier, equations of identical form, with f_i replaced by $k_i/(\alpha K_0)$ and b_i by a_i/a_n with $K_0 = a_n/\alpha$, are used to determine the summing coefficients K_i of the output summer, which establishes the transmission zeros. Thus, given a geometrically symmetrical bandpass function with center frequency ω_0, quality factor Q, and bandwidth B, Eq. (83.31) can be used to calculate the parameter q and all feedback and summing coefficients required for a PRB design. All second-order bandpass sections, Eq. (83.20), are tuned to the same pole-frequency, $\omega = \omega_0$, and have the same pole quality factor, $Q_p = Q/q$, where $Q = \omega_0/B$.

© 2003 by CRC Press LLC

As discussed, the design procedure computes only the *products* f_i and k_i; the actual values of F_i, K_i, and A_i are not uniquely determined. As a matter of fact, the gain constants A_i are *free* parameters that are selected to maximize the circuit's dynamic range in much the same way as for cascade designs.[5] With a few simple approximations, it can be shown [5, ch. 6] that the appropriate choice of gain constants in the FLF circuit is

$$A_i \approx \sqrt{1+\left(Q_i/Q\right)^2} = \sqrt{1+q_i^{-2}} \qquad i=1,\ldots,n \tag{83.32a}$$

The same equation holds for the PRB case where $Q_i = Q_p$ for all i so that

$$A_i = A \approx \sqrt{1+\left(Q_p/Q\right)^2} = \sqrt{1+q^{-2}} \tag{83.32b}$$

The following example demonstrates the complete FLF (PRB) design process.

Let us illustrate the multiple-loop feedback procedure by realizing again the bandpass function (83.10), but now as an FLF (PRB) circuit. The previous data specify that the bandpass function should be converted into a prototype lowpass function with bandcenter $\omega_0/(2\pi) = \sqrt{12\cdot 36}$ kHz and bandwidth $B/(2\pi) = (36 - 12)$ kHz by the transformation (83.23),

$$p = Q\frac{s^2+1}{s} = \frac{\omega_0}{B}\frac{s^2+1}{s} = \frac{\sqrt{12\cdot 36}}{36-12}\frac{s^2+1}{s} = 0.866\,\frac{s^2+1}{s} \tag{83.33}$$

where s is normalized by ω_0 as before. Substituting (83.33) into (83.10) results in

$$H_{\mathrm{LP}}(s) = \frac{0.491}{p^3+0.984p^2+1.236p+0.491} \tag{83.34}$$

which corresponds to (83.27) with $a_i = 0$, $i = 1, 2, 3$. To realize this function, we need three first-order lowpass sections of the form (83.24), i.e.,

$$T_{\mathrm{LP}}(p) = A\frac{q}{p+q} \tag{83.35}$$

where $A = \sqrt{1+1/q^2}$ from (83.32b). We proceed with (83.31a) to choose $q = 0.984/3 = 0.328$, so that $A = 3.209$. With these numbers, we can apply (83.33) to (83.35) to obtain the second-order bandpass that must be realized:

$$T_{\mathrm{BP}}(p) = 3.209\,\frac{0.328}{0.866\dfrac{s^2+1}{s}+0.328} = \frac{1.2153s}{s^2+0.379s+1} \tag{83.36}$$

The feedback resistors we obtain by (83.30):

$$\begin{aligned} 1.052\,F_1 = f_1 = 0 &\rightarrow F_1 = 0 \\ 1.108\,F_2 = f_2 = b_1 - 3q^2 = 0.913 &\rightarrow F_2 = 0.777 \\ 1.166\,F_3 = f_3 = b_0 - q^3 - qf_2 = 0.371 &\rightarrow F_3 = 0.318 \end{aligned} \tag{83.37}$$

[5]For practical FLF (PRB) designs, this step of scaling the signal levels is very important because an inadvertently poor choice of gain constants can result in *very* large internal signals and, consequently, very poor dynamic range.

© 2003 by CRC Press LLC

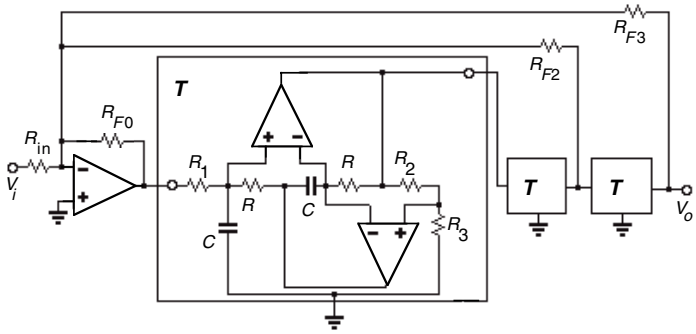

FIGURE 83.4 PRB topology with three identical GIC bandpass sections. The circuit for one section is shown explicitly, as is the input summer with the feedback resistors.

Choosing, e.g., $R_{F0} = 10$ kΩ results in $R_{Fi} = R_{F0}/F_i$, that is, $R_{F1} = \infty$, $R_{F2} = 12.9$ kΩ, and $R_{F3} = 31.5$ kΩ. Also, $R_{F0}/R_{\text{in}} = \alpha = 0.491(Aq)^{-3} = 0.421 \rightarrow R_{\text{in}} = 23.7$ kΩ.

There remains the choice of second-order bandpass sections. Notice from (83.19) that the sections must have positive, i.e., non-inverting, gain to keep the feedback loops stable. We choose GIC (general impedance converter) sections [5, ch. 4], [9, ch. 4.5], one of which is shown explicitly in Fig. 83.4. They realize

$$T(s) = \frac{V_o}{V_i} = \frac{\left(1+\dfrac{G_3}{G_2}\right)\dfrac{G_1}{C}s}{s^2 + \dfrac{G_1}{C}s + \left(\dfrac{G}{C}\right)^2\dfrac{G_3}{G_2}} = \frac{K\dfrac{\omega_0}{Q}s}{s^2 + \dfrac{\omega_0}{Q}s + \omega_0^2} \tag{83.38}$$

Comparing (83.38) with (83.36), choosing $R_3 = 5$ kΩ, $C = 2$ nF, and remembering that s is normalized with respect to $\omega_0 = 130{,}590$ s^{-1} results in the rounded values

$$R = 5.5 \text{ k}\Omega, \quad R_1 = 10 \text{ k}\Omega, \quad R_2 = 10 \text{ k}\Omega$$

The Leapfrog Topology

The leapfrog (LF) configuration is pictured in Fig. 83.5. Each of the boxes labeled T_i realizes a second-order transfer function. The feedback loops always comprise two sections; thus, inverting and non-inverting sections must alternate to keep the loop gains negative and the loops stable. If the circuit is derived from a resistively terminated lossless ladder filter as is normally the case, T_1 and T_n are lossy and all the internal sections are lossless. A lossless block implies a function T_i with infinite Q, which may not be stable by itself, but the overall feedback connection guarantees stability.

An LF circuit can be derived from the configuration in Fig. 83.5 by direct analysis with, e.g., bandpass transfer functions as in (83.20) assumed for the blocks T_i. Comparing the resulting equation with that of a prescribed filter yields expressions that permit determining all circuit parameters in a similar way as for FLF filters [1]. Because the topology is identical to that derived from a signal-flow graph representation of an *LC* ladder filter, we do not consider the details of the LF approach here, but instead proceed directly to the ladder simulation techniques.

83.4 Ladder Simulations

Although transfer functions of *LC* ladders are more restrictive than those realizable by cascade circuits (see footnote 1 on page 2516), lossless ladder filters designed for maximum power transfer have received considerable attention in the active filter literature because of their significant advantage of having the lowest possible sensitivities to component tolerances in the passband. Indeed, the majority of high-order active filters with demanding specifications are being designed as simulated *LC* ladders. Many active circuit structures have been developed, which simulate the performance of passive *LC* ladders and inherit their good sensitivity performance. The ladder simulations can be classified into two main groups: *operational simulation* and *element substitution*. Starting from an existing *LC* prototype ladder, the operational simulation models the internal operation of the ladder by simulating the circuit equations, i.e., Kirchhoff's voltage and current laws and the *I-V* relationships of the ladder arms. Fundamentally, this procedure simulates the *signal-flow graph* (SFG) of the ladder where all voltages and all currents are considered signals, which are integrated on the inductors and capacitors, respectively. The SFG method is developed in the next subsection. The element substitution procedure replaces all inductors or inductive branches by active networks whose input impedance is inductive over the frequency range of interest. A practical approach to this method is presented in the section on element substitution. For more detailed discussions of these important and practical procedures, we refer the reader to a modern text on active filters, such as [5], [6], or [9] and, for approaches using operational transconductance amplifiers, to Section 84.3 in this text.

Signal-Flow Graph Methods

To derive the signal-flow graph (SFG) method, consider the ladder structure in Fig. 83.6, whose branches may contain arbitrary combinations of capacitors and inductors. In general, resistors are permitted to allow for lossy components. Labeling the combination of elements in the series arms as admittances Y_i, $i = 2, 4$, and those in the shunt branches as impedances Z_j, $j = 1, 3, 5$, we can readily analyze the ladder by writing Kirchhoff's laws and the *I-V* relationships for the ladder arms as follows:

$$\begin{aligned} I_i &= G_i\left(V_i - V_1\right), \quad V_1 = Z_1\, I_1 = Z_1\left(I_i - I_2\right) \\ I_2 &= Y_2 V_2 = Y_2\left(V_1 - V_3\right), \quad V_3 = Z_3 I_3 = Z_3\left(I_2 - I_4\right) \\ I_4 &= Y_4 V_4 = Y_4\left(V_3 - V_5\right), \quad V_5 = V_o = Z_5 I_5 = Z_5\left(I_4 - I_6\right), \quad I_6 = G_o V_o \end{aligned} \tag{83.39}$$

In the active simulation of this circuit, all currents and voltages are to be represented as *voltage* signals. To reflect this in the expressions, we use a resistive scaling factor R as shown in one of these equations as an example:

$$V_3 = \frac{Z_3}{R} I_3 R = \frac{Z_3}{R}\left(I_2 R - I_4 R\right) \tag{83.40}$$

and introduce the notation

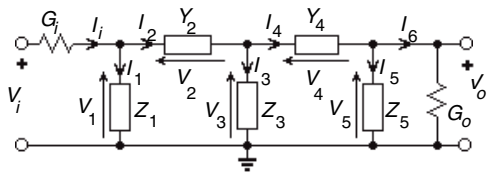

FIGURE 83.6 Ladder network.

© 2003 by CRC Press LLC

$$I_k R = i_k \qquad V_k = v_k \qquad G_i R = g_i \qquad Z_k / R = z_k \qquad Y_k R = y_k \tag{83.41}$$

The lower-case symbols are used to represent the *scaled* quantities; notice that z_k and y_k are dimensionless voltage transfer functions, also called *transmittances*, and that both i_k and v_k are voltages. We shall retain the symbol i_k to remind ourselves of the origin of that signal as a current in the original ladder. Equation (83.39) then takes on the form

$$\begin{gathered} i_i = g_i\left[v_i + \left(-v_1\right)\right] \qquad -v_1 = -z_1\, i_1 = -z_1\left[i_i + \left(-i_2\right)\right] \\ -i_2 = y_2\left(-v_2\right) = y_2\left[\left(-v_1\right) + v_3\right] \qquad v_3 = -z_3\left(-i_3\right) = -z_3\left[\left(-i_2\right) + i_4\right] \\ i_4 = y_4 \quad v_4 = y_4\left[v_3 + \left(-v_5\right)\right] \qquad -v_5 = -v_o = -z_5\, i_5 = -z_5\left[i_4 + \left(-i_6\right)\right] \qquad -i_6 = g_o\left(-v_o\right) \end{gathered} \tag{83.42}$$

where we have made all the transmittances z_i inverting and assigned signs to the signals in a consistent fashion, such that only *signal addition* is required in the circuit to be derived from these equations. We made this choice because addition can be performed at op amp summing nodes with no additional circuitry (see below), whereas subtraction would require either differential amplifiers or inverters. The price to be paid for this convenience is that in some cases the overall transfer function suffers a sign inversion (a 180° phase shift), which is of no consequence in most cases. The signal-flow block diagram implementing (83.42) is shown in Fig. 83.7. As is customary, all voltage signals are drawn at the bottom of the diagram, and those derived from currents at the top. We observe that the circuit consists of a number of interconnected loops of two transmittances each and that all loop-gains are negative as required for stability. Notice that redrawing this figure in the form of Fig. 83.5 results in an identical configuration, i.e., as mentioned earlier, the leapfrog method is derived from a ladder simulation technique.

To determine how the transmittances are to be implemented, we need to know which elements are in the ladder arms. Consider first the simple case of an all-pole lowpass ladder where $Z_i = 1/(sC_i)$ and $Y_j = 1/(sL_j)$, i.e., $z_i = 1/(sC_i R)$ and $y_i = 1/(sL_i/R)$ (see Fig. 83.11). Evidently then, for this case all transmittances are integrators. Suitable circuits are shown in Fig. 83.8 where for each integrator we have used two inputs in anticipation of the final realization, which has to sum two signals as indicated in Fig. 83.7. The circuits realize

$$V_o = \pm\frac{G_1 V_1 + G_2 V_2}{sC + G_3} \tag{83.43}$$

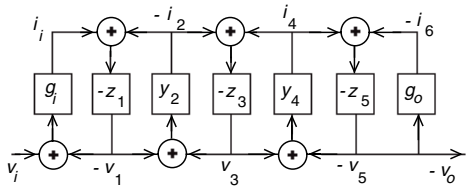

FIGURE 83.7 Signal-flow graph block diagram realizing (83.42).

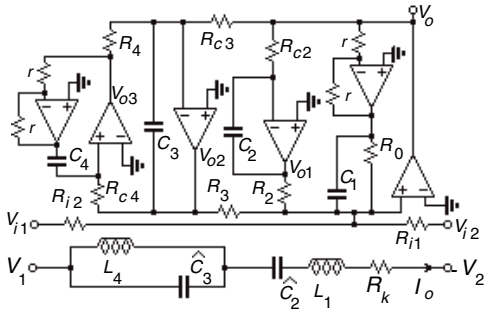

FIGURE 83.9 Active realization of a series ladder branch [plus sign in (83.46)].

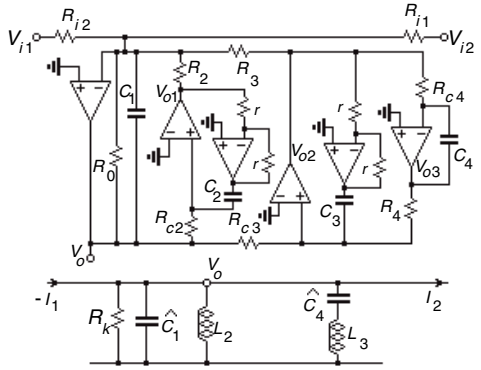

FIGURE. 83.10 Active realization of a shunt ladder branch [minus sign in (83.46)].

where the plus sign is valid for the series transmittances $y_i(s)$ in Fig. 83.8(b) and the minus sign for the shunt transmittances $z_i(s)$[6] in Fig. 83.8(a). G_3 is zero if the integration is lossless as required in an internal branch of the ladder; in the two end branches, G_3 is used to implement the source and load resistors of the ladder.

The next question to be answered is what circuitry will realize more general ladder arms which may contain both series and parallel *LC* elements, and resistors to handle the source or load terminations (or losses if required). Such general series and shunt branches are shown at the bottom of Figs. 83.9 and 83.10, respectively, where we have labeled the capacitors in the *passive* network as "$\hat{C}$" to be able to distinguish them from the capacitors in the active circuit (labeled C without circumflex). We have chosen the signs of the relevant voltages and currents in Figs. 83.9 and 83.10 appropriately to obtain *non-inverting transmittances* $y(s)$ for the series arms and *inverting transmittances* $z(s)$ for the shunt arms as requested in Fig. 83.7. Recall that this choice permits the flowgraph to be realized with only *summing* functions. For easy reference, the active *RC* circuits realizing these branches are shown directly above the passive *LC* arms [5, ch. 6], [9, ch.15].

The passive series branch in Fig. 83.9 realizes the current I_o

[6]These two circuits are good candidates for building two-integrator loops as required in Fig. 83.7 because the op amp in the Miller integrator causes a phase lag, whereas the op amps in the non-inverting integrator cause a phase lead of the same magnitude. In the loop, these two phase shifts just cancel and cause no errors in circuit performance. Notice that the Åckerberg-Mossberg biquad in Fig. 83.2 is also constructed as a loop of these two integrators.

© 2003 by CRC Press LLC

$$I_o R_p = +Y(s) R_p \left(aV_1 + bV_2\right)$$

$$= + \frac{1}{R_k/R_p + sL_1/R_p + \dfrac{1}{s\hat{C}_2 R_p} + \dfrac{1}{s\hat{C}_3 R_p + \dfrac{1}{sL_4/R_p}}} \left(aV_1 + bV_2\right) \tag{83.44a}$$

which was converted into a voltage through multiplication with a scaling resistor R_p. (p stands for *passive*; R_p is the resistor used to scale the *passive* circuit.) Also, we have multiplied the input signals by two constants, a and b, in anticipation of future scaling possibilities in the *active* circuit. Using, as before, *lower-case* symbols for the *normalized* variables, we obtain for the series branch

$$i_o = +y(s)\left(av_1 + bv_2\right) = + \frac{1}{r_k + sl_1 + \dfrac{1}{sc_2} + \dfrac{1}{sc_3 + \dfrac{1}{sl_4}}} \left(av_1 + bv_2\right) \tag{83.44b}$$

In an analogous fashion we find for the voltage V_o in the passive shunt branch in Fig.83.10, after impedance-level scaling with R_p and signal-level scaling with a and b, the expression

$$V_o = -\frac{Z(s)}{R_p}\left(aI_1 R_p + bI_2 R_p\right)$$

$$= - \frac{1}{G_k R_p + s\hat{C}_1 R_p + \dfrac{1}{sL_2/R_p} + \dfrac{1}{sL_3/R_p + \dfrac{1}{s\hat{C}_4 R_p}}} \left(aI_1 R_p + bI_2 R_p\right) \tag{83.45a}$$

which with lower-case notation gives

$$v_o = -z(s)\left(ai_1 + bi_2\right) = - \frac{1}{g_k + sc_1 + \dfrac{1}{sl_2} + \dfrac{1}{sl_3 + \dfrac{1}{sc_4}}} \left(ai_1 + bi_2\right) \tag{83.45b}$$

Turning now to the active *RC* branches in Figs. 83.9 and 83.10, elementary analysis of the two circuits, assuming ideal op amps,[7] results in

$$V_o = \pm \frac{R_a G_{i1} V_{i1} + R_a G_{i2} V_{i2}}{R_a G_0 + sC_1 R_a + \dfrac{R_a G_2}{sC_2 R_{c2}} + \dfrac{R_a G_3}{sC_3 R_{c3} + \dfrac{G_4 R_{c3}}{sC_4 R_{c4}}}} \tag{83.46}$$

[7]Using a more realistic op amp model, $A(s) \approx \omega_t/s$, one can show [5; ch. 6] that (84.46) to a first-order approximation is multiplied by $(1 + j\omega/\omega_t) \approx \exp(j\omega/\omega_t)$ for the series arm [plus sign in (84.46)] and by $(1 - j\omega/\omega_t) \approx \exp(-j\omega/\omega_t)$ for the shunt arm [minus sign in (84.46)]. Thus, in the loop gains determined by the product of an inverting and a non-inverting branch, op amp effects cancel to a first order, justifying the assumption of ideal op amps. See also footnote 6.

© 2003 by CRC Press LLC

where we used a normalizing resistor R_a. (a stands for *active*; R_a is the resistor used to scale the *active* circuit.) In (83.46) the plus sign is valid for the series arm, Fig. 83.9, and the minus sign for the shunt arm, Fig. 83.10.

Notice that (83.46) is of the same form as (83.44) and (83.45) so that we can compare the expressions term-by-term to obtain the component values required for the active circuit(s) to realize the prescribed passive ladder arms. Thus, we find for the *series* branch, Fig. 83.9, by comparing coefficients between (83.46) and (83.44a), and assuming all equal capacitors C in the active circuit:

$$R_{i1} = \frac{R_a}{a} \quad R_{i2} = \frac{R_a}{b} \quad R_0 = \frac{R_a R_p}{R_k} \quad C = \frac{L_1}{R_a R_p}$$
$$R_{c2}R_2 = \frac{\hat{C}_2}{C} R_a R_p \quad R_{c3}R_3 = \frac{\hat{C}_3}{C} R_a R_p \quad R_{c4}R_4 = \frac{L_4 \hat{C}_3}{C^2} \tag{83.47a}$$

In an identical fashion we obtain from (83.46) and (83.45a) for the components of the *shunt* arm

$$R_{i1} = \frac{R_a}{a} \quad R_{i2} = \frac{R_a}{b} \quad R_0 = R_k \frac{R_a}{R_p} \quad C = \hat{C}_1 \frac{R_p}{R_a}$$
$$R_{c2}R_2 = \frac{L_2}{C} \frac{R_a}{R_p} \quad R_{c3}R_3 = \frac{L_3}{C} \frac{R_a}{R_p} \quad R_{c4}R_4 = \frac{L_3 \hat{C}_4}{C^2} \tag{83.47b}$$

The scaling resistors R_a and R_p are chosen to obtain convenient element values. Note that each of the last three equations for both circuits determines only the *product* of two resistors. This leaves three degrees of freedom that are normally chosen to maximize dynamic range by equalizing the maximum signal levels at all op amp outputs. We provide some discussion of these matters in the next subsection.

We have displayed the active and passive branches in Figs. 83.9 and 83.10 together to illustrate the one-to-one correspondence of the circuits. For example, if we wish to design an all-pole lowpass filter, such as the one in Fig. 83.11, where the internal series arms consist of a single inductor and each internal shunt arm of a single capacitor, the corresponding active realizations reduce to those of Fig. 83.8(b) and (a), respectively, with $R_3 = \infty$. For the end branches, R_s in series with L_1 and R_l in parallel with $\hat{C}_4$, we obtain the circuits in Fig. 83.8(b) and (a), respectively, with R_3 *finite* to account for the source and load resistors. The remaining branches in the active circuits are absent. Assembling the resulting circuits as prescribed in Fig. 83.7 leads to the active SFG filter in Fig. 83.12, where we have for convenience chosen all identical capacitors, C, and have multiplied the input by an arbitrary constant K because the active circuit may realize a gain scaling factor. The component values are computed from a set of equations similar to (83.47). To show in some detail how they are arrived at, we derive the equations for each integrator in Fig. 83.12 and compare them with the corresponding arm in the passive ladder. Recalling that signals with lower-case symbols in the active circuit are voltages, we obtain

$$\frac{G_1 R_a V_{\text{in}} + G_2 R_a (-v_2)}{sCR_a + G_3 R_a} \rightarrow \frac{KV_{\text{in}} - V_2}{sL_1/R_p + R_s/R_p} \tag{83.48a}$$

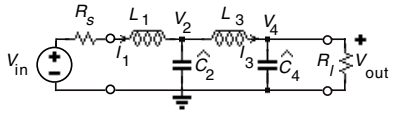

FIGURE. 83.11 Fourth-order all-pole lowpass ladder.

© 2003 by CRC Press LLC

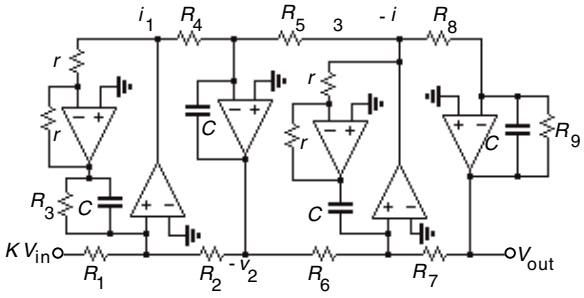

FIGURE 83.12 Active realization of the ladder in Fig. 83.11.

$$\frac{G_4R_a i_1 + G_5R_a(-i_3)}{sCR_a} \rightarrow \frac{I_1 - I_3}{s\hat{C}_2R_p} \tag{83.48b}$$

$$\frac{G_6R_a(-v_2) + G_7R_aV_{\text{out}}}{sCR_a} \rightarrow \frac{-V_2 + V_4}{sL_3/R_p} \tag{83.48c}$$

$$\frac{G_8R_a(-i_3)}{sCR_a + G_9R_a} \rightarrow \frac{-i_3}{s\hat{C}_4R_p + R_p/R_l} \tag{83.48d}$$

where we used scaling resistors for the active (R_a) and the passive (R_p) circuits as before. Choosing a convenient value for C in the active circuit and equating the time constants and the *dc* gains in (83.48a) results in the following expressions:

$$R_3 = \frac{L_1}{C}\frac{1}{R_s} \quad R_1 = R_3\frac{R_s}{KR_p} \quad R_2 = R_3\frac{R_s}{R_p} \tag{83.49a}$$

Similarly,

$$R_4 = R_5 = \frac{\hat{C}_2}{C} \quad R_6 = R_7 = \frac{L_3}{C}\frac{1}{R_p} \quad R_8 = \frac{\hat{C}_4}{C} \quad R_9 = \frac{\hat{C}_4}{C}\ R_l = \frac{R_l}{R_p}\ R_8 \tag{83.49b}$$

Maximization of the Dynamic Range

The remaining task in a signal-flow graph simulation of an *LC* ladder is that of voltage-level scaling for dynamic range maximization. As in cascade design, we need to achieve that all op amps in $0 \le \omega \le \infty$ see the same maximum signal level so that no op amp becomes overdriven sooner than any other one. It may be accomplished by noting that a scale factor can be inserted into any signal line in a signal-flow graph *as long as the loop gains are not changed*. Such signal-level scaling will not affect the transfer function except for an overall gain factor. The procedure can be illustrated in the flow diagram in Fig. 83.7. If we simplify the circuit by combining the self-loops at input and output and employ the scale factors α, β, γ, δ, and their inverses to the loops in Fig. 83.7, we obtain the modified flow diagram in Fig. 83.13. Simple analysis shows that the transfer function has not changed except for a multiplication by the factor $\alpha\beta\gamma\delta$, which is canceled by the multiplier $(\alpha\beta\gamma\delta)^{-1}$ at the input. To understand how the scale factors are computed, assume that in Fig. 83.7, i.e., before scaling, the maximum of $|i_4(j\omega)|$ is α times as large as the maximum of $|v_o(j\omega)|$, where α may be less than or larger than unity. Since

© 2003 by CRC Press LLC

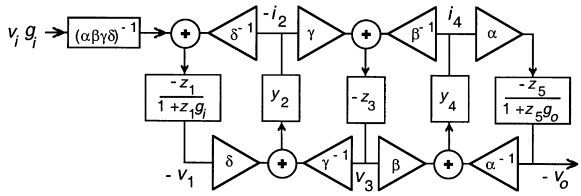

FIGURE 83.13 Using scale factor for signal-level equalization.

$$-v_o = \frac{-z_5}{1+z_5 g_o} i_4$$

the maxima can be equalized, i.e., the level of v_o can be increased by α, if we apply a gain scale factor α as indicated in Fig. 83.13. To keep the loop gain unchanged, a second scale factor α^{-1} is inserted as shown. Continuing, if in Figure 83.7 max $|v_3(j\omega)|$ is β times as large as max $|i_4(j\omega)|$, we raise the level of $|i_4|$ by a gain factor β and correct the loop gain by a second factor β^{-1} as shown in Fig. 83.13. In a similar fashion we obtain the maxima of the remaining voltages and apply the appropriate scale factors γ, δ, γ^{-1}, and δ^{-1} in Fig. 83.13.

It is easy to determine the relevant maxima needed for calculating the gain factors. Recall that the node voltages v_i, v_1, i_2, v_3, i_4, and $v_5 = v_o$ in the signal-flow graph of Fig. 83.13 correspond directly to the actual currents and voltages in the original ladder, Fig. 83.6, and that their maxima in $0 \le \omega \le \infty$ can be evaluated readily with any network analysis program. For the circuit in Fig. 83.13, the scale factors that ensure that the currents (normalized by R_p) in all series ladder arms and the voltages in all shunt ladder arms have the same maxima are then obtained as

$$\alpha = \frac{\max|i_4|}{\max|v_o|} \quad \beta = \frac{\max|v_3|}{\max|i_4|} \quad \gamma = \frac{\max|i_2|}{\max|v_3|} \quad \delta = \frac{\max|v_1|}{\max|i_2|} \tag{83.50}$$

The procedure thus far takes care of ladders with only one element in each branch, such as all-pole lowpass filters (Fig. 83.11). In the more general case, we must also equalize the maxima of the magnitudes of V_{o1}, V_{o2}, and V_{o3} at the *internal* op amp outputs in Figs. 83.9 and 83.10. This is achieved easily if we remember that the "external" voltage maxima of $|V_{i1}|$, $|V_{i2}|$, and $|V_o|$ are already equalized by the previous steps leading to (83.50), and that in the passive *series* branch V_{o1} represents the voltage on $\hat{C}_2$, V_{o2} stands for the voltage on $\hat{C}_3$, and V_{o3} corresponds to the current (times R_p) through the inductor L_4. After finding the maxima of these signals with the help of a network analysis program and computing the scale factors

$$m_1 = \frac{\max|V_{o1}|}{\max|V_o|} \quad m_2 = \frac{\max|V_{o2}|}{\max|V_o|} \quad m_3 = \frac{\max|V_{o3}|}{\max|V_o|} \tag{83.51}$$

we can equalize all internal branch voltages of the *series* arm (Fig. 83.9) by modifying the design equations [83.47(a)] as follows [5, ch. 6]:

$$R_{i1} = \frac{R_a}{a} \quad R_{i2} = \frac{R_a}{b} \quad R_0 = \frac{R_a R_p}{R_k} \quad C = \frac{L_1}{R_a R_p}$$

$$m_1 R_{c2} \frac{R_2}{m_1} = \frac{\hat{C}_2}{C} R_a R_p \quad m_2 R_{c3} \frac{R_3}{m_2} = \frac{\hat{C}_3}{C} R_a R_p \quad \frac{m_3}{m_2} R_{c4} \frac{R_4}{m_3/m_2} = \frac{L_4 \hat{C}_3}{C^2} \tag{83.52}$$

© 2003 by CRC Press LLC

A possible choice for the element values given by products is:

$$m_1 R_{c2} = \frac{R_2}{m_1} = \sqrt{\frac{\hat{C}_2}{C} R_a R_p} \qquad m_2 R_{c3} = \frac{R_3}{m_2} = \sqrt{\frac{\hat{C}_3}{C} R_a R_p}$$
$$\frac{m_3}{m_2} R_{c4} = \frac{m_2}{m_3} R_4 = \frac{\sqrt{L_4 \hat{C}_3}}{C} \tag{83.53a}$$

In the passive *shunt* branch, V_{o1} and V_{o2} represent the currents (times R_p) through the inductors L_2 and L_3, respectively, and V_{o3} stands for the voltage across $\hat{C}_4$. In an identical fashion we obtain then with (83.50) from (83.47b) for the components of the *shunt* arm

$$R_{i1} = \frac{R_a}{a} \quad R_{i2} = \frac{R_a}{b} \quad R_0 = R_k \frac{R_a}{R_p} \quad C = \hat{C}_1 \frac{R_p}{R_a}$$
$$m_1 R_{c2} = \frac{R_2}{m_1} = \sqrt{\frac{L_2}{C} \frac{R_a}{R_p}} \qquad m_2 R_{c3} = \frac{R_3}{m_2} = \sqrt{\frac{L_3}{C} \frac{R_a}{R_p}} \tag{83.53b}$$
$$\frac{m_3}{m_2} R_{c4} = \frac{m_2}{m_3} R_4 = \frac{\sqrt{L_3 \hat{C}_4}}{C}$$

Next we present an example [2], [5, ch. 6] in which the reader may follow the different steps discussed.

To simulate the fourth-order elliptic lowpass ladder filter in Fig. 83.14(a) by the signal-flow graph technique, we first reduce the loop count by a source transformation. The resulting circuit, after impedance scaling, is shown in Fig. 83.14(b). To use signal-level scaling for optimizing the dynamic range, the relevant maxima of the *LC* ladder currents and voltages are needed. Table 83.1 lists the relevant data obtained with the help of network analysis software. From these numbers we find

$$\alpha = \frac{\max|v_3|}{\max|i_4 R_p|} = \frac{0.69}{0.866} = 0.797 \qquad \beta = \frac{\max|i_2 R_p|}{\max|v_3|} = \frac{1.125}{0.690} = 1.630$$
$$\gamma = \frac{\max|v_1|}{\max|i_2 R_p|} = \frac{0.699}{1.125} = 0.621 \tag{83.54}$$

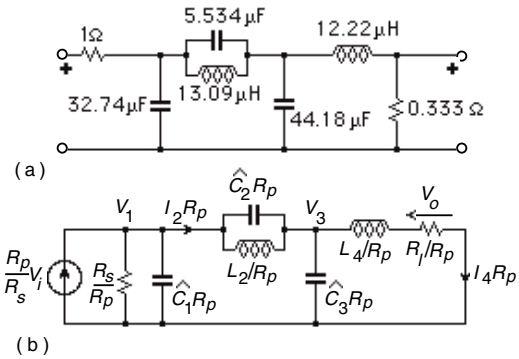

FIGURE 83.14 (a) Fourth-order elliptic *LC* lowpass ladder; (b) the circuit after source transformation and impedance scaling.

TABLE 83.1 Voltage and current maxima for Fig. 83.14a

Voltage or Current	Maximum of Voltage or Current
Voltage across $\hat{C}_1$	0.699 V
Current through L_2	1.550 A
Voltage across $\hat{C}_2$	1.262 V
Current through $(L_2 \| \hat{C}_2)$	1.125 A
Voltage across $\hat{C}_3$	0.690 V
Current through L_4	0.866 A

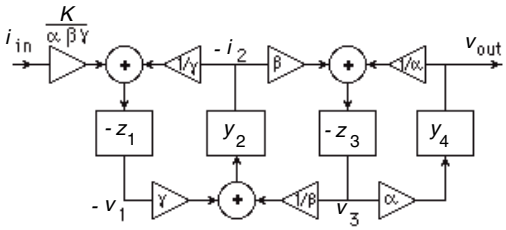

FIGURE 83.15 Signal-flow graph for the filter in Fig. 83.14.

For ease of reference, the signal-flow graph with scaling factors is shown in Fig. 83.15. Let $R_p = 1\ \Omega$. Note that the input signal voltage $i_{\text{in}} = R_p V_i / R_s$ has been multiplied by a factor K to permit realizing an arbitrary signal gain. If the desired gain is unity, and since the *dc* gain in the passive *LC* ladder equals

$$\frac{V_o}{V_i} = \frac{R_l}{R_s + R_l} = \frac{0.333}{1.333} = 0.25$$

we need to choose $K = 1/0.25 = 4$. Thus, the input signal i_i is multiplied by

$$\frac{K}{\alpha\beta\gamma} = \frac{4}{0.797 \cdot 1.630 \cdot 0.621} = 4.958 \tag{83.55}$$

The transmittances are defined as

$$z_1 = \frac{1}{s\hat{C}_1 R_p + G_s R_p} \qquad y_2 = \frac{1}{\dfrac{1}{s\hat{C}_2 R_p + R_p / (sL_p)}}$$
$$z_3 = \frac{1}{s\hat{C}_3} \qquad y_4 = \frac{1}{sL_4 / R_p + R_l / R_p} \tag{83.56}$$

With the numbers in (83.54) and (83.55) we obtain from the signal-flow graph

$$-v_1 = -z_1 \left(4.958\, i_{\text{in}} - \frac{1}{0.621}\, i_2 \right) \qquad -i_2 = y_2 \left(-0.621 v_1 + \frac{1}{1.630}\, v_3 \right)$$
$$v_3 = -z_3 \left(-1.630 i_2 + \frac{1}{0.797}\, v_{\text{out}} \right) \qquad v_{\text{out}} = y_4\, 0.792 v_3 \tag{83.57}$$

The reader is encouraged to verify from (83.56) and (83.57) and Figs. 83.9 and 83.10 that the active SFG realization of the ladder is as shown in Fig. 83.16. For instance, the circuitry between the nodes v_1, v_3, and i_2 implements the parallel *LC* series branch to realize the finite transmission zero, obtained from

© 2003 by CRC Press LLC

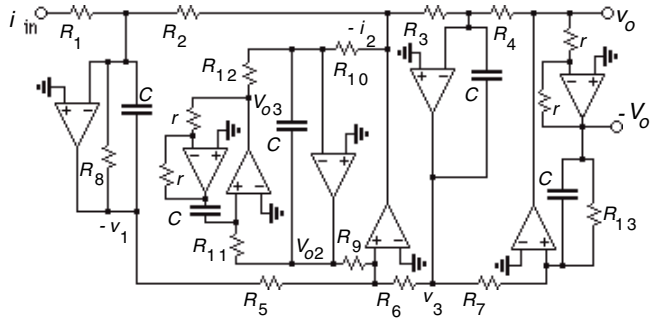

FIGURE 83.16 Active realization of the circuit in Fig. 83.14.

Fig. 83.9 by setting the components G_0, C_1, G_2, G_{c2}, and C_2 to zero. The element values in the active circuit are now determined readily by comparing the circuit equations for the active circuit,

$$-v_1 = -\frac{G_1 R_{a1} i_{in} + G_2 R_{a1}(-i_2)}{sCR_{a1} + G_8 R_{a1}} \qquad -i_2 = \frac{G_5 R_{a2}(-v_1) + G_6 R_{a2} v_3}{\dfrac{G_9 R_{a2}}{sCR_{10} + \dfrac{G_{12} R_{10}}{sCR_{11}}}} \tag{83.58}$$

$$v_3 = -\frac{G_3 R_{a3}(-i_2) + G_4 R_{a3} v_o}{sCR_{a3}} \qquad v_o = \frac{G_7 R_{a4} v_3}{sCR_{a4} + G_{13} R_{a4}}$$

to (83.57) and using (83.56).[8] Comparing the coefficients results in

$$G_1 R_{a1} = 4.958 \qquad G_2 R_{a1} = \frac{1}{0.621} \qquad G_5 R_{a2} = 0.621 \qquad G_6 R_{a2} = \frac{1}{1.630}$$

$$G_3 R_{a3} = 1.630 \qquad G_4 R_{a3} = \frac{1}{0.797} \qquad G_7 R_{a4} = 0.797$$

Further,

$$\hat{C}_1 R_p = CR_{a1} \qquad \hat{C}_2 R_p = C\frac{R_9 R_{10}}{R_{a2}} \qquad \hat{C}_3 R_p = CR_{a3} \qquad \frac{L_4}{R_p} = CR_{a4}$$

Thus, with $R_p = 1\ \Omega$ and choosing $C = 5$ nF,

$$R_{a1} = \frac{\hat{C}_1}{C} R_p = 6.55\ \text{k}\Omega \qquad R_{a3} = \frac{\hat{C}_3}{C} R_p = 8.84\ \text{k}\Omega \qquad R_{a4} = \frac{L_4}{CR_p} = 2.44\ \text{k}\Omega$$

R_{a2} is undetermined; choosing $R_{a2} = 5\ \text{k}\Omega$ leads to the feed-in resistors for each branch

$$R_1 = \frac{R_{a1}}{4.958} = 0.800\ \text{k}\Omega \qquad R_2 = 0.621 R_{a1} = 4.07\ \text{k}\Omega \qquad R_3 = \frac{R_{a3}}{1.630} = 5.42\ \text{k}\Omega$$

$$R_4 = 0.797 R_{a3} = 7.05\ \text{k}\Omega \qquad R_5 = \frac{R_{a2}}{0.621} = 8.05\ \text{k}\Omega$$

$$R_6 = 1.630 R_{a3} = 8.15\ \text{k}\Omega \qquad R_7 = \frac{R_{a4}}{0.797} = 3.06\ \text{k}\Omega$$

[8]Observe that for greater flexibility we permitted a different scaling resistor R_{ai}, $i = 1, \ldots, 4$, in each branch.

© 2003 by CRC Press LLC

The remaining components are determined from the equations

$$R_8 = R_s \frac{R_{a1}}{R_p} = 6.55\ \text{k}\Omega \qquad R_{13} = \frac{R_{a4} R_p}{R_l} = 7.33\ \text{k}\Omega$$

and

$$R_9 R_{10} = R_p R_{a2} \frac{\hat{C}_2}{C} = \left(2.35\ \text{k}\Omega\right)^2 \qquad R_{11} R_{12} = \frac{L_2}{C} \frac{R_9 R_{10}}{R_{a2} R_p} = \left(1.70\ \text{k}\Omega\right)^2$$

Since only the products of these resistors are given, we select their values uniquely for dynamic range maximization. According to (83.51) we compute from Table 83.1

$$m_2 = \frac{\max |v_{c2}|}{\max |i_2|} = \frac{1.262}{1.125} = 1.12 \quad \text{and} \quad m_3 = \frac{\max |i_{L2}|}{\max |i_2|} = \frac{1.550}{1.125} = 1.38$$

to yield from (83.53a):

$$R_9 = m_2\ 2.35\ \text{k}\Omega = 2.64\ \text{k}\Omega \qquad R_{10} = \frac{2.35\ \text{k}\Omega}{m_2} = 2.10\ \text{k}\Omega$$

$$R_{11} = \frac{m_2}{m_3} 1.70\ \text{k}\Omega = 1.38\ \text{k}\Omega \qquad R_{12} = \frac{m_3}{m_2} 1.70\ \text{k}\Omega = 2.09\ \text{k}\Omega$$

Element Substitution

LC ladders are known to yield low-sensitivity filters with excellent performance, but high-quality inductors cannot be implemented in microelectronic form. An appealing solution to the filter design problem is, therefore, to retain the ladder structure and to simulate the behavior of the inductors by circuits consisting of resistors, capacitors, and op amps. A proven technique uses *impedance converters*, electronic circuits whose input impedance is proportional to frequency when loaded by the appropriate element at the output. The best-known impedance converter is the gyrator, a two-port circuit whose input impedance is inversely proportional to the load impedance, i.e.,

$$Z_{\text{in}}(s) = \frac{r^2}{Z_L(s)} \tag{83.59}$$

The parameter r is called the *gyration resistance*. Clearly, when the load is a capacitor, $Z_L(s) = 1/(sC)$, $Z_{\text{in}}(s) = sr^2C$ is the impedance of an inductor of value $L = r^2C$. Gyrators are very easy to realize with transconductors (voltage-to-current converters) and are widely used in transconductance-C filters; see Section 84.3. However, no high-quality gyrators with good performance beyond the audio range have been designed to date with op amps. If op amps are to be used, a different kind of impedance converter is employed, one that converts a load resistor R_L into an inductive impedance, such that

$$Z_{\text{in}}(s) = (sk)R_L \tag{83.60}$$

A good circuit that performs this function is Antoniou's general impedance converter (GIC) shown in Fig. 83.17(a). The circuit, with elements slightly rearranged, was encountered in Fig. 83.4, where we used the GIC to realize a second-order bandpass function. The circuit is readily analyzed if we recall that the

© 2003 by CRC Press LLC

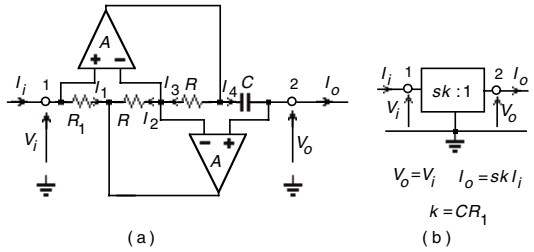

FIGURE 83.17 General impedance converter: (a) circuit, (b) symbolic representation.

voltage measured between the op amp input terminals and the currents flowing into the op amp input terminals are zero. Thus, we obtain from Fig. 83.17(a) the set of equations

$$V_o = V_i \quad \frac{I_4}{sC} = I_3 R \quad I_2 R = I_1 R_1 \quad I_2 = I_3 \quad I_i = I_1 \quad I_4 = I_o \tag{83.61}$$

These equations indicate that the terminal behavior of the general impedance converter is described by

$$V_o = V_i \quad I_o = sCR_1 L_i = skI_i \tag{83.62}$$

that is

$$\frac{V_i}{I_i} = Z_{\text{in}}(s) = sk\frac{V_o}{I_o} = sk\ Z_L(s) \tag{83.63}$$

Notice that the input impedance is inductive as prescribed by (83.60) if the load is a resistor.[9] Figure 83.17(b) also shows the circuit symbol we will use for the GIC in the following to keep the circuit diagrams simple. This impedance converter and its function of converting a resistive load into an inductive input impedance is the basis for Gorski-Popiel's embedding technique [5, ch. 6], [9, ch. 14.4], which permits replacing the inductors in an *LC* filter by resistors.

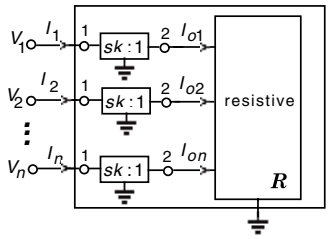

FIGURE 83.18 Simulation of an inductance network.

Inductor Replacement — Gorski-Popiel's Method

To understand the behavior of the circuit in Fig. 83.18, recall from (83.62) that the voltages at terminals 1 and 2 of the GICs are the same. Then, by superposition the typical input current I_{oi} into the resistive network ***R*** can be written as

$$I_{oi} = \frac{1}{R_{i1}}V_1 + \frac{1}{R_{i2}}V_2 + \ldots + \frac{1}{R_{in}}V_n = \sum_{j=1}^{n}\frac{1}{R_{ij}}V_j, \qquad i = 1, \ldots, n \tag{83.64}$$

where the parameters R_{ij} are given by the resistors and the configuration of ***R***. Using the current relationship $I_{oi} = skI_i$ of the impedance converters in (83.64) results in

[9]To optimize the performance of the GIC, i.e., to make it optimally independent of the finite gain-bandwidth product of the op amps, the GIC elements should be chosen as follows: For an arbitrary load $Z_L(s)$ one chooses $\omega_c C = 1/|Z_L(j\omega_c)|$. ω_c is some critical frequency, normally chosen at the upper passband corner. If the load is resistive, $Z_L = R_L$, select $C = 1/(\omega_c R_L)$ [6].

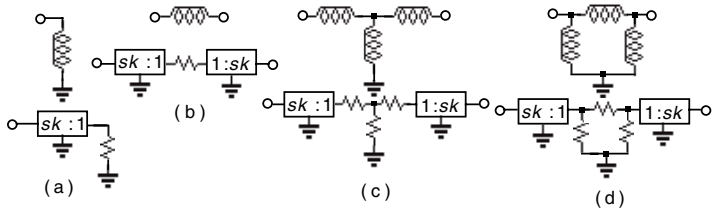

FIGURE 83.19 Elementary inductance networks and their GIC-*R* equivalents: (a) grounded inductor, (b) floating inductor, (c) inductive T, (d) inductive Π.

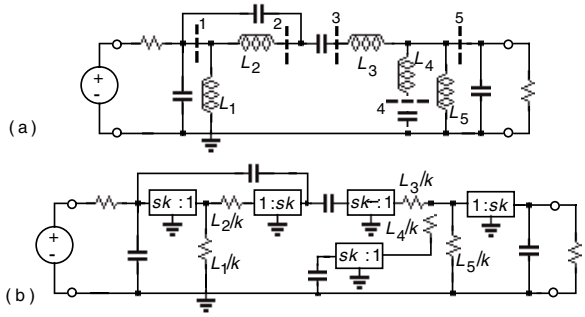

FIGURE 83.20 *LC* ladder realization with GICs: (a) a choice of cuts; (b) the cuts replaced by GICs.

$$I_i = \sum_{j=1}^{n} \frac{1}{skR_{ij}} V_j \qquad i = 1, \ldots, n \tag{83.65}$$

which makes the combined network consisting of the n GICs and the network $\boldsymbol{R}$ look purely inductive, i.e., each resistor R_r in the network $\boldsymbol{R}$ appears replaced by an inductor of value

$$L_r = skR_r = sCR_1R_r \tag{83.66}$$

Examples of this process are contained in Fig. 83.19. Figures 83.19(a) and (b) illustrate the conventional realizations of a grounded and a floating inductor requiring one and two converters, respectively. This is completely analogous to the use of gyrators, where a grounded inductor requires one gyrator, but a floating inductor is realized with two gyrators connected back-to-back. Figures 83.19(c) and (d) show how the process is extended to complete inductive subnetworks: the GICs are used to isolate the subnetworks from the remainder of the circuit; there is no need to convert each inductor separately. The method is further illustrated with the filter in Fig. 83.20. The *LC* ladder is designed to specifications by use of the appropriate design tables [4], [7] or filter design software [8]. In the resulting ladder, the inductive subnetworks are separated as shown in Fig. 83.20(a) by the five dashed cuts. The cuts are repaired by inserting GICs with conversion factor k and the correct orientation (output, terminal 2 in Fig. 83.17, toward the inductors). Note that all GICs must have the same conversion factor k. Finally, the inductors L_i are replaced by resistors of value L_i/k as shown in Fig. 83.20(b). A numerical example will illustrate the design steps:

Assume we wish to implement a sixth-order bandpass filter with the following specifications:

Maximally flat passband with ≤ 3-dB attenuation in 900 Hz ≤ f ≤ 1200 Hz;
Transmission zero at f_z = 1582.5 Hz; source and load resistors R = 3 kΩ

Using the appropriate software or tables, the *LC* filter in Fig. 83.21(a) is found with element values in kΩ, mH, and nF. Figure 83.21(b) shows the circuit redrawn to help identify the inductive subnetwork

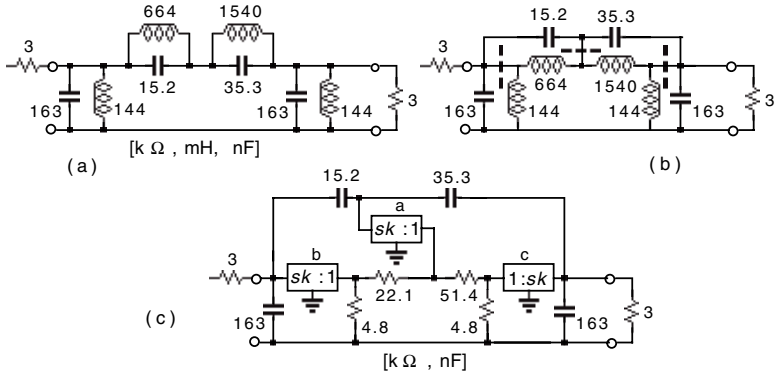

FIGURE 83.21 Sixth-order *LC* bandpass filter and active realization using impedance converters.

and the locations of the cuts. Note that only three impedance converters are used rather than six (two each for the two floating inductors and one each for the grounded ones) if a direct conversion of the individual inductors had been attempted.

For the final active realization, we assumed a conversion parameter $k = CR_1 = 30$ μs. Finally, to design the GICs we compute the impedances seen into the nodes where the GICs see the (now) resistive subnetworks. Using analysis software to compute $|V_i/I_i|$ at these nodes, we find

$$\text{for GIC}_a,\ |Z_a| \approx 18\ \text{k}\Omega,\ \text{and for GIC}_b \text{ and GIC}_c,\ |Z_b| \approx |Z_c| \approx 4.7\ \text{k}\Omega$$

so that with $\omega_c = 2\pi \cdot 1.2$ kHz and $k = 30$ μs the design elements are:

$$C_a = \frac{1}{\omega_c |z_a|} \approx 7.4\ \text{nF} \qquad R_{1a} = \frac{k}{C_a} \approx 4\ \text{k}\Omega \qquad C_b = C_c \approx 28\ \text{nF} \qquad R_b = R_c \approx 1\ \text{k}\Omega$$

To complete the design, we choose the resistors R in Fig. 83.17(a) as $R = 1$ kΩ.

83.5 Summary

In this chapter, we discussed the more practical techniques for the design of active filters of order higher than two: *cascade* design, *multiple-loop feedback* approaches, and methods that *simulate the behavior of LC ladder* filters. We pointed out that direct realization methods are impractical because they result in high sensitivities to component values. In many applications, a cascade design leads to satisfactory results. The practical advantages of cascade circuits are modularity, ease of design, flexibility, very simple tuning procedures, and economical use of op amps with as few as one op amp per pole pair. Also, we pointed out again that an arbitrary transfer function can be realized with the cascade design method, i.e., no restrictions are placed on the permitted locations of poles and zeros.

For challenging filter requirements, the cascade topologies may still be too sensitive to parameter changes. In those cases the designer can use the FLF configuration or, for best performance, a ladder simulation, provided that a passive prototype ladder exists. FLF circuits retain the advantage of modularity, but if optimal performance is desired, computer-aided optimization routines must generally be used to adjust the available free design parameters. However, excellent performance with very simple design procedures, no optimization, and high modularity can be obtained by use of the *primary-resonator-block* (PRB) method, where all biquad building blocks are identical.

From the point of view of minimum passband sensitivity to component tolerances, the best active filters are obtained by simulating *LC ladders*. If the prescribed transfer characteristic can at all be realized as a passive *LC* ladder, the designer can make use of the wealth of available information about the design

© 2003 by CRC Press LLC

of such circuits, and simple procedures are available for "translating" the passive *LC* circuit into its active counterpart. We may either take the passive circuit and replace the inductors by active networks, or we imitate the mathematical behavior of the whole *LC* circuit by realizing the integrating action of inductors and capacitors via active *RC* integrators. Both approaches result in active circuits of high quality; a disadvantage is that more op amps may be required than in cascade or FLF methods. This drawback is offset, however, by the fact that the sensitivities to component tolerances are very nearly as low as those of the originating ladder.

An alternative method for the active realization of a passive *LC* ladder is obtained by scaling each impedance of the passive circuit by $1/(ks)$ (Bruton's transformation) [5, ch. 6], [9, ch. 14.5]. This impedance transformation converts resistors into capacitors, inductors into resistors and capacitors into "*frequency-dependent negative resistors* (FDNRs)," which can readily be realized with Antoniou's GIC circuit. The procedure is especially useful for passive prototype circuits that have only *grounded* capacitors because capacitors are converted to FDNRs and floating FDNRs are very difficult to implement in practice. The method results in biasing difficulties for active elements, and because the *entire* ladder must be transformed, the active circuit no longer contains source and load resistors. If these two components are prescribed and must be maintained as in the original passive circuit, additional buffers are required. The method was not discussed in this text because it shows no advantages over the Gorski-Popiel procedure.

An important practical aspect is the *limited dynamic range* of active filters, restricted by noise and by the finite linear signal swing of op-amps. Dynamic range maximization should be addressed whenever possible. Apart from designing low-noise circuits, the procedures always proceed to equalize the op amp output voltages by exploiting available free gain constants or impedance scaling factors. It is a disadvantage of the element substitution method that no general dynamic range scaling method appears to be available.

The methods discussed in this chapter dealt with the design of filters in *discrete* form, that is, separate passive components and operational or transconductance amplifiers are assembled on, e.g., a printed circuit board to make up the desired filter. Chapter 84 addresses modifications in the design approach that lead to filters realizable in fully integrated form.

84.1 Introduction

All modern signal-processing systems include various types of electrical filters that the designer has to realize in an appropriate technology. The literature contains many well-defined filter design techniques [4], [8], [9], and computer programs are available, which help the designer find the appropriate transfer function that describes the required filter characteristics mathematically. We also refer the reader to Sections XI and the remaining chapters of Section XII in this volume.

Once the filter's transfer function is obtained, implementation methods must be found that are compatible with the technology selected for the design of the total system. In some situations, considerations of power consumption, frequency range, signal level, or production numbers may dictate *discrete* (*passive* or *active*) filter realizations. Often, however, as much as possible of the total system must be *fully integrated* in microelectronic form, so that the filters can be implemented in the same technology.

Often, digital (Section XIII) or sampled-data (Chapter 86) implementations are suitable for realizing the filter requirements. However, in modern communications applications, the required frequency range is so high that digital or sampled-data circuitry is inappropriate or too expensive so that *continuous-time* (*c-t*) filters are necessary. In addition, filters in many signal-processing situations must interface with the "real world," where the input and output signals take on continuous values as functions of the continuous variable time, i.e., they are *c-t* signals. In these situations *c-t* antialiasing and reconstruction filters are often required. Because the performance of the total filter system is of relevance and not just the performance of the intrinsic filter, the designer may have to consider if it might not be preferable to implement the entire system in the *c-t* domain rather than as a digital or sampled-data system. At least at low frequencies the latter methods have the advantages of very high accuracy, better signal-to-noise ratio, and little or no parameter drifts, but they entail a number of problems connected with analog-to-digital (A/D) and digital-to-analog (D/A) conversion (Chapter 62), sample-and-hold, switching, antialiasing, and reconstruction circuitry.

Traditionally, *c-t* filters were implemented as discrete designs. Well-understood procedures exist for deriving passive *LC* filters (Section XI) from a given transfer function with prescribed complex natural

© 2003 by CRC Press LLC

frequencies, e.g., [4, ch. 2], [8], [9, ch. 13]. To date no practical methods exist for building high-quality, i.e., low-loss, inductors on an integrated circuit (IC) chip.[1] The required complex natural frequencies must, therefore, be realized by using *gain*, i.e., as we saw earlier in this section, by embedding an operational amplifier (op amp; see Chapter 15) in an *RC* feedback network [4], [9]. Since op amps, resistors, and capacitors can be implemented on an integrated circuit, it appears that with active *RC* networks the problem of monolithic filter design is solved in principle: all active devices and any necessary capacitors and resistors can be integrated together on one silicon chip. Although this conclusion is correct, the designer needs to consider four other factors that are important in integrated *c-t* filter design and perhaps are not immediately obvious.

The first item concerns the most important design task for achieving commercially practical designs: integrated filters must be *electronically tunable*, preferably by an *automatic* tuning scheme. Because of its importance, we shall devote a separate section, 84.4, to this topic. The second item deals with the economics of practical implementations of active filters: in *discrete* designs, the cost of components and stocking them usually necessitate designing the filter with a minimum number of active devices. One, two, or possibly three op amps per pole pair are used and the smallest number of different (if possible, all identical) capacitors. In *integrated* realizations, capacitors are determined by processing mask dimensions and the number of different capacitor values is unimportant, as long as the *element spread* is not excessive. Further, active devices frequently occupy less chip area than passive elements so that it is often preferable to use active elements instead of passive ones.[2] Also, the designer should remember that in IC technology it is not easy to generate accurate absolute component values, but that *ratios* of like components, such as capacitor ratios, can be realized very precisely. The third observation pertains to the fact that filters usually have to share an integrated circuit with other, possibly switched or digital, systems so that the ac ground lines (power supply and ground wires) are likely to contain switching transients and generally are noisy. Measuring the analog signals relative to ac ground, therefore, may result in designs with poor signal-to-noise ratio and low power-supply rejection. The situation is remedied in practice by building continuous-time filters in fully differential, balanced form, where the signals are referred to each other as $V = V^+ - V^-$ as shown in Figs. 84.4(b), (c), and (d). An additional advantage of this arrangement is that the signal range is doubled (for an added 6 dB of signal-to-noise ratio) and that the even-order harmonics in the nonlinear operation of the active devices cancel. All filters in this chapter are understood, therefore, to be designed in fully differential form. Finally, we point out that communication circuitry is often required to operate at hundreds of megahertz or higher, where op amp–based active *RC* filters will not function because of the op amps' limited bandwidth.

Today, *c-t* filters integrated in bipolar, CMOS, or BiCMOS technology are no longer academic curiosities but a commercial reality (see [12] for some recent advances in the field). In the following we discuss the main methods that have proven to be reliable. First, we present *MOSFET-C filters*, whose design methods resemble most closely the standard active *RC* procedures discussed in the earlier chapters of this section; they can, therefore, be most readily understood by the reader without requiring further background. Next, we introduce the *transconductance-C* (also referred to as g_m-*C*) technique, which is currently the predominant method for *c-t* integrated filters. Designs based on transconductors lead to filters for the higher operating frequencies that are important for modern communication systems.

[1]Spiral inductors of a few nanohenry or microhenry in size, however, can be used at gigahertz frequencies. Typically, they are extremely lossy, with quality factors of the order of only 10. Since such low values of Q are unacceptable for the design of high-quality selective filters, the inductor losses must be reduced. This is accomplished by placing a simulated negative resistor [Fig. 84.17(c)] in series or parallel with the inductor. Similarly, since the spiral inductor itself cannot be tuned, variable current-shunting circuitry is employed to change the effective inductor value; see [10].

[2]However, keeping the number of active devices small remains important because active devices consume power and generate noise.

© 2003 by CRC Press LLC

84.2 MOSFET-C Filters

As mentioned in the introduction, the MOSFET-*C* method follows standard op amp-based active filter techniques [6], which, as we saw in previous chapters, rely heavily on the availability of integrators and summers. The only difference is that the method replaces the resistors used in the conventional active *RC* integrating and summing circuitry by MOSFET devices (Fig. 84.1) based in the triode (ohmic) region ($V_C - V_T > V_D$, see Chapter 55.3). Defining the source (V_S), drain (V_D), gate (V_C), and substrate (V_B) voltages as shown in Fig. 84.1, the resulting nonlinear drain current I becomes

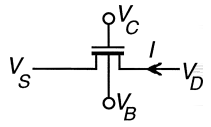

FIGURE 84.1 MOS transistor biased in the triode region.

$$\begin{aligned} I &= \frac{W}{L}\mu C_{ox}\left[\left(V_C - V_T\right)\left(V_D - V_S\right) + a_2\left(V_D^2 - V_S^2\right) + a_3\left(V_D^3 - V_S^3\right) + \ldots\right] \\ &= \left[\frac{W}{L}\mu C_{ox}\left(V_C - V_T\right)\right]\left(V_D - V_S\right) + b_2\left(V_D^2 - V_S^2\right) + b_3\left(V_D^3 - V_S^3\right) + \ldots \end{aligned} \tag{84.1}$$

W and L are the channel width and length, respectively, μ is the effective mobility, C_{ox} is the gate capacitance per unit area, and V_T is the threshold voltage of the device. The term in brackets is a tunable conductor,

$$G\left(V_C\right) = \frac{W}{L}\mu C_{ox}\left(V_C - V_t\right) \tag{84.2}$$

where the gate voltage V_C is used for control or *tuning*. Thus, the drain current of a MOSFET in the triode region is proportional to the drain-to-source voltage, but contains nonlinear second- and higher order terms. Third- and higher order terms can be shown to be small and will be neglected in the following. Now consider placing two of these MOS conductances in parallel as shown in Fig. 84.2(a). Note that the two devices are driven in balanced form by $+V_1$ and $-V_1$ at one pair of terminals and that the other terminals are at the same voltage V. Applying these conditions to (84.1) results in

$$I_1 = G\left(V_C\right)\left(+V_1 - V\right) + b_2\left[\left(+V_1\right)^2 - V^2\right] \tag{84.3a}$$

$$I_2 = G\left(V_C\right)\left(-V_1 - V\right) + b_2\left[\left(-V_1\right)^2 - V^2\right] \tag{84.3b}$$

Consequently, apart from the neglected high-order odd terms, the difference current $I_1 - I_2$ is perfectly linear in the applied signal voltage V_1:

$$I_1 - I_2 = 2G\left(V_C\right)V_1 \tag{84.4}$$

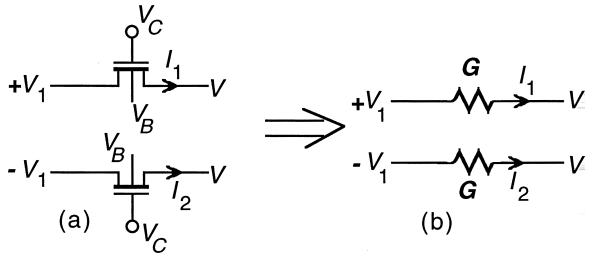

FIGURE 84.2 (a) Balanced linear MOSFET conductance; (b) equivalent resistor circuit.

© 2003 by CRC Press LLC

Thus, in the MOSFET-*C* method, the even-order nonlinearities can be shown to be eliminated by carefully balanced circuit design, where all signals are measured strictly differentially [6]. Note that the expression for $I_1 - I_2$ in (84.4) is the same as that for the linear resistive equivalent circuit in Fig. 84.2(b). This means that the MOSFET circuit in Fig. 84.2(a) can be substituted for a pair of resistors in any *appropriate* active *RC* circuit; appropriate means that the resistor pair is driven by balanced signals at one end and that the voltages at the other two terminals are the same (in practice, usually virtual ground). In addition to these conditions, the substitution is valid if the MOSFETs are operated in the triode region and if $v_1(t)$ and $v(t)$ are safely within the range $|V_C - V_B|$. Of course, in practice there remains some small distortion due to mismatches and the neglected odd-order terms. Odd-order nonlinearities are usually small enough to be negligible. Typically, the remaining nonlinearities, arising from odd harmonics, device mismatch, and body effects, are found to be of the order of 0.1% for 1-V signals.

In the next section, we discuss the MOSFET-*C* integrator that is the fundamental building block used in *all* MOSFET-*C* active filter designs. The integrator will initially be used to construct first- and second-order MOSFET-*C* sections from which higher order filters can be assembled by the cascade method. In the section on ladders we show how simulated *LC* ladder filters are designed by use of integrators.

Basic Building Blocks

Substituting MOSFETs for resistors in an active *RC* prototype works correctly if the active *RC* circuit is of a form where all resistors come in balanced pairs, with one end of the resistor pair voltage-driven and the two other terminals seeing the same voltage [see Fig. 84.2(a)]. Active *RC* circuits do not normally satisfy these conditions, but many can readily be converted into that form if a balanced symmetrical op amp as pictured in Fig. 84.3 is available. It is important to note that this structure is not simply a differential op amp, but that the input and output voltages are symmetrical with respect to a ground reference. Using a balanced op amp, the conversion of many active *RC* prototypes into balanced form proceeds simply by taking the single-ended circuits and mirroring them at ground as shown below.

Integrators

Mirroring the active *RC* integrator structure in Fig. 84.4(a) at ground and using the balanced op amp in Fig. 84.3 leads to the balanced integrator in Fig. 84.4(b). Note that the two resistors are connected in the configuration prescribed in Fig. 84.2 with $V = 0$ (virtual ground) so that they may be replaced by the MOSFET equivalent in Fig. 84.4(c). Analysis of the circuit in the time domain results in

$$-v_{\text{out}} = v^+ - \frac{1}{C}\int_{-\infty}^{t} i_2(t)\,dt \qquad +v_{\text{out}} = v^- - \frac{1}{C}\int_{-\infty}^{t} i_1(t)\,dt \tag{84.5a}$$

$$v_{\text{out}} - \left(-v_{\text{out}}\right) = v^- - v^+ - \frac{1}{C}\int_{-\infty}^{t}\left[i_1(t) - i_2(t)\right]dt \tag{84.5b}$$

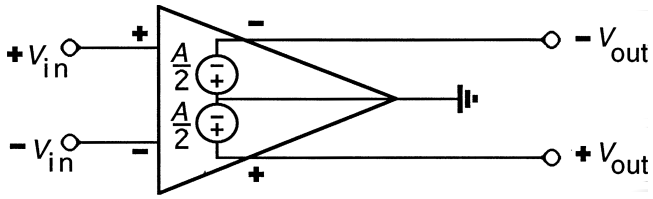

FIGURE 84.3 Balanced operational amplifier configuration realizing $V_{\text{out}} = -AV_{\text{in}}$.

© 2003 by CRC Press LLC

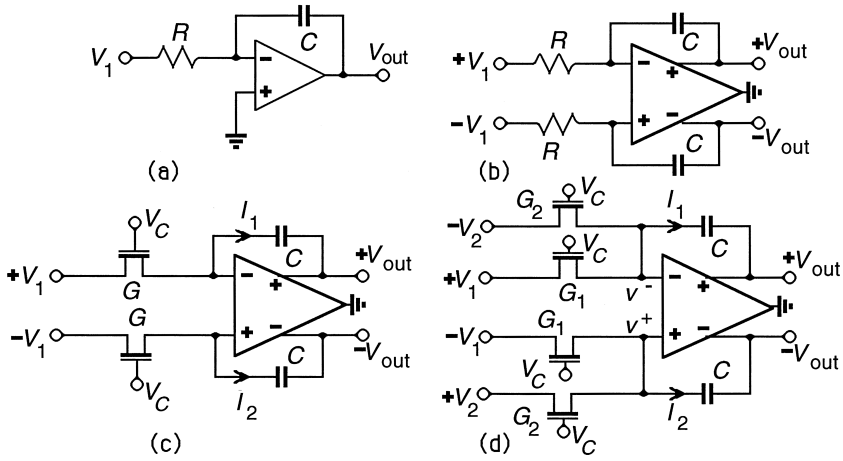

FIGURE 84.4 (a) Active *RC* integrator; (b) fully balanced equivalent; (c) MOSFET-*C* equivalent; (d) differential MOSFET-*C* integrator.

$$2v_{out} = 0 - \frac{1}{C}\int_{-\infty}^{t} 2G(V_C)v_1(t)dt = -\frac{1}{C}\int_{-\infty}^{t}\frac{2v_1(t)}{R(V_C)}dt \tag{84.5c}$$

or, after simplifying and using the Laplace transform, in the frequency domain,

$$v_{out} = -\frac{1}{CR(V_C)}\int_{-\infty}^{t} v_1(t)dt \rightarrow V_{out}(s) = -\frac{1}{sCR(V_C)}V_1(s) \tag{84.5d}$$

We see that the MOSFET-*C* integrator realizes exactly the same transfer function as the active *RC* prototype and that the integration time constant $CR(V_C)$ is tunable by the control voltage V_C that is applied to all gates. Note that the circuit in Fig. 84.4(c) is *not* a differential integrator. To build a differential integrator, one must connect a second pair of balanced resistors (MOSFETs) with inputs $-V_2$ and $+V_2$ as in Fig. 84.4(d) to yield:

$$v_{out} = -\frac{1}{C}\int_{-\infty}^{t}\left[\frac{v_1(t)}{R_1} - \frac{v_2(t)}{R_2}\right]dt \rightarrow V_{out}(s) = -\frac{1}{sC}\left[\frac{V_1(s)}{R_1} - \frac{V_2(s)}{R_2}\right] \tag{84.6}$$

The same principle can also be used to build *programmable* integrators and, therefore, programmable filters: consider in Fig. 84 4(d) the terminals for V_1 and $-V_2$ connected, i.e., $V_1 = -V_2$. The two resistors are then connected in parallel to give a resistive path $G_1 + G_2$, and the two resistor values can be controlled by different gate voltages V_{C1} and V_{C2}. Similarly, additional *balanced* MOSFET-resistor paths may be connected from V_1 or other signals to the integrator inputs (summing nodes). These paths can be turned on or off by an appropriate choice of gate voltages, so that transfer functions with different parameters (such as gains, quality factors or pole-frequencies) or even transfer functions of different types (such as bandpass, low-pass, etc.) are obtainable.

If better linearity is required than is obtainable with the two-transistor MOSFET circuit in Fig. 84.4(c) that replaces each resistor in the balanced active *RC* structure by one MOSFET, a four-MOSFET cross-coupled modification for each resistor pair can be used instead [5, paper 2-B.7]. The configuration is illustrated in Fig. 84.5. The current difference can be shown to equal

© 2003 by CRC Press LLC

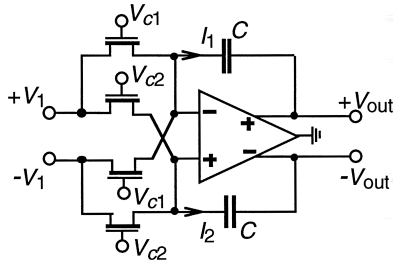

FIGURE 84.5 Integrator using a four-MOSFET configuration for greater linearity.

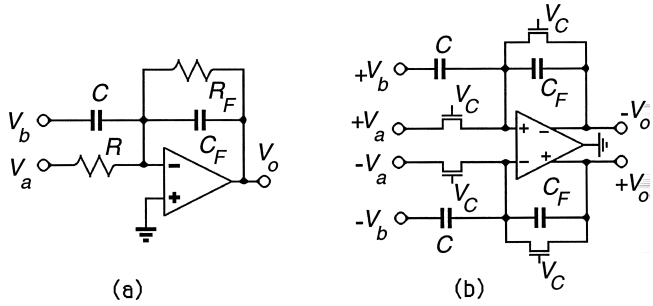

FIGURE 84.6 (a) Lossy integrator with capacitive feed-in branch; (b) MOSFET-*C* equivalent.

$$\Delta I = I_1 - I_2 = K\left(V_{C1} - V_{C2}\right)\left[V_1 - \left(-V_1\right)\right] \tag{84.7}$$

that is, ΔI is proportional to the product of the difference of the input signals and the difference of the applied gate voltages V_{Ci}, $i = 1, 2$. This indicates that one may interchange the input and gate-control voltages and reduce the drive requirements of the previous op amp stage because no resistive current flows, only the small gate-capacitor current flows with the input applied at the control gates (now at $\pm V_1$). The price paid for this advantage is that the requirements on the control voltage source become more difficult and may necessitate an appropriate common-mode voltage on the signal lines.

Additional resistive or capacitive inputs may, of course, be used to design more general lossy integrators as illustrated in Fig. 84.6. By writing the node equation at the summing node, this circuit may be analyzed to realize

$$V_o = -\frac{1}{sC_F + G_F}\left(GV_a + sCV_b\right) \tag{84.8}$$

where the conductors are implemented in Fig. 84.6(b) as

$$R\left(V_C\right) = \frac{1}{\mu C_{ox}\left(W/L\right)\left(V_C - V_T\right)} \qquad R_F\left(V_C\right) = \frac{1}{\mu C_{ox}\left(W_F/L_F\right)\left(V_C - V_T\right)} \tag{84.9}$$

as was derived in (84.2). The controlling gate voltages V_C for the two resistors R and R_F may, in general, be different so that the resistor values may be tuned (or turned on or off) independently.

With lossy and lossless MOSFET-*C* integrators available, we can obtain not only first- and second-order filters as shown in the next subsection, but also simulations of *LC* ladders in much the same way as was done in Chapter 83 for active *RC* circuits. We discuss this procedure in some detail in the section on ladder simulations.

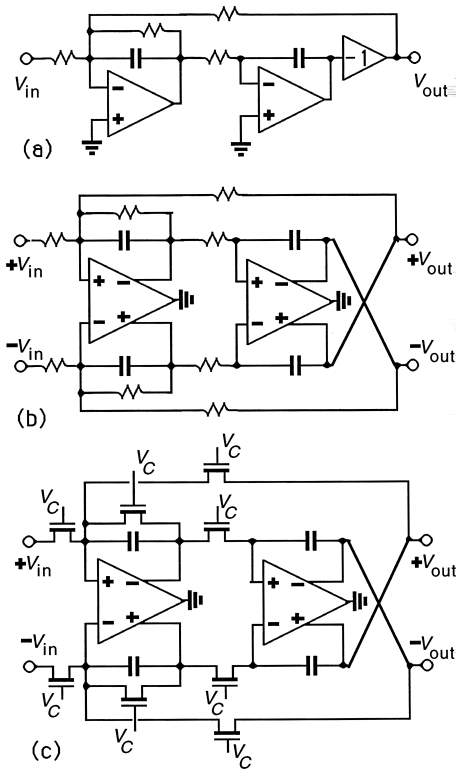

FIGURE 84.7 (a) Active *RC* prototype (Tow-Thomas biquad) for conversion into a MOSFET-*C* structure; (b) fully balanced version of the biquad with resistors; (c) fully balanced version of the biquad with MOSFETs.

First- and Second-Order Sections

Based on the principle of balancing a single-ended structure, appropriate[3] standard classical active *RC* filters from the literature can be converted into balanced form and resistors can be replaced by MOSFETs. As an illustration, consider the single-ended prototype (Tow-Thomas) biquad in Fig. 84.7(a). As is typical for second-order active *RC* filter sections (see Chapter 81), the circuit is a two-integrator loop consisting of inverting lossy and lossless integrators (in addition to an inverter to keep the loop gain negative for stability reasons). The realized transfer function is not important to our discussion, but we point out that all resistors are voltage-driven (by the signal source or by an op amp) and at their other ends all resistors are connected to an op amp input, i.e., they are at virtual ground. Thus, this circuit satisfies our earlier condition for conversion to a MOSFET-*C* structure. Figure 84.7(b) shows the balanced active *RC* equivalent that is necessary to eliminate the nonlinear performance. Replacing the resistors by MOSFETs biased in the triode region leads to the final MOSFET-*C* version in Fig. 84.7(c). The *W*/*L* ratios are chosen appropriately to realize the prescribed resistor values

$$G_i = \frac{W_i}{L_i}\,\mu\, C_{ox}\left(V_C - V_T\right) \tag{84.10}$$

with excellent resistor matching given by aspect ratios

$$\frac{G_i}{G_k} = \frac{\left(W/L\right)_i}{\left(W/L\right)_k} \tag{84.11}$$

[3]All resistors must be voltage-driven from one side and see the same voltage, usually virtual ground, on the other.

© 2003 by CRC Press LLC

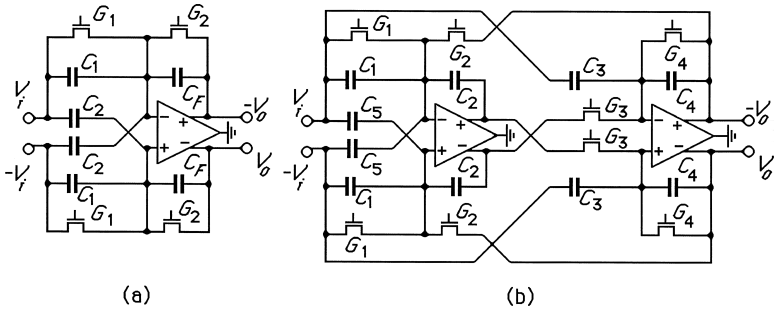

FIGURE 84.8 General (a) first- and (b) second-order MOSFET-*C* sections. The MOSFETs are labeled by the conductance values they are to implement.

The voltage-variable resistors given by (84.10) permit loss and time constants to be electronically tuned. Note that the inverter in the original circuit is not needed in Figs. 84.7(b) and (c) because inversion in the differential topology is obtained by crossing wires.

The circuit may be made *programmable* by connecting additional MOSFET resistors with appropriate *W*/*L* ratios in parallel with the fundamental ones shown in Fig. 84.7(c) and then switching them on or off as required by the desired values of the filter coefficients.

The above method indicates how first- or second-order sections can be obtained by choosing any suitable configuration from the active *RC* filter literature [4, ch. 5], [9, chs. 4 and 5] and converting it to balanced MOSFET-*C* form. Next we show a couple of entirely general first- and second-order sections that can be developed from the integrator in Fig. 84.6(b). The resulting circuits are shown in Fig. 84.8 [5, paper 2-A.2]. If we combine the inputs $V_a = V_b = V_i$ of the integrator in Fig. 84.6(b) and add two further cross-coupled feed-in capacitors, we obtain the first-order circuit in Fig. 84.8(a). Writing the node equation at the (inverting or non-inverting)[4] op-amp input results in the transfer function

$$T_1(s) = \frac{V_o}{V_i} = \frac{s(C_1 - C_2) + G_1}{sC_F + G_2} \tag{84.12}$$

Note that this first-order circuit can realize zeros anywhere on the real axis. Similarly, if we combine two such integrators in a loop, with the individual signal paths and signs selected to assure negative feedback, we obtain the general second-order section in Fig. 84.8(b). Writing again the node equations at the op-amp input nodes leads to the transfer function

$$T_2(s) = \frac{V_o}{V_i} = \frac{s^2C_2C_3 + s(C_1 - C_5)G_3 + G_1G_3}{s^2C_2C_4 + sC_2G_4 + G_2G_3} \tag{84.13}$$

Observe that this circuit can realize zeros anywhere in the *s*-plane, depending on the choice of element values. Consequently, the sections in Fig. 84.8 can be used to implement arbitrary high-order transfer functions in a cascade topology. Specifically, for the indicated choice of elements the general biquad function in (84.13) realizes the different transfer functions in Table 84.1.

Cascade Realizations

The realization of high-order transfer functions as a connection of low-order sections, including the *cascade*, *multiple-loop feedback*, and *coupled-biquad* approaches, is identical to that discussed for discrete

[4]Because the circuit is completely symmetrical, it is only necessary to derive the equations for one side, e.g., for V_o; the expressions for the other side, i.e., $-V_o$, are the same.

TABLE 84.1 Functions Realizable with Fig. 84.8(b)

Function	Choice of Elements
Bandpass	$G_1 = C_3 = 0$; $C_5 = 0$ if non-inverting, $C_1 = 0$ if inverting
Low-pass	$C_1 = C_3 = C_5 = 0$
High-pass	$C_1 = C_5 = G_1 = 0$
Notch	$C_1 = C_5$
All-pass	$(C_1 - C_5)G_3 = -C_2G_4$

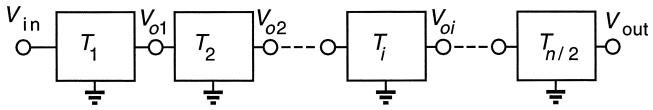

FIGURE 84.9 Cascade realization of an *n*th-order transfer function.

active *RC* filters. The difference lies only in the implementation of the sections in fully integrated form. We do not repeat the process here but only discuss the most prevalent method, cascade design, in terms of an example and encourage the reader to refer to the earlier discussion in Chapter 83 for details. To repeat briefly, if a high-order function

$$H(s) = \frac{V_{\text{out}}}{V_{\text{in}}} = \frac{N(s)}{D(s)} = \frac{a_m s^m + a_{m-1}s^{m-1} + \cdots + a_1 s + a_0}{s^n + b_{n-1}s^{n-1} + \cdots + b_1 s + b_0} \tag{84.14}$$

with $m \le n$ and $n > 2$ is given, it is factored into second-order sections (and one first-order section if n is odd),

$$H(s) = \prod_{i=1}^{n/2} T_i(s) = \prod_{i=1}^{n/2} k_i \frac{a_{2i}s^2 + a_{1i}s + a_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = \prod_{i=1}^{n/2} k_i t_i(s) \tag{84.15}$$

where each of the second-order functions

$$T_i(s) = \frac{V_{oi}}{V_{oi-1}} = k_i \frac{a_{2i}s^2 + a_{1i}s + a_{0i}}{s^2 + s\omega_{0i}/Q_i + \omega_{0i}^2} = k_i\, t_i(s) \tag{84.16}$$

is implemented as a suitable biquad with specified pole quality factor Q_i and pole frequency ω_{0i}, such as the one in Fig. 84.8(b) realizing (84.13). As was explained in Chapter 83, k_i is a suitable gain constant, chosen to equalize the signal levels in order to optimize the dynamic range, and $t_i(s)$ is a gain-scaled transfer function. Note that in writing (84.15) we assumed that n is even. Figure 84.9 shows the general (single-ended) structure of the filter.

To provide an example, assume we wish to realize a delay of $\tau_D = 0.187$ μs via a fifth-order Bessel approximation, but with a transmission zero at $f/f_n = 4.67$ to improve the attenuation in the stopband.[5] The transfer function is found to be

$$H_5(s) = \frac{43.3315\left(s^2 + 21.809\right)}{\left(s + 3.6467\right)\left(s^2 + 6.7040s + 14.2729\right)\left(s^2 + 4.6494s + 18.1563\right)} \tag{84.17}$$

[5]Note that transmission zeros on the $j\omega$-axis can be added [9, ch. 10.8] to a linear-phase network, such as a Bessel filter, without changing the phase because a zero factor, $(\omega_z^2 - \omega^2)$, is a purely real number on the $j\omega$ axis.

© 2003 by CRC Press LLC

The normalizing frequency is $f_n = 1/(2\pi\tau_D) = 850$ kHz [4, ch. 1], [9, ch. 10]. Let us choose a cascade implementation with the circuits in Fig. 84.8. Factoring (84.17) leads to the first-order and the two second-order functions on the left-hand side of (84.18) to be realized by the functions on the right, which are obtained from (84.12) and (84.13):

$$T_1(s) = \frac{3.6467}{s+3.6467} \rightarrow T_1(s) = \frac{V_{o1}}{V_{in}} = \frac{G_1}{sC_F + G_2} \tag{84.18a}$$

$$T_2(s) = \frac{14.2729}{s^2+6.7040s+14.2729} \rightarrow T_2(s) = \frac{V_{o2}}{V_{o1}} = \frac{G_1G_3}{s^2C_2C_4 + sC_2G_4 + G_2G_3} \tag{84.18b}$$

$$T_3(s) = \frac{0.8325\left(s^2+21.809\right)}{s^2+4.6494s+18.1563} \rightarrow T_3(s) = \frac{V_{o3}}{V_{o2}} = \frac{s^2C_2C_3 + G_1G_3}{s^2C_2C_4 + sC_2G_4 + G_2G_3} \tag{84.18c}$$

The components of the first- and second-order filters in Fig. 84.8 are to be determined from these equations. The gain constants in the function were chosen to result in unity gain at dc. Comparing coefficients, we find with $\omega_n = 1/\tau_D \approx 2\pi\cdot 850$ krad $s^{-1} \approx 5.341$ Mrad s^{-1}:

From (84.18a): $$G_1 = G_2 = 3.6467\ \omega_n C_F \tag{84.19a}$$

Choosing $C_F = 2$ pF gives $G_1 = G_2 = 38.952$ μS; also $C_1 = C_2 = 0$.

From (84.18b): $$G_1G_3 = G_2G_3 = 14.2729\ \omega_n^2C_2C_4;\ G_4 = 6.7040\ \omega_nC_4 \tag{84.19b}$$

Choosing $C_2 = C_4 = 2$ pF results in $G_1 = G_2 = G_3 = 40.354$ μS and $G_4 = 71.6$ μS; also, $C_1 = C_3 = C_5 = 0$.

From (84.18c): $$G_1G_3 = 0.8325 \times 21.809\omega_n^2C_2C_4 = 18.1563\ \omega_n^2C_2C_4;$$
$$G_2G_3 = 18.1563\ \omega_n^2C_2C_4;\ G_4 = 4.6494\ \omega_nC_4;\ C_3 = 0.8325C_4 \tag{84.19c}$$

Choosing $C_2 = 2$ pF and $C_4 = 10$ pF yields $C_3 = 8.325$ pF, $G_1 = G_2 = G_3 = 101.77$ μS and $G_4 = 248.32$ μS; also, $C_1 = C_5 = 0$. The remaining task is to convert the resistors into MOSFET devices. Assume the process provides transistors with $\mu C_{ox} = 120$ μA/V^2 and $V_T = 0.9$V. For the choice of $V_C = 2$V, the aspect ratios are then calculated from the above conductance values and from (84.10) via:

$$\frac{W_i}{L_i} = \frac{G_i(V_C)}{\mu C_{ox}(V_C - V_T)} = \frac{G_i(V_C)}{120\mu A/V^2 \cdot 1.1V} = \frac{G_i/\mu S}{132} \tag{84.20}$$

For instance, in the first-order section we find $W_1/L_1 = W_2/L_2 = 38.952/132 = 1/3.389$. The resulting circuit is shown in Fig. 84.10.

Ladder Simulations

Using MOSFET-*C* integrators, the ladder simulation method for the MOSFET-*C* approach is entirely analogous to the active *RC* procedures discussed earlier in this book (see Chapter 83). The process is illustrated by a step-by-step generic example, which should guide the reader when implementing a specific design.

Assume a fifth-order elliptic low-pass filter with the transfer function

$$H_{ell}(s) = \frac{\left(s^2+\omega_1^2\right)\left(s^2+\omega_2^2\right)}{(s+a)\left(s^2+bs+c\right)\left(s^2+ds+e\right)} \tag{84.21}$$

© 2003 by CRC Press LLC

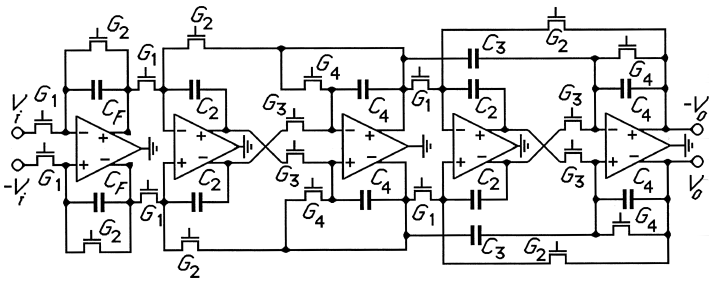

FIGURE 84.10 Circuit to realize the filter described by (84.17). Note that for easy reference we have kept the subscripts on the elements in each section the same as in Fig. 84.8.

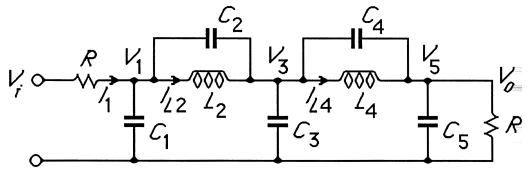

FIGURE 84.11 Fifth-order elliptic *LC* low-pass filter.

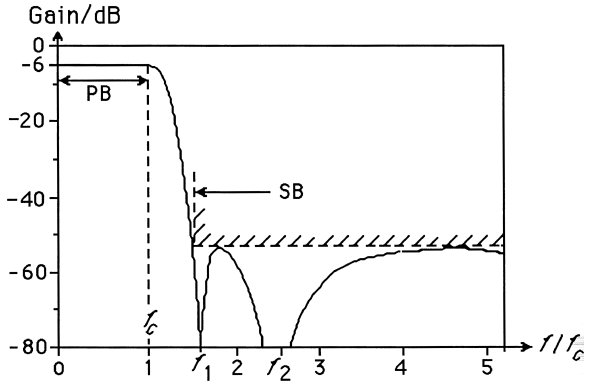

FIGURE 84.12 Transfer function magnitude of a fifth-order elliptic low-pass function.

is prescribed, which with the help of readily available ladder synthesis software is realized by the *LC* ladder structure in Fig. 84.11 with known component values. A plot of such a function is shown in Fig. 84.12. The two transmission zeros f_1 and f_2 in the figure are obtained when L_2, C_2, and L_4, C_4, respectively, resonate. The *LC* active simulation proceeds by deriving the signal-flow graph equations [4, ch. 6], [9, ch. 15] or by writing the loop and node equations of the ladder along with the *V-I* relationships describing the functions of the elements:

$$I_1 = \frac{V_i - V_1}{R}, \quad I_{L2} = \frac{V_1 - V_3}{sL_2}, \quad I_{L4} = \frac{V_3 - V_5}{sL_4} \tag{84.22a}$$

$$V_1 = \frac{I_1 - \left[I_{L2} + sC_2\left(V_1 - V_3\right)\right]}{sC_1} \tag{84.22b}$$

$$V_3 = \frac{I_{L2} - I_{L4} + sC_2\left(V_1 - V_3\right) - sC_4\left(V_3 - V_5\right)}{sC_1} \tag{84.22c}$$

© 2003 by CRC Press LLC

$$V_5 = V_o = \frac{I_{L4} + sC_4\left(V_3 - V_5\right)}{sC_5 + G} \tag{84.22d}$$

We recognize that these equations represent *integrations* of voltages into currents and currents into voltages. We also note that the currents through the capacitors C_2 and C_4 can be taken care of efficiently without resorting to integration: by connecting C_2 and C_4 directly to the voltage nodes V_1, V_3, and V_3, V_5, respectively, they conduct the currents as prescribed in (84.22b)–(84.22d). Next we reformat (84.22a)–(84.22d) by eliminating I_1 from (84.22a) and (84.22b) and rewriting (84.22b), (84.22c), and (84.22d) such that V_1, V_3, and V_5, respectively, appear only on the left-hand side. The result is the new set of equations

$$I_{L2} = \frac{V_1 - V_3}{sL_2}, \quad I_{L4} = \frac{V_3 - V_5}{sL_4} \tag{84.23a}$$

$$V_1 = \frac{V_i G - I_{L2} + sC_2 V_3}{s\left(C_1 + C_2\right) + G} \tag{84.23b}$$

$$V_3 = \frac{I_{L2} - I_{L4} + sC_2 V_1 + sC_4 V_5}{s\left(C_2 + C_3 + C_4\right)} \tag{84.23c}$$

$$V_5 = V_o = \frac{I_{L4} + sC_4 V_3}{s\left(C_4 + C_5\right) + G} \tag{84.23d}$$

Recall that all signals in the MOSFET-*C* circuit are voltages, which in turn produce currents summed at the op amp inputs, and that the integration constant must be *time* rather than *capacitance*. This is achieved by scaling the equations by a resistor *R*. We illustrate the process on (84.23a) and (84.23b):

$$I_{L4} = \frac{V_3 - V_5}{sL_4} \rightarrow \frac{I_{L4}}{G} = \frac{GV_3 - GV_5}{s\left(L_4 G\right)G} \tag{84.24a}$$

$$V_1 = \frac{V_i G - I_{L2} + sC_2 V_3}{s\left(C_1 + C_2\right) + G} \rightarrow V_1 = \frac{V_i G - \left(I_{L2}/G\right)G + sC_2 V_3}{s\left(C_1 + C_2\right) + G} \tag{84.24b}$$

Notice that L_4G^2 has the unit of *farad*, i.e., it is a capacitor that, however, in Figs. 84.13 and 84.14 will be labeled L_4 (and L_2, respectively) to help keep track of its origin. Similarly, I_{L2}/G and I_{L4}/G will be labeled V_{I2} and V_{I4}, respectively. The integrators can now be realized as in Fig. 84.6(b) and then interconnected as the equations prescribe. Figure 84.13 illustrates the process for (84.24). The MOSFET-*C* implementation of all appropriately scaled equations (84.23) leads to the fifth-order elliptic filter shown in

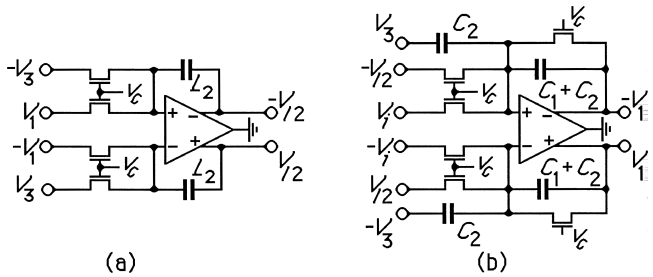

FIGURE 84.13 MOSFET-*C* implementation of (a) Eq. (84.24a), and (b) Eq. (84.24b) All MOSFETs realize the value *G*.

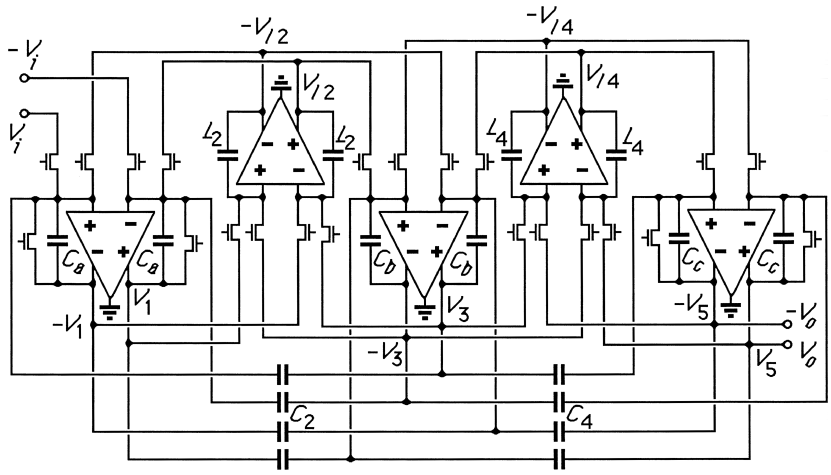

FIGURE 84.14 Operational simulation of the *LC* ladder of Fig. 84.11 with MOSFET-*C* integrators; $C_a = C_1 + C_2$, $C_b = C_2 + C_3 + C_4$, $C_c = C_4 + C_5$.

Fig. 84.14. As given in (84.10), the aspect ratio of each MOSFET and the control voltage V_C are adjusted to realize the corresponding resistor values of the standard active *RC* implementation and all MOSFET gates are controlled by the same V_C for tuning purposes. Arrays of MOSFETs controlled by different values of V_C can be used to achieve programmable filter coefficients.

An often cited advantage of the MOSFET-*C* technique is the reduced sensitivity to parasitic capacitors, whereas the g_m-*C* approach discussed next must carefully account for parasitics by predistortion. Note from Figs. 84.6(b), 84.8, 84.10, and 84.14 that all capacitors and the MOSFET resistors are connected to voltage-driven nodes or to virtual ground so that parasitic capacitors to ground are of no consequence as long as amplifiers with sufficiently high gain and wide bandwidth are used. Fortunately, such amplifiers are being developed [5, paper 2-B.5] so that MOSFET-*C* circuits promise to become increasingly attractive in the future.

84.3 g_m-*C* Filters

At the time of this writing, the dominant active device used in the design of integrated continuous-time filters is the *transconductor* (g_m) or the *operational transconductance amplifier* (OTA) [7, ch. 5], [9. ch. 16]. Both names, g_m-*C* filters and OTA-*C* filters, are used in the literature; we will use the term g_m-*C* filter in this text. The main reasons for this prevalence appear to be the simple systematic design methods for g_m-*C* filters and, especially, the higher range of frequencies over which g_m-based filters can operate. Also, OTAs often have simpler circuitry (fewer elements) than op amps. A transconductor is a voltage-to-current converter described by

$$I_{\text{out}} = g_m(s)V_{\text{in}} \tag{84.25}$$

where $g_m(s)$ is the frequency-dependent transconductance parameter with units of [Ampere/Volt] or [Siemens], abbreviated [S]. Typical values for g_m are tens to hundreds of μS in CMOS and up to mS in bipolar technology. A simplified small-signal equivalent circuit is shown in Fig. 84.15. The dashed components in Fig. 84.15 are parasitics that in an ideal OTA should be zero but that in practice must be accounted for. For common designs in CMOS technology, the input conductance g_i is zero; the input and output capacitances, c_i and c_o, are typically of the order of 0.05 pF or less and the output resistance $r_o = 1/g_o$ is in the range of 50 kΩ to 1 MΩ. The bandwidth of well-designed transconductors is so large that g_m in many cases can be regarded as constant, $g_m(s) = g_{m0}$, but for critical applications in high-frequency designs the transconductance pole and the resulting phase errors must be considered. A good model for these situations is

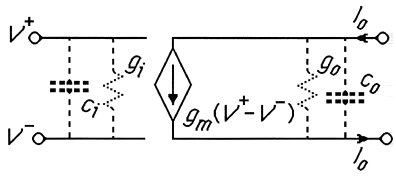

FIGURE 84.15 Small-signal equivalent circuit.

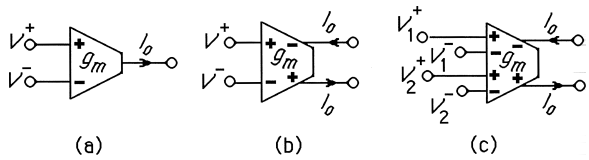

FIGURE 84.16 OTA symbols (a) differential input–single-ended output: $I_o = g_m(V^+ - V^-)$; (b) fully differential; (c) with multiple inputs: $I_o = g_m[(V_1^+ - V_1^-) + (V_2^+ - V_2^-)]$.

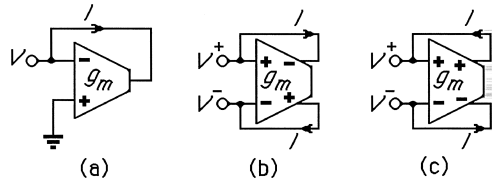

FIGURE 84.17 Simulated resistors: (a) positive single-ended of value $V/I = 1/g_m$, (b) positive differential resistor of value $(V^+ - V^-)/I = 1/g_m$, (c) negative differential resistor $-1/g_m$.

$$g_m(s) \approx g_{m0}e^{-s\tau} \approx \frac{g_{m0}}{1+s\tau} \approx g_{m0}(1-s\tau) \tag{84.26}$$

where $f = 1/(2\pi\tau)$ is the pole location (typically at several 100 MHz to 10 GHz) and the phase error $\Delta\phi = -\omega\tau$ is considered small, i.e., $\omega\tau \ll 1$. The three different approximations in (84.26) for representing the frequency dependence are equivalent; the pole is used most often, the zero frequently results in simpler equations and algebra, and the phase may give better insight into the behavior of feedback loops.

The most commonly used circuit symbols are shown in Fig. 84.16. Note that OTA designs with multiple differential inputs as in Fig. 84.16(c) are readily available. They often lead to simpler filter designs with less silicon area and power consumption because only the OTA input stages must be duplicated, whereas the remaining parts of the OTA, such as output and common-mode feedback circuitry, can be shared. Essentially, if two OTAs with the same g_m value in a filter have a common output node (a frequent situation), the two OTAs can be merged into the circuit of Fig. 84.16(c), thus saving circuitry and power.

Filter design methods discussed in this section use only OTAs and capacitors: OTAs to provide gain and capacitors to provide integration. To establish time constants, resistors may also be required, but their function can be obtained from OTAs: "resistors" of value $1/g_m$ can be simulated by connecting the OTA output to its input with the polarities shown in Figs. 84.17(a) and (b). Inverting one pair of terminals results in a negative resistor as in Fig. 84.17(c).[6] Since transconductors and capacitors can be used to build all components necessary for designing the filters, they are called transconductance-C or g_m-C

[6]Such "negative resistors" are often used to cancel losses, for example to increase the dc gain of transconductors or the quality factors of filter stages. Specifically, a negative resistor can be employed to increase the quality factor of the inductor in Figs. 84.21 and 84.22.

© 2003 by CRC Press LLC

filters. We discuss the remaining "composite" building blocks, integrators and gyrators[7] subsequently in the section on basic building blocks.

In this subsection we will not go into the electronic circuit design methods for OTAs, but refer the reader to the literature, which contains a great number of useful transconductance designs in all current technologies. References [5] and [12] contain numerous papers that discuss practical transconductance circuits. The most popular designs currently use CMOS, but bipolar and BiCMOS are also widely employed, and GaAs has been proposed for applications at the highest frequencies or under unusually severe environmental conditions. Since transconductors are almost always used in open loop without local feedback, their input stages must handle the full amplitude of the signal to be processed. Typically, the OTA input stage is a differential pair with quite limited signal swing before nonlinearities become unacceptable. Thus, much design expertise has gone into developing linearization schemes for transconductance circuits. They have resulted in designs that can handle signals of the order of volts with nonlinearities of a fraction of 1%. Apart from simple source-degeneration techniques, the most commonly employed approaches use variations of the principle of taking the difference between the drain currents of two MOS devices in the saturation region but driven differentially, so that the difference current is linear in V_{gs}:

$$\begin{aligned} I_d^+ &= k\left(V_{gs} - V_T\right)^2 = k\left(V_{gs}^2 + V_T^2 - 2V_{gs}V_T\right) \\ I_d^- &= k\left(-V_{gs} - V_T\right)^2 = k\left(V_{gs}^2 + V_T^2 + 2V_{gs}V_T\right) \\ \Delta I_d &= I_d^+ - I_d^- = -4V_{gs}V_T \end{aligned} \tag{84.27}$$

Another approach reasons that the most linear (trans)conductance behavior should be obtainable from the current through a resistor. Thus, operating an MOS device in the resistive (triode) region,

$$I_d = k\left[\left(V_{gs} - V_T\right)V_{ds} - 0.5V_{ds}^2\right]$$

and taking the derivative with respect to V_{gs} for constant $V_{ds} = V_{DS}$ results in a perfectly linear transconductance,

$$g_m = \frac{\mathrm{d}I_d}{\mathrm{d}V_{gs}} = kV_{DS} \tag{84.28}$$

that furthermore can be adjusted (tuned) by varying a dc bias voltage (V_{DS}) as long as V_{DS} stays small enough for the transistor to remain in the triode region. The circuitry surrounding the triode-region MOS device must assure that V_{DS} remains constant and independent of the signal.

As mentioned, the literature contains numerous practical CMOS, bipolar, or biCMOS transconductance designs that require low power supply voltages (±1.5 V, or 0 to 3 V, or even less for low-power applications), and have acceptable signal swing (of the order of volts), with low nonlinearities (as low as a small fraction of 1%) and wide bandwidth (up to several hundred megahertz and even into the gigahertz range). Two further aspects of OTA design should be stressed at this point. First, since g_m-C filters often contain many transconductors, the designer ought to strive for simple OTA circuitry. It saves silicon real estate and at the same time often results in better frequency performance because of reduced parasitics at internal nodes. We point out though that there exists a trade-off between simple circuitry and large

[7] A gyrator is a two-port circuit whose input impedance is inversely proportional to the load impedance: $Z_{\text{in}}(s) = r^2/Z_{\text{load}}(s)$. If $Z_{\text{load}} = 1/(sC)$, the input is inductive, $Z_{\text{in}}(s) = sr^2C = sL$. r is called the gyration resistance (see the discussion to follow).

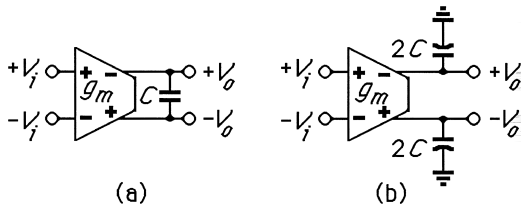

FIGURE 84.18 Integrator. The integrator capacitor may be floating (a) or grounded (b). Note that the grounded-capacitor realization requires four times the area.

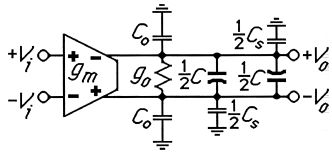

FIGURE 84.19 Parasitic capacitors associated with a g_m-C integrator.

voltage swing: a wide linear signal range always requires special linearizing circuit techniques and, therefore, additional components. The second issue pertains to tuning. We mentioned earlier that continuous-time filters always require tuning steps to eliminate the effects of fabrication tolerances and component drifts. In IC technologies this implies that the circuit components must be electronically adjustable. Since (MOS) capacitors are generally fixed,[8] all tuning must be handled via the transconductance cells by changing one or more bias points. Usually two adjustments are needed: the magnitude of g_m must be varied to permit tuning the frequency parameters set by g_m/C-ratios and, as explained later, the phase $\Delta\phi$ must be varied to permit tuning the filters' quality factors. We discuss tuning methods in some detail in Section 84.4.

In the next subsection we introduce the central building blocks from which g_m-C filters are constructed, the integrator and the gyrator. Just as we saw in the discussion of MOSFET-C circuits and in the earlier treatment of active RC filters, integrators are fundamental to the development of active filter structures, both for second-order sections and cascade designs, as well as for higher order LC ladder simulations. Gyrators along with capacitors are used to replace inductors in passive RLC filters so that many passive filter structures, such as LC ladders, can be directly translated into g_m-C form.

Basic Building Blocks

Integrators

Integrators are obtained readily by loading an OTA with a floating or a grounded capacitor as shown in Fig. 84.18. Observe that the simpler technology of grounded capacitors requires four times the capacitor value and silicon area. Ideally, the integrator realizes the transfer function

$$\frac{V_o}{V_i} = -\frac{g_m}{sC} \tag{84.29a}$$

but notice that the function is sensitive to unavoidable parasitic capacitors as well as to the OTA output conductance g_o. Observe from Fig. 84.19 that the output conductance is in parallel with the integrating capacitor C, and that the output capacitances C_o from the positive and negative output nodes of the OTA circuitry to ground add to the value of C. Furthermore, the designer should bear in mind that in IC

[8]To implement small values of variable capacitor, MOS transistors connected as varactors can be used. The capacitor can be varied, e.g., via substrate bias.

© 2003 by CRC Press LLC

technology floating capacitors have a substantial parasitic capacitance C_s (about 10% of the value of C) from the bottom plate to the substrate, i.e., to ac ground. To maintain symmetry, the designer may wish to split the integrating capacitor into two halves connected such that the parasitic bottom plate capacitors $0.5C_s$ appear at the two OTA outputs. The situation is illustrated in Fig. 84.19. Taking the parasitics into consideration, evidently, the integrator realizes

$$\frac{V_o}{V_i} = -\frac{g_m}{sC_{\text{int}} + g_o}\bigg|_{s=j\omega} = -\frac{g_m}{j\omega C_{\text{int}}\left(1 - j/Q_{\text{int}}\right)} \tag{84.29b}$$

that is, it becomes lossy with a finite integrator quality factor

$$Q_{\text{int}} = \frac{\omega C_{\text{int}}}{g_o} \tag{84.30a}$$

and an effective integrating capacitor equal to

$$C_{\text{int}} = C + \frac{1}{2}\left(\frac{C_s}{2} + C_o\right) \tag{84.30b}$$

To maintain the correct integration constant as nominally designed, the circuit capacitor C should be predistorted to reflect the parasitics appearing at the integration nodes. The parasitics should be estimated as best as possible, for example from a layout process file, and their values subtracted from the nominal value of C in the final layout. If grounded capacitors are used as in Fig. 84.18(b), the bottom plate should, of course, be connected to ground so that the substrate capacitances are connected between ground and the power supply. Thus, they are shorted out for the signals and play no role. Observe that the presence of parasitic capacitors tends to limit the high-frequency performance of these filters because high-frequency filters require large time constants, g_m/C, i.e., small capacitors.[9] The smallest capacitor C, however, must obviously be larger than the sum of all parasitics connected at the integrator output nodes to be able to absorb these parasitics.[10] Because the values of the parasitic capacitors can generally only be estimated, one typically chooses C to be three to five times larger than the expected parasitics to maintain some predictability in the design. The reader will notice that integrators with grounded capacitors, Fig. 84.18(b), have a small advantage in high-frequency circuits where parasitic capacitors become large relative to C. Because of the problem with parasitic capacitors, an alternative "g_m-C–op amp" integrator is also used. It employs an op amp to minimize their effects for the price of a second active device, increased noise, silicon area, and power consumption. Figure 84.20(a) shows the configuration. Notice that now the parasitic capacitors play no role because they are connected between ground and virtual ground (the op amp inputs) so that they are never charged. A more careful analysis shows that the integrator realizes

$$\frac{V_o}{V_i} = \frac{g_m}{sC}\frac{1}{1 + \dfrac{1}{A(s)}\left(1 + \dfrac{C_p}{C}\right)} \approx \frac{g_m}{sC}\frac{1}{1 + \dfrac{s}{\omega_t}\left(1 + \dfrac{C_p}{C}\right)} \tag{84.31}$$

[9]Increasing g_m is generally not a satisfactory solution because it also increases the parasitics.

[10]Obviously, the highest operating frequencies are obtained for $C = 0$, that is, when a parasitic capacitor C_p is used as the integrating capacitor C. In that case, operating frequencies in the gigahertz range can be realized: $g_m/C \approx 2\pi\times$ 1 GHz for $g_m = 100$ μS and $C_p \approx 15$ fF. Naturally, because of the uncertainty in the design values, an automatic tuning scheme is unavoidable.

© 2003 by CRC Press LLC

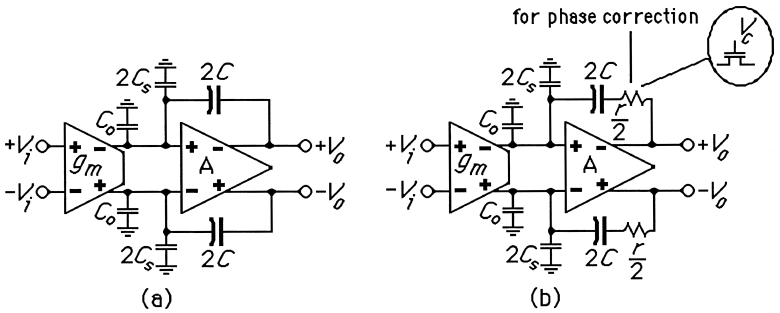

FIGURE. 84.20 (a) g_m-C–op amp integrator; (b) nominal correction for phase errors.

where $C_p = 0.5(C_o + 2C_s)$ represents the total parasitic capacitance at each of the op amp input terminals. Evidently, the integrator has acquired a parasitic pole at

$$s = -\omega_t \frac{C}{C + C_p} \tag{84.32}$$

where we have modeled the amplifier gain as $A(s) \approx \omega_t / s$. The high-frequency performance is now limited by the op amp behavior. It has been shown, though, that a low-gain wideband amplifier, essentially a second OTA with dc gain g_m/g_o, can be used for this application. Nevertheless, the second active device introduces parasitic poles (and zeros) whose effects must be carefully evaluated in practice. The dominant pole introduced by the op amp may be canceled *nominally* by an rC phase lead as shown in Fig. 84.20(b). The circuit realizes

$$\frac{V_o}{V_i} = \frac{g_m}{sC} \frac{1 + sCr}{1 - \dfrac{\omega}{\omega_t} \omega C_p r + \dfrac{s}{\omega_t}\left(1 + \dfrac{C_p}{C}\right)} \approx \frac{g_m}{sC} \frac{1 + sCr}{1 + \dfrac{s}{\omega_t}\left(1 + \dfrac{C_p}{C}\right)} \tag{84.33}$$

so that r should be chosen as

$$r = \frac{1}{\omega_t C}\left(1 + \frac{C_p}{C}\right) \tag{84.34}$$

to cancel the pole. The small resistor r may be a MOSFET in the triode region as indicated in Fig. 84.20(b) so that $r(V_C)$ becomes variable for any necessary fine adjustments. Notice that the cancellation is only *nominal* because (84.34) can never be satisfied exactly because of the uncertain values of ω_t and C_p.

Gyrators

A gyrator is defined by the equations

$$I_i = \frac{1}{r} V_o \qquad I_o = -\frac{1}{r} V_i \tag{84.35a}$$

where r is the so-called gyration resistance and the currents are defined as positive when flowing into the gyrator. Thus, the input impedance $Z_{\text{in}}(s)$ is inversely proportional to the load impedance $Z_{\text{load}}(s)$:

$$Z_{\text{in}}(s) = \frac{V_i}{I_i} = r^2 \frac{-I_o}{V_o} = r^2 \frac{1}{Z_{\text{load}}(s)} \tag{84.35b}$$

© 2003 by CRC Press LLC

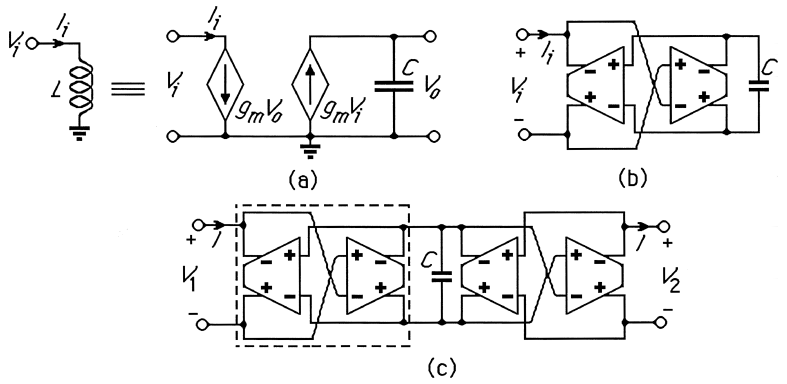

FIGURE 84.21 (a) Controlled-source realization of capacitively loaded gyrator to realize a grounded inductor; (b) differential g_m-C implementation; (c) a floating inductor requires two gyrators.

If a gyrator is loaded by a capacitor, $Z_{\text{load}}(s) = 1/(sC)$, the input impedance is proportional to frequency, i.e., it behaves like an inductor of value r^2C:

$$Z_{\text{in}}(s) = sr^2C = sL \tag{84.36}$$

Equation (84.35a) indicates that a gyrator can be interpreted as a connection of an inverting and a non-inverting transconductor of value $g_m = 1/r$ as shown in Fig. 84.21(a). This fact makes it very easy to build excellent gyrators with OTAs [see Figs. 84.21(b), and (c)], whereas it has been found quite difficult to obtain good gyrators with op amps. An exception is Antoniou's general impedance converter (GIC) [4, ch. 5], [9, ch.14.1]. However, it is useful only at relatively moderate frequencies (up to about 5 to 10 percent of the op amp's gain-bandwidth product);[11] also, the circuit contains resistors that are not voltage-driven and, therefore, cannot readily be translated into a MOSFET-C equivalent as was discussed previously. The availability of good gyrators provides us with a convenient method for building high-frequency integrated g_m-C ladder filters, which is based on inductor-replacement to be discussed in the section on element replacement methods.

Notice that the comments made earlier about the effects of parasitic capacitors also apply to inductor simulation: the parasitic input and output capacitors of the OTAs and the bottom-plate–to–substrate capacitances (Fig. 84.19) add to the capacitor used to set the value of the simulated inductor. For instance, using the same notation as in Fig. 84.19, the effective capacitor in Fig. 84.21(b) equals

$$C_{\text{eff}} = C + \frac{1}{2}\left(\frac{C_s}{2} + C_i + C_o\right) \tag{84.37}$$

where C_i is the parasitic capacitance at the input terminals of the OTA, see Fig. 84.15, and C is assumed to be split as in Fig. 84.19. Note also that a parasitic capacitor of value $C_{\text{in}} = C_i + C_o$ is measured across the inductor of Fig. 84.21(b) so that the inductor

$$L_{\text{eff}} = \frac{C_{\text{eff}}}{g_m^2} \tag{84.38}$$

[11]As stated, Antoniou's GIC is really an *impedance converter*, not a gyrator [see Eq. (83.63) and Fig. 83.17]. The GIC converts a load resistor into an inductive input impedance, rather than inverting a capacitor as described in (84.35b).

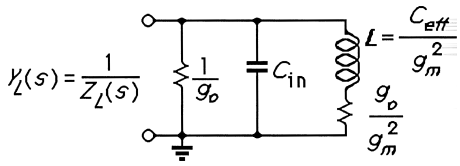

FIGURE 84.22 Passive equivalent circuit for the grounded inductor simulated in Fig. 84.21(b).

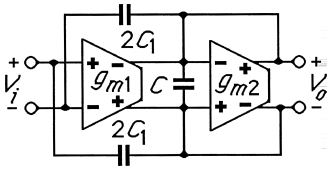

FIGURE 84.23 First-order g_m-C section.

has a self-resonance frequency[12]

$$\omega_0 = \frac{1}{\sqrt{L_{\text{eff}} C_{\text{in}}}} \tag{84.39}$$

Finally, to complete the inductor model, recall that the OTAs have finite differential output conductances,[13] g_o (see Fig. 84.15), which appear across the input and load terminals of the gyrator in Fig. 84.21(b). Consequently, the full inductive admittance realized by Fig. 84.21(b) equals

$$Y_L(s) = g_o + sC_{\text{in}} + \frac{g_m^2}{sC_{\text{eff}} + g_o} \tag{84.40}$$

to yield the equivalent circuit in Fig. 84.22 for the inductor L. The designer should keep this circuit in mind when using this method to develop a filter.

Evidently, the realized quality factor of the inductor equals $Q_L = \omega C_{\text{eff}}/g_o$. This means OTAs with large output resistance $r_o = 1/g_o$ are needed for high-quality inductor simulations.

Next we discuss first- and second-order g_m-C sections used as building blocks for the cascade approach to high-order filter design. As was the case for the MOSFET-C method, we will see that g_m-C sections are constructed by interconnecting integrators.

First- and Second-Order Sections

Consider the integrator in Fig. 84.18(a); we make it lossy by loading it with the resistor in Fig. 84.17(b). Let the input signals also be fed through capacitors into the integrator output nodes as shown in Fig. 84.23. The circuit is readily analyzed by writing Kirchhoff's current law at the output node to yield

$$\frac{V_o}{V_i} = -\frac{sC_1 + g_{m1}}{s(C_1 + C) + g_{m2}} \tag{84.41}$$

The circuit may realize any desired first-order function by choosing the appropriate values for the transconductances and the capacitors. For example, a low-pass can be obtained by setting $C_1 = 0$; a high-pass results from $g_{m1} = 0$ and possibly $C = 0$; and $C = 0$ and $g_{m1} = -g_{m2}$ results in an all-pass function.

[12]With modern submicron CMOS processes, the self-resonance frequency of electronic inductors can be as high as a few gigahertz with quality factors in the range of a few 100. See [11].

[13]As was mentioned, the input conductances can normally be neglected.

© 2003 by CRC Press LLC

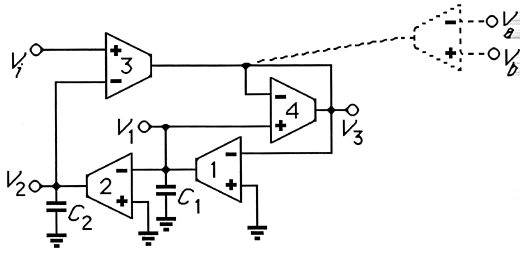

FIGURE 84.24 A general biquadratic g_m-C section.

A second-order block can be designed by interconnecting two integrators in a variety of feedback configurations. To keep the method more transparent, we show one such possibility in Fig. 84.24 with single-ended outputs. A differential structure is obtained by mirroring the circuit at ground and duplicating the appropriate components as was demonstrated in connection with Fig. 84.4. Let us disregard for now the dashed OTA with inputs V_a and V_b and apply an input signal V_i; writing the node equations for Fig. 84.24 we obtain

$$g_{m3}\left(V_i - V_2\right) + g_{m4}\left(V_1 - V_3\right) = 0 \qquad sC_1V_1 = -g_{m1}V_3 \qquad sC_2V_2 = -g_{m2}V_1 \tag{84.42}$$

By eliminating two of the three voltages V_1, V_2, or V_3 from these equations, we obtain the bandpass, low-pass, and high-pass functions, respectively,

$$\frac{V_1}{V_i} = H_{BP}(s) = \frac{-sC_2g_{m1}g_{m3}}{s^2C_1C_2g_{m4} + sC_2g_{m1}g_{m4} + g_{m1}g_{m2}g_{m3}} \tag{84.43a}$$

$$\frac{V_2}{V_i} = H_{LP}(s) = \frac{g_{m1}g_{m2}g_{m3}}{s^2C_1C_2g_{m4} + sC_2g_{m1}g_{m4} + g_{m1}g_{m2}g_{m3}} \tag{84.43b}$$

$$\frac{V_3}{V_i} = H_{HP}(s) = \frac{s^2C_1C_2g_{m3}}{s^2C_1C_2g_{m4} + sC_2g_{m1}g_{m4} + g_{m1}g_{m2}g_{m3}} \tag{84.43c}$$

In *any* electrical network, one can generate different numerator polynomials, i.e., different transmission zeros, without disturbing the poles, i.e., the system polynomial, by applying an input *voltage* to any node that is lifted off *ground*, or by sending an input *current* into any *floating* node. The second of these possibilities is illustrated in Fig. 84.24 in dashed form where a current $g_m(V_b - V_a)$ is sent into Node 3. We leave the analysis to the reader. We demonstrate the first possibility by applying V_i to the non-inverting terminals of OTA_1 and OTA_2, which are grounded in Fig. 84.24. The reader may show by routine analysis that lifting these two nodes off ground and then applying V_i to both of them (in addition to the original input) results in the complete biquadratic transfer function

$$\frac{V_3}{V_i} = \frac{s^2C_1C_2g_{m3} + sg_{m1}\left(C_2g_{m4} - C_1g_{m3}\right) + g_{m1}g_{m2}g_{m3}}{s^2C_1C_2g_{m4} + sC_2g_{m1}g_{m4} + g_{m1}g_{m2}g_{m3}} \tag{84.44}$$

with which, for example, a notch filter may be realized by setting $C_2g_{m4} = C_1g_{m3}$.

A great variety of second-order sections can be found in the literature, e.g., [9, ch. 16.3]. Many are designed for specific transfer functions rather than the general circuit in Fig. 84.24, and are often simpler and contain fewer OTAs. Readers are well advised to scan the available literature for the best circuit for their applications.

Cascade Realizations

Apart from modularity and simple design methods, the main advantage of the cascade approach is its generality: a cascade structure can realize a transfer function with arbitrary zero locations, whereas simulations of lossless *LC ladders* discussed below are restricted to $j\omega$-axis transmission zeros. Implementing a prescribed transfer function by the cascade method with g_m-C integrated filters follows the same principles that were discussed in Chapter 83 for discrete active *RC* filters and leads to the filter structure in Fig. 84.9. The difference lies only in the final realization of the sections in monolithic form. We demonstrate the principle with the example of a high-frequency filter for the read/write channel of a magnetic disk storage system,[14] where the most critical specification is constant delay, i.e., linear phase. To this end, let us discuss the design of a seventh-order cascade low-pass with a constant delay approximated in the Chebyshev (equiripple) sense. The specifications call for a delay variation of maximally 1 ns over the passband and a bandwidth $f_c = 10$ MHz. The transfer function to be implemented is

$$H_7(s) = \frac{K_0\left(s^2 - \sigma_z^2\right)}{\left(s+\sigma\right)\left(s^2 + s\frac{\omega_1}{Q_1} + \omega_1^2\right)\left(s^2 + s\frac{\omega_2}{Q_2} + \omega_2^2\right)\left(s^2 + s\frac{\omega_3}{Q_3} + \omega_3^2\right)} \tag{84.45}$$

with the required parameters given in Table 84.2. The purpose of the symmetrical pair of zeros at $\pm\sigma_z$ is magnitude equalization to effect a gain boost for pulse slimming. Note that these zeros do not affect the phase or the delay because the factor $(\omega^2 + \sigma_z^2)$ is real on the $j\omega$ axis. The fully differential second-order circuit chosen for the low-pass sections is shown in Fig. 84.25a. Simple analysis shows that it realizes the function

$$H_{LP}(s) = \frac{V_{LP}}{V_i} = \frac{g_{m1}g_{m2}}{s^2C_1C_2 + sC_1g_{m2} + g_{m1}g_{m2}} = \frac{\omega_0^2}{s^2 + s\omega_0/Q_0 + \omega_0^2} \tag{84.46}$$

where

[14] A similar commercially successful design in bipolar technology is discussed in [1].

© 2003 by CRC Press LLC

$$\omega_0 = \sqrt{\frac{g_{m1}g_{m2}}{C_1C_2}} \tag{84.47a}$$

and

$$Q_0 = \sqrt{\frac{g_{m1}C_2}{g_{m2}C_1}} \tag{84.47b}$$

are the pole frequency and pole quality factor, respectively. There remains the question of how to obtain the two real transmission zeros at $\pm\sigma_z$. For this purpose we recall that the zeros of a transfer function can be changed without destroying the poles by feeding the input signal or a fraction thereof into any of the ground nodes lifted off ground. For the situation at hand this can be accomplished by lifting the capacitors $2C_2$ in the low-pass off ground and feeding KV_i with the appropriate polarity into the terminals so generated. Figure 84.25(b) shows the resulting circuit, which may be analyzed to yield the transfer function

$$\frac{V_o}{V_i} = \frac{-Ks^2C_1C_2 + g_{m1}g_{m2}}{s^2C_1C_2 + sC_1g_{m2} + g_{m1}g_{m2}} \tag{84.48}$$

with the zero at $\sigma_z = \pm\omega_0K^{-1/2}$. Observe that the two transconductors labeled g_{m1} and g_{m2}, respectively, have common output terminals; they can, therefore, be merged into one double-input transconductor each as discussed in connection with Fig. 84.16(c). Further, we need the circuit in Fig. 84.23 with $C_1 = 0$ to realize a first-order section, a lossy integrator with the function

$$\frac{V_o}{V_i} = -\frac{g_{m1}}{sC + g_{m2}} \tag{84.49}$$

Finally, we must determine the component values. To this end we compute from (84.47) and (84.49) the relationships

$$C_1 = \frac{g_m}{\omega_iQ_i} = \frac{12.5}{\omega_iQ_i}\ \text{pF}; \quad C_2 = g_m\frac{Q_i}{\omega_i} = 12.5\frac{Q_i}{\omega_i}\ \text{pF};$$
$$C = \frac{g_m}{\sigma} = \frac{12.5}{\sigma}\ \text{pF}; \quad K = \left(\frac{\omega_1}{\sigma_z}\right)^2 \tag{84.50}$$

where we used that ω_i in Table 84.2 was normalized by a factor 10^7s^{-1} and we assumed for simplicity that all OTAs have the same transconductance values,[15] $g_{m1} = g_{m2} = g_m = 125\ \mu\text{S}$. Lastly, to illustrate the need to account for parasitics, we observe that in Fig. 84.25 the capacitor C_1 is paralleled by $2C_o$ and $1C_i$, and the capacitor C_2 by $2C_o$ and $3C_i$. The third input capacitor in parallel with C_2 is arrived at by the fact that each biquad must drive the next biquad in the cascade connection and there sees an OTA input. The capacitor C in Figure 84.23 is in parallel with $2C_o$ and $1C_i$. To arrive at numerical values we will assume $C_o = 0.09$ pF and $C_i = 0.04$ pF. Consequently, the capacitor values are obtained from (84.50) as

$$C_1 = \frac{12.5}{\omega_iQ_i}\ \text{pF} - 0.22\ \text{pF}; \quad C_2 = 12.5\frac{Q_i}{\omega_i}\ \text{pF} - 0.3\ \text{pF}; \quad C = \frac{12.5}{\sigma}\ \text{pF} - 0.22\ \text{pF} \tag{84.51}$$

[15]This assumption is for convenience of design and layout because it permits a given transconductance cell to be used throughout the circuit. However, using different transconductance values in different sections has the advantage that capacitor values may be equalized, since by (85.50) the capacitors are proportional to g_m.

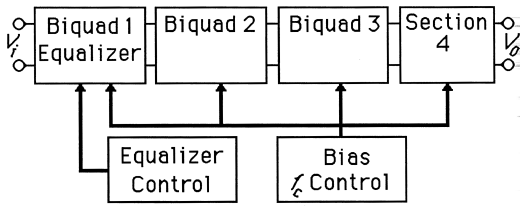

FIGURE 84.26 Structure of the seventh-order low-pass filter including control circuitry.

Table 84.3 contains the computed capacitor values and Fig. 84.26 shows the final cascade block diagram with the equalizer section leading and the first-order low-pass at the end. The two control blocks are necessary to be able to tune the filter electronically: the gain K is varied via the *Equalizer Control* block to set the position of the zeros and thereby the amount of gain boost, i.e., pulse slimming. Electronic tuning of the frequency parameter g_m/C is accomplished via adjusting the bias currents of the OTAs by the block labeled *Bias* f_c *Control*. Thereby uncontrollable changes in the value g_m/C due to process variations or temperature can be accounted for. Details of such a control scheme are discussed in Section 84.4.

Ladder Simulations

As mentioned earlier, the main reason for using the popular *LC* ladder simulation method for filter design is the generally lower passband sensitivity of this topology to component tolerances [4, ch. 3], [9. ch. 13], see also Chapter 75. As before, the procedures are, in principle, identical to those discussed in connection with discrete circuits and are best illustrated with the help of a generic example. Let us consider again the classical ladder structure in Fig. 84.11, which realizes the fifth-order elliptic low-pass characteristic (84.21) and is described by (84.22). Two methods are available to simulate the ladder. The first and most intuitive method replaces the inductors L_2 and L_4 by capacitively loaded gyrators (Fig. 84.21). The second method recognizes that the inductors and the grounded capacitors in Fig. 84.11 perform the function of integration. This signal-flow graph method is completely analogous to the process discussed earlier in Chapter 83 and for MOSFET-*C* filters, and will be presented in the section on signal-flow graph methods. We point out here that the element replacement and the signal-flow graph methods lead to the same circuitry [9, ch. 16.4] so that either method can be used at the designer's convenience.

Element Replacement Methods

Replacing the inductors L_2 and L_4 in Fig. 84.11 by capacitively loaded gyrators and using differential balanced circuitry leads to the circuit in Fig. 84.27(a). It is obtained by first converting the voltage source to a current source (Norton transformation), which also converts the series source resistor R into a shunt resistor. The first OTA in Fig. 84.27(a) performs the source transformation, the second OTA is the grounded resistor. Since the two inductors are floating, the implementation of each requires two gyrators, i.e., four OTAs [see Fig. 84.21(c)]. Note that all OTAs are identical, and that all capacitors except C_2 and C_4 could be grounded; for example, instead of connecting C_1 *between* nodes A and B in Fig. 84.27(a),

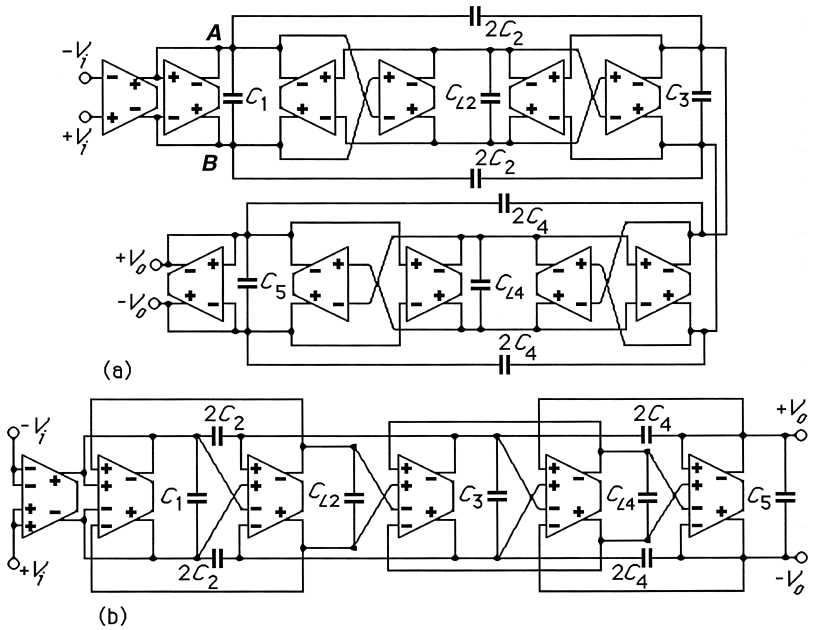

FIGURE 84.27 (a) Transconductor-*C* simulation by the element replacement method of the fifth-order elliptic low-pass ladder in Fig. 84.11, including source and load resistors. All g_m-cells are identical. Note that the floating inductors require two gyrators for implementation. (b) The circuit with dual-input OTAs.

capacitors of value $2C_1$ could be connected from *both* nodes *A* and *B* to ground. Comparing the active circuit with the *LC* prototype readily identifies both structure[16] and components. The element values are obtained directly from the prototype *LC* ladder, e.g., from published tables, such as [8], or from appropriate synthesis software. Labeling for the moment the normalized components in the prototype *LC* ladder by the subscript *n*, i.e., R_n, $C_{i,n}$, and $L_{i,n}$, the transformation into the real component values with units of [F] and [H] is achieved by the following equations:

$$R = \frac{R_n}{g_m}, \quad C_i = C_{i,n}\frac{g_m}{\omega_c}, \quad L_i = L_{i,n}\frac{1}{g_m\omega_c} = \frac{C_{Li}}{g_m^2} \rightarrow C_{Li} = L_{i,n}\frac{g_m}{\omega_c} \tag{84.52}$$

g_m is the transconductance value chosen by the designer, ω_c is the normalizing frequency (usually the specified passband corner frequency), and R_n is in most prototype designs normalized to $R_n = 1$. Naturally, as discussed earlier, all capacitor values must be predistorted to account for the parasitic capacitors appearing at the capacitor nodes. For example, note that C_{L2} is paralleled by two OTA input and two OTA output capacitors, and for symmetrical layout (Fig. 84.19), by $0.25C_s$. We see that the element replacement method is a very straightforward design process; it has been found to work very well in practice.

Figure 84.27(b) shows the same circuit but realized with dual-input OTAs [Fig. 84.16(c)]. As was pointed out earlier, this merging of OTAs can always be used when two (or more) OTAs share a common output node. It results in simplified circuitry, and possibly reduced power consumption and chip area. In such cases, only the linearized input stages of the OTA must be duplicated, but bias, output, and common-mode rejection circuitry can be shared. Observe also that the input voltage is applied to both inputs of the first dual-input OTA in Fig. 84.27(b), thereby doubling its value of g_m. This multiplies the transfer function by a factor of two and eliminates the 6-dB loss inherent in the *LC* ladder (see Fig. 84.12).

[16]The number of floating capacitors is of course doubled because of the balanced differential structure of the active implementation.

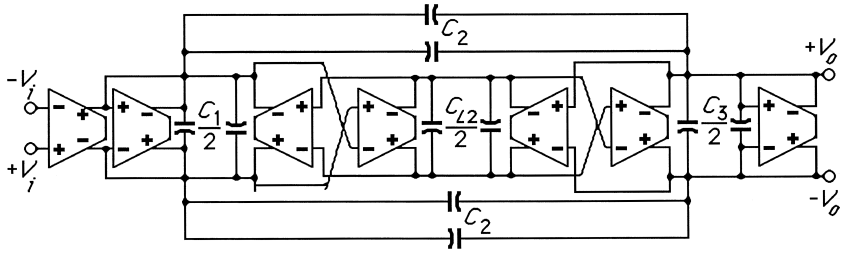

FIGURE 84.28 (a) Realization of the third-order elliptic low-pass ladder of (84.53). The capacitor values indicated refer to *each* of the pair of capacitors.

A small example will show the design process. For an antialiasing application we need to realize a third-order elliptic low-pass filter with f_c = 10 MHz bandwidth, 0.5-dB passband ripple, 17.5-MHz stopband edge, and 23-dB stopband attenuation. It leads to the transfer function [8]

$$H(s)=\frac{0.28163\left(s^2+3.2236\right)}{\left(s+0.7732\right)\left(s^2+0.5016s+1.1742\right)} \tag{84.53}$$

and the normalized element values $R_n = 1$, $C_{1n} = C_{3n} = 1.293$, $C_{2n} = 0.3705$, and $L_{2n} = 0.8373$. The topology is as in Fig. 84.11 with $C_{4n} = L_{4n} = C_{5n} = 0$. Figure 84.28 shows the active circuit. Observe that we have realized each of the floating capacitors C_j as $0.5C_j + 0.5C_j$, j = 1, 2, 3, $L2$, with inverted bottom-plate connections. This design choice preserves symmetry in the balanced differential layout by placing the unavoidable substrate capacitors of value $\approx 0.1 \times (0.5C_{L2})$ *at each* of the upper and lower nodes of C_{L2} and $\approx 0.1 \times (0.5C_k + 0.5C_2)$ at the upper and lower nodes of C_k, k = 1, 3. Choosing the value of transconductance as $g_m \approx 180$ μS, using (84.51), $\omega_c = 2\pi \cdot 10 \cdot 10^6$ s^{-1}, and observing the necessary predistortion for the *differential* parasitic OTA input and output capacitors, $C_i = 0.03$ pF and $C_o = 0.08$ pF, respectively, and for the bottom-plate capacitors C_s assumed to be 10% of the corresponding circuit capacitor value, results in

$$\begin{aligned}
C_1 &= C_{1n}\frac{g_m}{\omega_c}-3C_o-2C_i-0.1\,\frac{1}{2}\left(C_2+\frac{C_1}{2}\right)=3.191\text{ pF}\\
C_2 &= C_{2n}\frac{g_m}{\omega_c}=1.061\text{ pF}\\
C_3 &= C_{3n}\frac{g_m}{\omega_c}-2\left(C_o+C_i\right)-0.1\left(\frac{C_2}{2}+\frac{C_3}{4}\right)=3.268\text{ pF}\\
C_{L2} &= L_{2n}\frac{g_m}{\omega_c}-2\left(C_o+C_i\right)-0.1\frac{C_L}{4}=2.120\text{ pF}
\end{aligned} \tag{84.54}$$

Notice that in a ladder structure all parasitic capacitors can be absorbed in the circuit capacitors. Consequently, no new parasitic poles or zeros are created that might destroy the transfer function shape. This is a further important advantage of the ladder-simulation method for g_m-C filters.

Signal-Flow Graph Methods

As we have seen earlier, the signal-flow graph (SFG) or operational-simulation method takes the circuit equations describing the ladder (Kirchhoff's laws and the I-V relationships for the elements) and realizes them directly via summers (for Kirchhoff's laws) and integrators (for inductors and grounded capacitors). The procedure was detailed in connection with Eqs. (84.22)–(84.24). Recall that (84.23) represents *integrations* of voltages into currents and currents into voltages. As was the case for the op amp–based

© 2003 by CRC Press LLC

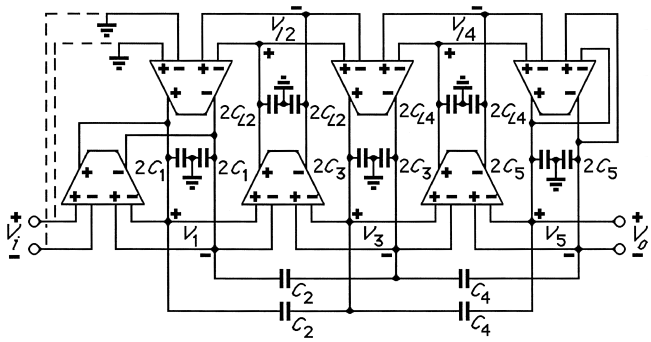

FIGURE 84.29 Signal-flow graph g_m-C realization of a fifth-order elliptic low-pass function. The circuit is an active simulation of the *LC*-ladder in Fig. 84.11, including source and load resistors. All g_m-cells are identical.

active *RC* filters in Chapter 83 and the MOSFET-*C* design, all signals in the SFG g_m-C circuit are voltages. They are summed at the OTA inputs, then are multiplied by g_m to produce an output current that is integrated by a capacitor to produce a voltage as input for the OTA of the next stage. To reflect these facts in the relevant equations, we scale (84.23) analogously to (84.24) to obtain:

$$\frac{I_{L2}}{g_m} = \frac{g_m\left(V_1 - V_3\right)}{s\left(L_{2n}g_m\right)g_m}; \quad \frac{I_{L4}}{g_m} = \frac{g_m\left(V_3 - V_5\right)}{s\left(L_{4n}g_m\right)g_m} \tag{84.55a}$$

$$V_1 = \frac{g_m V_i - \left(I_{l2}/g_m\right)g_m + sC_{2n}V_3}{s\left(C_{1n} + C_{2n}\right) + g_m} \tag{84.55b}$$

$$V_3 = \frac{\left(I_{L2}/g_m\right)g_m - \left(I_{L4}/g_m\right)g_m + sC_{2n}V_1 + sC_{4n}V_5}{s\left(C_{2n} + C_{3n} + C_{4n}\right)} \tag{84.55c}$$

$$V_5 = V_o = \frac{\left(I_{L4}/g_m\right)g_m + sC_{4n}V_3}{s\left(C_{4n} + C_{5n}\right) + g_m} \tag{84.55d}$$

The scaling factor in this case is the design transconductance g_m. Note that $L_i g_m^2$ in (84.55a) has units of capacitance and that source and load resistors in (84.55b) and (84.55d) have the value $1/g_m$. Implementing these equations with lossless or lossy, as appropriate, integrators in fully differential form results in the circuit in Fig. 84.29, where we used a signal notation similar to that in Fig. 84.14 and chose all integrating capacitors grounded. Starting from a normalized *LC* prototype, the actual component values are obtained again via (84.52). Note that the OTA at the input performs the voltage-to-current conversion (V_i to I_1) and that the last OTA both here and in Fig. 84.27 implements the load resistor. The second OTA in Fig. 84.27, realizing the source resistor, is saved in Fig. 84.29 by sending the current I_1 directly into the integrating node (the capacitor C_1), as suggested by (84.55b).[17] Also observe that circuit complexity in Fig. 84.29 was kept low by resorting to OTAs with dual inputs. We note again that all transconductors in Figs. 84.27–84.29 are identical[18] so that a single optimized g_m-cell (an *analog gate*) can be used throughout the filter chip for an especially simple IC design process, analogous to that of a gate array.

[17]Had we used this "resistor," the current into the integration node would have been realized as $g_m V_i = g_m V_i \times (1/g_m) \times g_m$, clearly a redundant method.

[18]This can generally be achieved in g_m-C ladder simulations; the only exception occurs for those *LC* ladders that require unequal terminating resistors, such as even-order Chebyshev filters; in that case, one of the transconductors will also be different.

© 2003 by CRC Press LLC

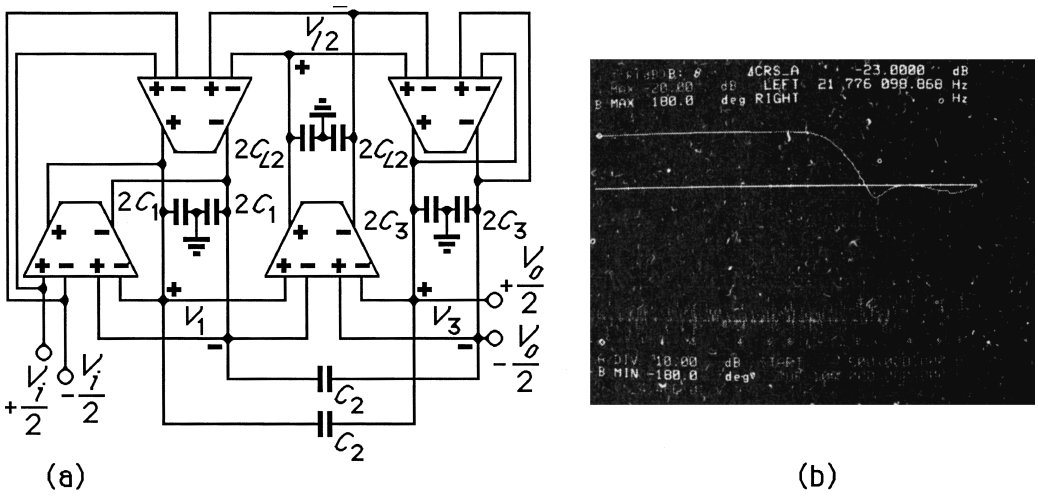

FIGURE 84.30 (a) SFG g_m-C third-order elliptic low-pass filter; (b) experimental performance in 2-μm CMOS technology.

The inherent 6-dB loss of the *LC* ladder can also be eliminated, if desired, by lifting the two grounded inputs of the second OTA in Fig. 84.29 off ground and connecting them to the input voltage $\pm V_i/2$ as indicated by the dashed connections.

As a simple design example, consider again the realization of the third-order elliptic low-pass filter described by (84.53). The nominal *LC* elements were given earlier; the circuit is described by (84.55) with $C_{4n} = C_{5n} = L_{4n} = 0$, i.e.,

$$\frac{I_{L2}}{g_m} = \frac{g_m(V_1 - V_3)}{s(L_{2n}g_m)g_m} \tag{84.56a}$$

$$V_1 = \frac{2g_mV_i - (I_{L2}/g_m)g_m + sC_{2n}V_3}{s(C_{1n} + C_{2n}) + g_m} \tag{84.56b}$$

$$V_3 = V_o = \frac{(I_{L2}/g_m)g_m + sC_{2n}V_1}{s(C_{2n} + C_{3n}) + g_m} \tag{84.56c}$$

which leads to the circuit in Fig. 84.30(a), as the reader may readily verify. Note the connection of the input, which realizes the term $2g_mV_i$ in (84.56b) and eliminates the 6-dB loss as mentioned earlier. We observe again that the capacitors must be predistorted to account for parasitics as was discussed in connection with (84.54); specifically, labeling as before the *differential* OTA input and output capacitors as C_i and C_o, respectively, we find

$$C_1 \approx C_{1,\text{ nominal}} - 2C_o - 2C_i;\quad C_{L2} \approx C_{L2,\text{ nominal}} - C_o - 2C_i;\quad C_3 \approx C_{3,\text{ nominal}} - C_o - 2C_i$$

Figure 84.30(b) shows the experimental performance of the circuit fabricated in 2-μm CMOS technology with design-automation software that uses the OTAs from a design library as "analog gates," and *automatically* lays out the chip and predistorts the capacitors according to the process file. The transconductance value used is $g_m \approx 180$ μS, and the capacitors are approximately the same as the ones for the example in Fig. 84.28. We will see in Section 84.5 that apart from differences due to layout parasitics, it is no coincidence that the element values are essentially the same as before. Notice that the filter meets all design specifications. The lower trace is the thermal noise at ≈70 dB below the signal; the measured total harmonic distortion was THD <1% for a 2-$V_{p\text{-}p}$ input signal at 3 MHz.

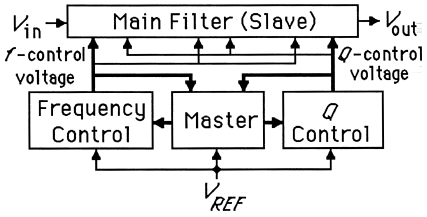

FIGURE 84.31 Block diagram of Master-Slave control system for integrated *c-t* filters.

84.4 Tuning

To obtain accurate filter performance with frequency-parameters set by *RC* products or C/g_m ratios, accurate *absolute* values of components are required. These must be realized by the IC process *and maintained during operation*. Although IC processing is very reliable in realizing accurate *ratios* of like components on a chip, the processing tolerances of *absolute values* must be expected to be of the order of 20 to 50% or more. Component tolerances of this magnitude are generally far too large for an untuned filter to perform within specifications. Consequently, filters *must be tuned* to their desired performance by adjusting element values. Clearly, in fully integrated filters, where all components are on a silicon chip, tuning must be performed electronically by some suitably designed automatic control circuitry that is part of the total continuous-time filter system. Tuning implies *measuring* filter performance, *comparing* it with a known standard, *calculating* the errors, and *applying a correction* to the system to reduce the errors. An accurate *reference frequency*, e.g., a system clock (V_{REF} in Fig. 84.31), is usually used as a convenient standard. From the filter's response to the signal at this known frequency, errors are detected and the appropriate correction signals, typically dc bias voltages, are applied via the control circuitry [4, ch. 7], [9, ch. 16.5]. Reference [5, pt. 6] contains many papers showing practical approaches to specific tuning problems.

Figure 84.31 shows a block diagram of this so-called "Master-Slave" architecture that is followed by most currently proposed designs. The Master-Slave system is used because the reference signal, V_{REF}, cannot be applied to the Main Filter simultaneously with the main signal, V_{in}, because of undesirable interactions (intermodulation) between V_{in} and V_{REF}. The approach is based on the premise that the filter must operate continuously, i.e., that V_{in} cannot be switched off occasionally to permit tuning in a signal-free environment. Therefore, V_{REF} is applied to a circuit, the "Master" filter, that is carefully designed to model the relevant behavior of the "Slave." Master-Slave design and layout require great care to avoid serious matching, noise, and crosstalk problems.

Figure 84.31 should help the reader understand the principle of the operation without having to consider the actual circuitry that is very implementation-specific, see [5, pt. 6] for design examples. The Main Filter (the "Slave") performs the required signal processing. Since the Master is designed to model the Slave, the behaviors of Master and Slave are assumed to match and track. Tuning is then accomplished by applying the generated correction or control signal simultaneously to both Master and Slave. The system contains a *Frequency-Control* block that detects frequency-parameter errors in the Master's response to the reference signal and generates a frequency-control voltage that is applied to the Master in a closed-loop control scheme such that any detected errors are minimized.[11] Since the Master is designed to be an accurate model of the Slave, their errors, too, can be assumed to match and track.

[11]In the designs reported to date, frequency-control blocks built around some type of phase-locked loop scheme, using a multiplier or an EXOR gate as phase detector, have been found most successful, but magnitude-locking approaches similar to those employed for Q control have also been used. A largely digital approach to frequency and Q tuning is discussed in [13].

© 2003 by CRC Press LLC

Consequently, when the frequency-control voltage is applied at the appropriate locations to the Slave, it can be expected to correct any frequency errors in the main filter.

The purpose of the additional block in Fig. 84.31, labeled *Q-Control*, is to tune the *shape* of the transfer characteristic. Once the frequency parameters are correct as tuned by the *f*-control loop, the transfer function shape is determined only by the quality factors Q_i of the poles and zeros. *Q*, as a ratio of two frequencies, is a *dimensionless* number and as such is determined by a *ratio* of like components [resistor-, capacitor-, and/or g_m-ratio; see e.g., (84.47b)]. *At fairly low frequencies and moderate values of Q,* the quality factor is realizable quite accurately in an IC design. For high-frequency, high-*Q* designs, however, *Q* is found to be a very sensitive function of parasitic elements and phase shifts so that it is unreasonable to expect *Q* to turn out correctly without tuning. Therefore, including for generality a *Q*-Control block[20] permits automatic tuning of the transfer function shape by a scheme that is completely analogous to the *f*-control method, as illustrated in Fig. 84.31.

With few exceptions, all currently proposed automatic tuning schemes follow the Master-Slave approach. A different concept proposed in [2] uses adaptive techniques to tune all poles *and* zeros of a filter function for improved tuning accuracy. Although the Master-Slave and the adaptive techniques work well, generally, the necessary circuitry has been found to be too large, noisy, and power hungry for many practical applications. Thus, alternative choices use a simple post-fabrication trim step[21] to eliminate the large fabrication tolerances, possibly together with careful design to make the electronic devices (OTAs) independent of temperature variations [1], [3].

We also point out that at the highest frequencies, higher than, say, 100 MHz, circuit capacitors to realize the prescribed frequency parameters, g_m/C, become very small ($C \approx 0.15$ pF at 100 MHz and $g_m =$ 100 μS). Filter behavior is then essentially determined by parasitics, and matching required between Master and Slave circuitry is unreliable. In that case, a form of direct tuning [5, paper 6.4] must be used, where the main filter is tuned during time periods when the signal is absent. The system is essentially as depicted in Fig. 84.31, except that the Master is absent and V_{REF} is applied to the main filter. When tuning is complete (taking a few milliseconds), V_{REF} is turned off, V_{in} is again applied to the filter, and the generated dc control signals are held on a capacitor until the next tuning update.

84.5 Discussion and Conclusions

In this chapter we discussed one of the fastest growing research and development areas in the topic of continuous-time filters, the field of fully integrated filters. Growing pressures to reduce costs and size, and improve reliability lead to increasingly larger parts of electronic systems being placed onto integrated circuits, a trend that *c-t* filters need to follow. As might have been expected, in most respects the methods for IC *c-t* filter design are identical to well-known active *RC* techniques, and follow directly the well-understood and proven standard active *RC* biquad-cascade or ladder-simulation methodologies. The difference lies in the final implementation, which the designer may adapt to any IC process and power supply level appropriate for the implementation of the system. Signal-to-noise ratios of the order of 65 to 80 dB and better, and distortion levels of less than 0.5% at signal levels of 1 V are obtainable. The two most prominent design approaches are the MOSFET-*C* and the g_m-*C* methods, both of which lead to easy and systematic designs and result in filters that have proven themselves in practice. At the time of this writing, g_m-*C* filters appear to have the edge in high-frequency performance: with OTA bandwidths reaching gigahertz frequencies even for CMOS technology, *c-t* filters can be designed readily for applications in the range of several 100 MHz, i.e., to about 40 to 60% of the active-device bandwidth. A second important difference that requires the designer's attention is that the IC filter must be automatically

[20]Because magnitude errors can be shown in many cases to be proportional to errors in quality factor, the *Q*-Control block is normally implemented around an amplitude-locking scheme, where the filter's magnitude response at a given frequency is locked to a known reference level.

[21]For example, an on-chip laser-trimmed resistor or an external resistor set to determine the bias for OTAs. It works for applications with very low quality factors or where no component drifts are expected during operation.

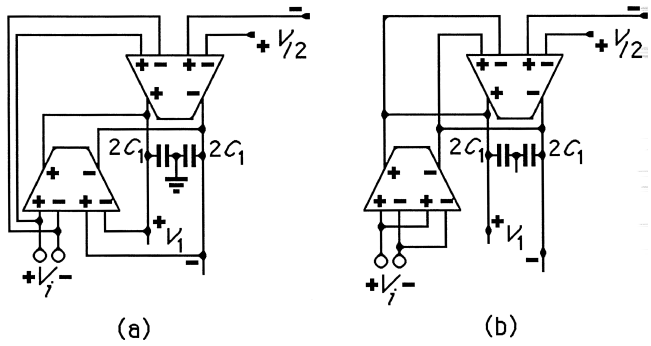

FIGURE 84.32 Excerpt from Fig. 84.28 (a) to illustrate alternative wiring (b) at the filter input 0.

tunable. This implies electronically variable components, OTAs or MOSFET "resistors," in the filter and some automatic control scheme for detecting errors and providing adjustments. Only area- and power-efficient designs, and simple low-noise circuitry for such tuning schemes will be acceptable and guarantee the ultimate commercial success of integrated filters. At the present time, many approaches have been proposed that the reader may modify or adapt to his/her system [5].

We point out again that the cascade design is the more general procedure because it permits the realization of arbitrary transmission zeros anywhere in the complex *s*-plane, as required, for example, in gain or phase equalizers. Lossless ladders, on the other hand, are more restrictive because their transmission zeros are constrained to lie on the $j\omega$ axis, but they have lower passband sensitivities to component tolerances than cascade filters. Since good gyrators are readily available for g_m-C filters — in contrast to MOSFET-C designs — two competing implementation methods appear to suggest themselves in the g_m-C approach: the signal-flow graph and the element-substitution methods. As mentioned, there is in fact no discernible difference between the two methods; indeed, they lead to the same structures. For instance, the reader may readily verify that apart from a minor wiring change at the inputs, the circuits in Figs. 84.27(b) and 84.29 are identical, as are the ones in Figs. 84.28 (after redrawing it for dual-input OTAs) and 84.30. The wiring change is illustrated in Fig. 84.32. Figure 84.32(a) shows the input section of Fig. 84.29 (wired for 0-dB dc gain) and the wiring in Fig. 84.32(b) is that of Fig. 84.27(b). Notice that both circuits realize

$$\left(sC_1 + g_m\right)V_1 = 2g_m V_i - g_m V_{I2} \tag{84.57}$$

The designer, therefore, may choose a ladder method based on his/her familiarity with the procedure, available tables, or prototype designs; the final circuits are the same.

A further item merits reemphasizing at this point: As the reader may verify from the examples presented, g_m-C ladder structures generally have at all circuit nodes a design capacitor that can be used to absorb parasitics by predistortion as was discussed earlier. It may be preferable, therefore, to avoid the g_m-C–op amp integrator of Fig. 84.20 with its increased noise level, power consumption, and with its associated parasitic poles (and zeros) and use parasitics-absorption as we have done in our examples. This method will *not* introduce any new parasitic critical frequencies into the filter and result in lower distortion of the transfer function shape and easier tuning. As we mentioned earlier, this feature is a substantial advantage of g_m-C ladder filters.

85.1 Introduction

The need to have monolithic analog filters motivated circuit designers in the late 1970s to investigate alternatives to conventional active-RC filters. A practical alternative appeared: switched-capacitors (SC) filters [1]-[3]. The original idea was to replace a resistor by a switched capacitor simulating the resistor. Thus, this equivalent resistor could be implemented with a capacitor, and two switches operating with two-clock phases. SC filters consist of switches, capacitors, and op-amps. They are characterized by difference equations in contrast to differential equations for continuous-time filters. Simultaneously, the mathematical operator to handle sample-data systems such as switched-capacitor circuits is the *z*-transform, while the Laplace transform is used for continuous-time circuits. Several key properties of SC circuits have made them very popular in industrial environments:

1. Reduced silicon area, since the equivalent of large resistors can be simulated using small-size capacitors. Furthermore, positive and/or negative equivalent resistors can be easily implemented with SC techniques.
2. The time constants (RC products) from active-RC filters become capacitor ratios multiplied by the clock period *T*. That is

$$RC \Rightarrow \frac{C}{C_R} T = \frac{C}{C_R f_C}$$

where f_c is the clock frequency.

© 2003 by CRC Press LLC

3. The above expression can be realized in real applications with a good accuracy of nearly 0.1%.
4. Typically, the load of an SC circuit is mainly capacitive; therefore the required op-amps do not require a low-impedance output stage. This allows the use of a single-stage operational transconductance amplifier, which is especially useful in high-speed applications.
5. SC filters can be implemented in digital circuit process technologies. Thus, useful mixed-mode signal circuits can be economically realized.
6. The SC design technique has matured. In the audio range, SC design techniques have became the dominant design approach. Furthermore, many circuits in communication applications and data converters use SC implementations.

In what follows, we discuss basic building blocks involved in low- and high-order filters. Limitations and practical considerations are presented. Furthermore, due to the industrial push for lower power supply voltages, a brief discussion on low-voltage circuit design is included.

85.2 Basic Building Blocks

The basic building blocks involved in SC circuits are voltage gain amplifiers, integrators, and second-order filters. A key building block is the integrator. By means of a two-integrator loop, a second-order (biquadratic) filter can be realized. Furthermore, a cascade connection of biquadratic filters yields higher order filters.

Gain Amplifiers

The gain amplifier is a basic building block in switched-capacitor circuits. Both the peak gain of a second-order filter and the link between the resonators in a ladder filter are controlled by voltage amplifier stages rather than by integrators. Many other applications such as pipeline data converters require voltage gain stages. A voltage amplifier can be implemented by using two capacitors and an operational amplifier, as shown in Fig. 85.1(a). Ideally, the gain of this amplifier is given by $-C_S/C_I$. This topology is compact, versatile, and time continuous. Although this gain amplifier is quite simple, several second-order effects present in the op-amp make its design more complex. A major drawback of this topology is the lack of dc feedback.

For dc, the capacitors behave as open circuits, hence the operating point of the operational amplifier is not stabilized by the integrating capacitor C_I. In addition, the leakage current present at the input of the op-amp is integrated by the integrating capacitor, whose voltage eventually saturates the circuit. The leakage current I_{leak} in switched-capacitor circuits is a result of the diodes associated with the bottom plate of the capacitors and the switches (drain and source junctions). The leakage current is typically about 1 nA/cm^2. Analysis of Fig. 85.1(a) considering the leakage current I_{leak} yields

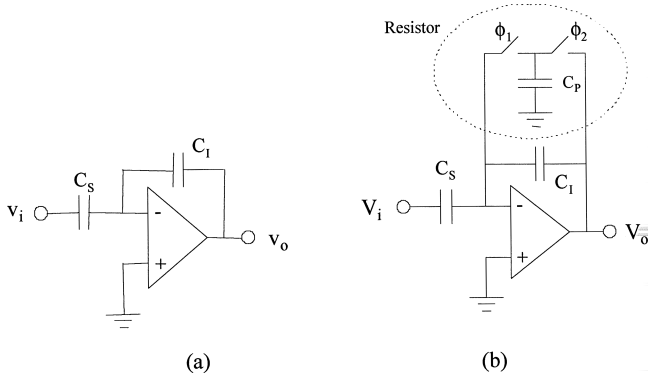

FIGURE 85.1 Voltage amplifiers. (a) Without dc feedback and (b) with dc feedback.

© 2003 by CRC Press LLC

$$v_o(t) = v_o(t_o) - \frac{C_S}{C_I} V_i(t) - \frac{I_{\text{leak}}}{C_I}(t - t_o) \tag{85.1}$$

Note that the dc output voltage is defined by the input signal and the initial conditions at $t = t_o$. In addition, the leakage current present at the input of the op-amp is integrated by C_I and eventually saturates the circuit. To overcome this drawback, a switched-capacitor resistor can be added as shown in Fig. 85.1(b). The switched-capacitor resistor gives a dc path for the leakage current but reduces further the low-frequency gain. A detailed analysis of this topology shows that the dc output voltage is equal to $-I_{\text{leak}}T/C_p$, with C_p the parasitic capacitor associated with the feedback path. However, using typical analysis method for switched-capacitor networks, it can also be shown that the z domain transfer function of this topology is

$$H(z) = \frac{V_o(z)}{V_i(z)} = -\frac{C_S}{C_I} \frac{1 - z^{-1}}{1 - \left(1 - \frac{C_p}{C_I}\right) z^{-1}} \tag{85.2}$$

with $z = e^{j2\pi fT}$. For low frequencies, $z \approx 1$, the transfer function is very small, and only for high frequencies, $z \approx -1$, the circuit behaves as an inverting voltage amplifier.

An offset free voltage amplifier is shown in Fig. 85.2. During the clock phase ϕ_2, the output voltage is equal to the op-amp offset voltage and it is sampled by both the integrating and sampling capacitors. Because of the sampling of the offset voltage during the previous clock phase, during the integrating clock phase the charge injected by the sampling capacitor is equal to $C_S V_I$, and the charge extracted from the integrating capacitor becomes equal to $C_I V_o$. In this case, the offset voltage does not affect the charge recombination, and z domain transfer function, during the clock phase ϕ_1, becomes

$$H(z) = -\frac{C_S}{C_I} \tag{85.3}$$

Equation (85.3) shows that ideally this topology is insensitive to the op-amp offset voltage. The topology behaves as an inverting amplifier if the clock phases shown in Fig. 85.2 are used. A noninverting amplifier is obtained if the clock phases associated with the sampling capacitor are interchanged. Because during ϕ_2 the op-amp output is short-circuited with the inverting input, this topology presents two drawbacks. First, the amplifier output is only available during the clock phase ϕ_1. This limitation could be important

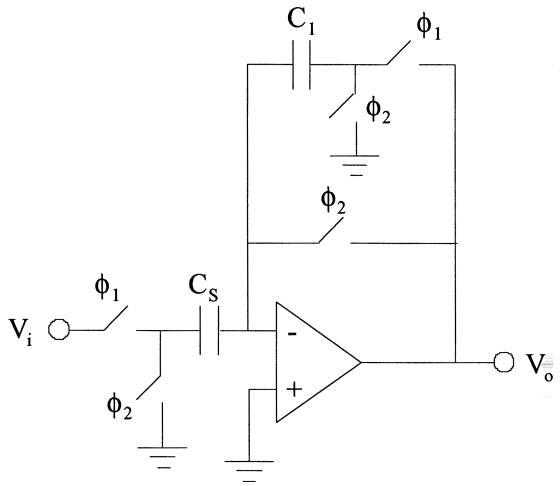

FIGURE 85.2 Voltage amplifier available during the ϕ_1 clock phase.

© 2003 by CRC Press LLC

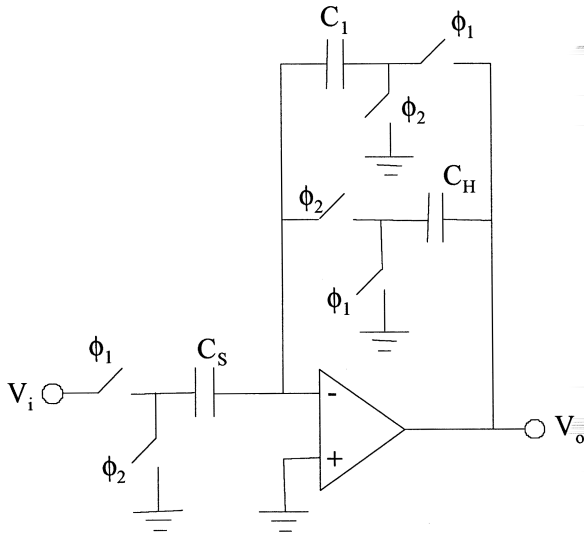

FIGURE 85.3 Voltage amplifier available during both clock phases.

in complex applications wherein the output of the amplifier has to be used during both clock phases. The second disadvantage of this topology is the large excursion of the op-amp output voltage. During the first clock phase, the op-amp output voltage is equal to the offset voltage and in the next clock phase this voltage is equal to $-(C_S/C_I)V_i$. Hence, an op-amp with large slew rate may be required.

Another interesting topology is shown in Fig. 85.3. During ϕ_2, the op-amp output voltage is equal to the previous voltage plus the op-amp offset voltage plus V_o/A_V, where A_V is the open-loop dc gain of the op-amp. In this clock phase, both capacitors C_I and C_S are charged to the voltage at the inverting terminal of the op-amp. This voltage is approximately equal to the op-amp offset voltage plus V_o/A_V. During the next clock phase, the sampling capacitor is charged to $C_S(V_I - V^-)$, but because it was precharged to $-C_S V^-$, the injected charge to C_I is equal to $C_S V_i$. As a result of this charge cancellation, the op-amp output voltage is equal to $-(C_S/C_I)V_i$. Therefore, this topology has low sensitivity to the op-amp offset voltage and the op-amp dc gain. A minor drawback of this topology is that the op-amp stays in open loop during the nonoverlapping clock phases transition times. This fact produces spikes during these time intervals. A solution for this is to connect a small capacitor between the op-amp output and the left-hand plate of C_S.

First-Order Blocks

The standard stray-insensitive integrators are shown in Fig. 85.4. Note that in sampled data systems both input and output signals can be sampled at different clock periods. This yields different transfer functions. We will assume a two-phase nonoverlapping clock: an odd clock phase ϕ_1, and an even clock phase ϕ_2.

For the noninverting integrator the following transfer functions are often used:

$$H^{oo}(z) = \frac{V_o^o(z)}{V_{\text{in}}^o(z)} = \frac{a_p z^{-1}}{1 - z^{-1}} = \frac{a_p}{z - 1} \tag{85.4a}$$

$$H^{oe}(z) = \frac{V_o^e(z)}{V_{\text{in}}^o(z)} = \frac{a_p z^{-1/2}}{1 - z^{-1}} = \frac{a_p}{z^{1/2} - z^{-1/2}} \tag{85.4b}$$

For the inverting integrator

$$H^{oe}(z) = \frac{V_o^o(z)}{V_{\text{in}}^o(z)} = -\frac{a_n}{1 - z^{-1}} = -\frac{a_n z}{z - 1} \tag{85.5a}$$

© 2003 by CRC Press LLC

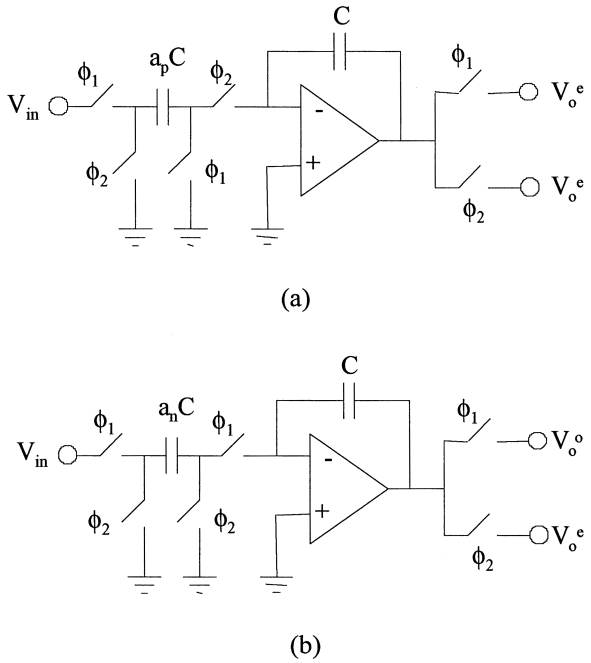

FIGURE 85.4 Conventional stray-insensitive SC integrators: (a) noninverting, (b) inverting.

$$H^{oe}(z)=\frac{V_o^e(z)}{V_{\text{in}}^o(z)}=-\frac{a_p z^{-1/2}}{1-z^{-1}}=-\frac{a_p}{z^{1/2}-z^{-1/2}} \tag{85.5b}$$

where z^{-1} represents a unit delay. A crude demonstration showing the integration nature of these SC integrators [1], [8] in the *s*-domain is to consider high-sampling rate, that is, a clock frequency ($f_c = 1/T$) much higher than the operating signal frequencies. Thus, let us consider (85.4a), and assuming high sampling rate we can write a mapping from the *z*- to the *s*-domain:

$$z \cong 1+sT \tag{85.6}$$

$$H(s)=\frac{a_p}{z-1}\Big|_{z\cong 1+sT}\cong\frac{1}{(T/a_p)s} \tag{85.7}$$

This last expression corresponds to a continuous-time noninverting integrator with a time constant of $T/a_p = 1/f_c a_p$, that is, a capacitance ratio times the clock period.

In many applications the capacitor ratios associated with the integrators are very large; thus, the total capacitance becomes excessive. This is particularly critical for biquadratic filters with high *Q*, where the ratio between the largest and smallest capacitance is proportional to the quality factor *Q*. A suitable inverting SC integrator for high-*Q* applications [11] is shown in Fig. 85.5; the corresponding transfer function during ϕ_2 is

$$H^{oe}(z)=\frac{V_o^e(z)}{V_{\text{in}}^o(z)}=-\frac{C_1C_3}{C_2(C_2+C_3)}\frac{z^{-1/2}}{1-z^{-1}} \tag{85.8}$$

This integrator is comparable in performance to the conventional of Fig. 85.3, in terms of stray sensitivity and finite gain error. Note from (85.8) that the transfer function is only defined during ϕ_2. During ϕ_1, the circuit behaves as a voltage amplifier plus the initial conditions of the previous clock

© 2003 by CRC Press LLC

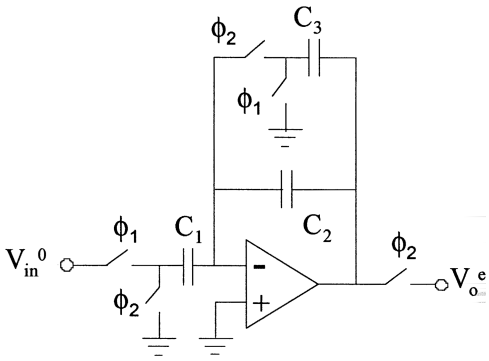

FIGURE 85.5 An SC integrator with reduced capacitance spread.

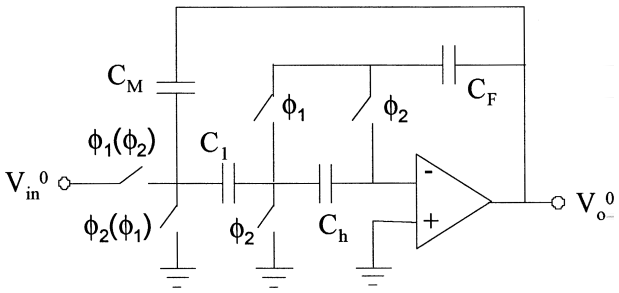

FIGURE 85.6 Offset and gain compensated integrator.

phase, and in the following clock phase the same amount of charge is extracted but the integrating capacitor is reduced due to the switches connected to C_1, thus relatively high slew-rate op-amps could be required. A serious drawback is the increased offset in comparison with the standard SC integrators. However, in typical two integrator loop filters, the other integrator can be chosen to be offset and low dc gain compensated as shown in Fig. 85.6.

The SC integrator performs the integration during ϕ_1 by means of C_1 and C_F and the hold capacitor C_h stores the offset voltage. The voltage across C_h compensates the offset voltage and the dc gain error of the op-amp. Note that the SC integrator of Fig. 85.6 can operate as a noninverting integrator if the clocking in parenthesis is employed. C_M provides a time-continuous feedback around the op-amp. The transfer function for infinite op-amp gain is

$$H^{oo}(z) = \frac{V_o^o(z)}{V_{\text{in}}^o(z)} = -\frac{C_1}{C_F}\frac{1}{1-z^{-1}} \tag{85.9}$$

Next we discuss a general form of a first-order building block; see Fig. 85.7. The output voltage during ϕ_2 can be expressed as

$$V_o^e = -\frac{C_1}{C_F}V_{i_1}^e - \frac{C_2}{C_F}\frac{1}{1-z^{-1}}V_{i_2}^e + \frac{C_3}{C_F}\frac{z^{-1}}{1-z^{-1}}V_{i_3}^e \tag{85.10}$$

Observe that the capacitor C_3 and switches can be considered as the implementation of a negative resistor leading to a non-inverting amplifier. Also note that $V_{i_2}^e$ could be V_o^e, this connection would make the integrator a lossy one. In that case, (85.10) can be written as

© 2003 by CRC Press LLC

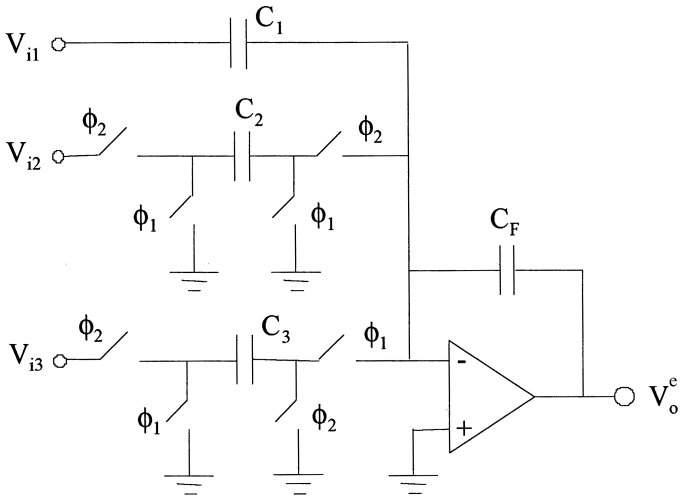

FIGURE 85.7 General form of a first-order building block.

$$V_o^e \frac{\left(1+\frac{C_2}{C_F}\right)z-1}{z-1} = -\frac{C_1}{C_F}V_{i_1}^e + \frac{C_3}{C_F}\frac{1}{z-1}V_{i_3}^e, \qquad \text{for } V_{i_2}^e = V_o^e \tag{85.11}$$

The building block of Fig. 85.7 is the basis of higher order filters.

SC Biquadratic Sections

The circuit shown in Fig. 85.8 can implement any pair of poles and zeros in the z-domain. For $C_A = C_B = 1$

$$H^{ee}(z) = \frac{V_o^e(z)}{V_{\text{in}}^e(z)} = -\frac{(C_5+C_6)z^2 + (C_1C_2 - C_5 - 2C_6)z + C_6}{z^2 + (C_2C_3 + C_2C_4 - 2)z + (1 - C_2C_4)} \tag{85.12}$$

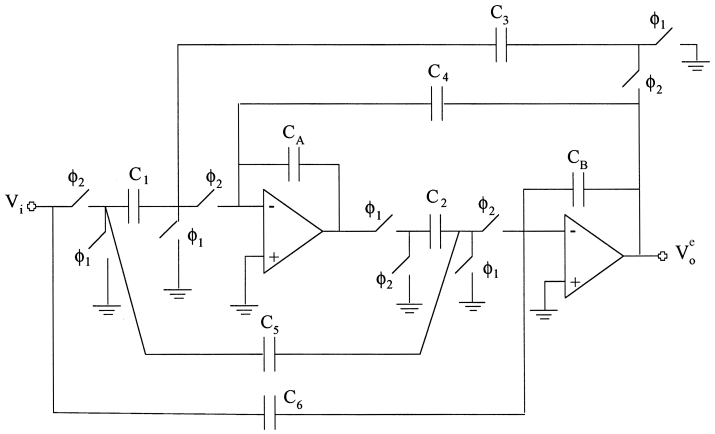

FIGURE 85.8 An SC biquadratic section [Martin-Sedra].

© 2003 by CRC Press LLC

Simple design equations follow:

$$\text{Low-pass case:} \quad C_5 = C_6 = 0 \tag{85.13a}$$

$$\text{High-pass case:} \quad C_1 = C_5 = 0 \tag{85.13b}$$

$$\text{Bandpass case:} \quad C_1 = C_6 = 0 \tag{85.13c}$$

Comparing the coefficients of the denominator of (85.12) with the general z-domain expression z^2-(2r cos θ)z + r^2, we can obtain the following expressions:

$$C_2C_4 = 1 - r^2 \tag{85.14a}$$

$$C_2C_3 = 1 - 2r\cos\theta + r^2 \tag{85.14b}$$

Note that in this expression it has been assumed that the filter poles are located at $z = re^{\pm j\omega_{0d}T}$. ω_{0d} and Q are the pole's frequency and the filter's quality factor, respectively. For equal voltage levels at the two integrator outputs, and assuming Q is greater than 3, and high-sampling rate ($\theta = \omega_{od}T \ll 1$) we can write

$$C_2 = C_3 = \sqrt{1 + r^2 - 2r\cos\theta} \cong \omega_{od}T \tag{85.14c}$$

$$C_4 = \frac{1 - r^2}{C_2} \cong \frac{1}{Q} \tag{85.14d}$$

The capacitance spread for high sampling rate and high Q can be expressed as

$$\frac{C_{\max}}{C_{\min}} = \max\left[\frac{C_1}{C_2}, \frac{C_1}{C_4}\right] = \max\left\{\frac{1}{\omega_{od}T}, Q\right\} \tag{85.15}$$

In some particular cases this capacitance spread becomes prohibited. For such cases the SC integrators shown in Figs. 85.5 and 85.6 can be used to replace the conventional building blocks. This combination yields the SC biquadratic section shown in Fig. 85.9. This structure, besides offering a reduction of the total capacitance, also yields a reduction of the offset voltage of the op-amps. Note that the capacitor C_h does not play an important role in the design, and can be chosen to have a small value. The design

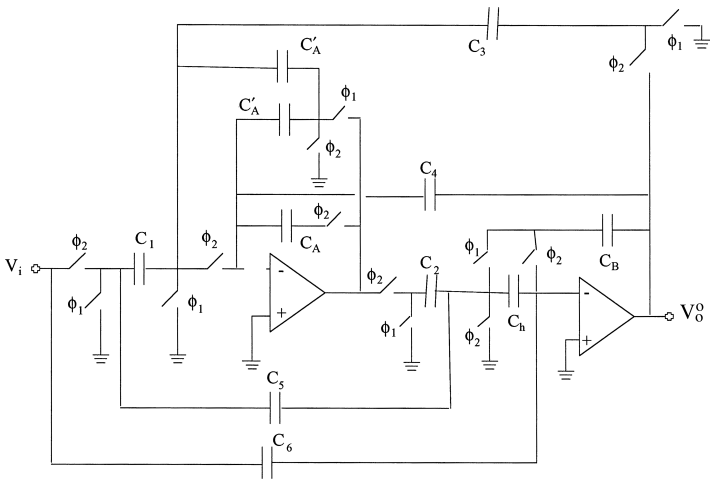

FIGURE 85.9 An improved capacitance area SC biquadratic section.

© 2003 by CRC Press LLC

equations for the zeros are similar to (85.13a) through (85.13c). For the poles, comparing with z^2-(2r cos θ)z + r^2 and the analysis of Fig. 85.9, we can write

$$\frac{C_2C_3}{C_A+C_B}=1+r^2-2r\cos\theta \tag{85.16a}$$

$$\frac{C'_AC_2C_4}{C_{A_1}C_AC_B}=1-r^2 \tag{85.16b}$$

where $C_{A1} = C'_A + C''_A$. Simple design equations can be obtained assuming high sampling rate, large Q, and $C_2 = C_3 = C_4 = C'_A = C_h = 1$; then

$$C_A+C_B\cong\frac{1}{\omega_{od}T} \tag{85.17a}$$

$$C''_A\cong Q\omega_{od}T-1 \tag{85.17b}$$

Another common situation is the use of SC filters in high frequencies; in such cases a structure with minimum gain-bandwidth product (GB = ω_u) requirements is desirable. This structure is shown in Fig. 85.10 and is often referred to as a decoupled structure. It is worthwhile to mention that two SC architectures can have ideally the same transfer function; however, with real op-amps their frequency (and time) response differs significantly. A rule of thumb to reduce the GB effects in SC filters is to minimize the direct connections between the output of one op-amp to the input of another op-amp. It is desirable to transfer the output of an op-amp to a grounded capacitor, and in the next clock phase transfer the capacitor charge into the op-amp input. If required, the connection to the next op-amp has to be done during the hold phase of the previous op-amp. If the connection is done during the charge injection phase, the output of the first integrator is a ramp (step response of the integrator), and the settling time for the next integrator increases further. More discussion on ω_u effects is given in the next section.

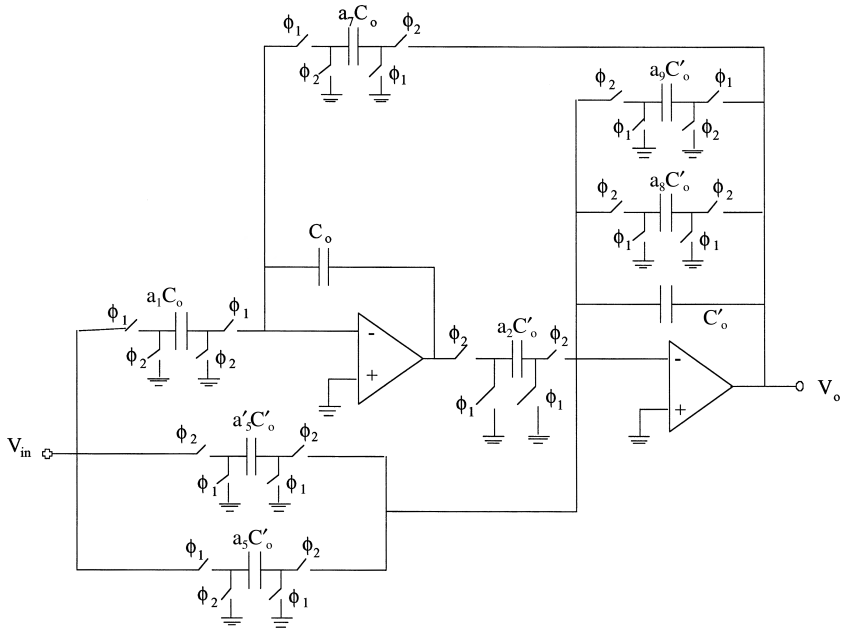

FIGURE 85.10 A decoupled SC biquadratic section.

© 2003 by CRC Press LLC

If the input signal is sampled during ϕ_2 and held during ϕ_1, the ideal transfer function is given by

$$H^e(z)=\frac{V_o^e(z)}{V_i^e(z)}=-\frac{a_5'}{1+a_8}\frac{z^2-z\left(a_5'+a_5-a_1a_2\right)/a_5'+a_5/a_5'}{z^2-z\dfrac{2+a_8+a_9-a_2a_7}{1+a_8}+\dfrac{1+a_9}{1+a_8}} \tag{85.18}$$

Analysis of this equation yields the following expressions:

$$r^2=\frac{1+a_9}{1+a_8} \tag{85.19a}$$

$$2r\cos\theta=\frac{2+a_8+a_9-a_2a_7}{1+a_8} \tag{85.19b}$$

The capacitor a_9C_o' can be used as a design trade-off parameter to optimize the biquad performance. A simple set of design equations follows:

$$a_8=\frac{\left(1+a_9\right)-r^2}{r^2} \tag{85.20a}$$

$$a_2=a_7=\left(1+a_9\right)\sqrt{\frac{1+r^2-2r\cos\theta}{r^2}} \tag{85.20b}$$

Under high sampling rate and high Q conditions, the following expressions can be obtained:

$$\omega_o\cong f_c\sqrt{\frac{a_2a_7}{1+a_8}} \tag{85.21a}$$

and

$$Q\cong\sqrt{\frac{a_2a_7\left(1+a_8\right)}{a_8-a_9}} \tag{85.21b}$$

A trade-off between Q-sensitivity and total capacitance is given by a_8 and a_9.

85.3 Effects of the Op-Amp Finite Parameters

Finite Op-Amp DC Gain Effects

The effect of finite op-amp dc voltage gain A_o in a lossless SC integrator is to transform a lossless integrator into a lossy one. This brings degradation in the transfer function both in magnitude and phase. Typically the magnitude deviation due to the integrator amplitude variation is not critical. By contrast, the phase deviation from the ideal integrator has a very important influence on the overall performance. When the real SC integrators are used to build a two-integrator biquadratic filter, it can be proved that the actual quality factor becomes

$$Q_A=\frac{1}{\dfrac{1}{Q}+\dfrac{2}{A_o}}\cong\left(1-\frac{2Q}{A_o}\right)Q \tag{85.22}$$

© 2003 by CRC Press LLC

where Q and A_o are the desired filter's quality factor and op-amp dc gain, respectively. The actual center frequency suffers small deviations.

$$\omega_{o_A} = \frac{A_o}{1+A_o}\omega_o \tag{85.23}$$

We can conclude that the ω_o deviations are negligible. However, the Q deviations can be significant depending on the Q and A_o values; e.g., Q_{error} is given by $-2Q/A_o$, which is more critical for high-Q applications.

Finite Op-Amp Gain-Bandwidth Product Effects

The op-amp bandwidth is very critical for high-frequency applications. The analysis is carried out when the op-amp voltage gain is modeled with one dominant pole, i.e.,

$$A_v(s) = \frac{A_o}{1+s/\omega_3} = \frac{A_o\omega_3}{s+\omega_3} = \frac{\omega_u}{s+\omega_3} \cong \frac{\omega_u}{s} \tag{85.24}$$

where A_o is the dc gain, ω_u is approximately the unity gain-bandwidth (GB), and ω_3 is the op-amp bandwidth. The analysis taking into account $A_v(s)$ is rather cumbersome because the op-amp input–output characterization is a continuous-time system modeled by a first-order differential equation, and the rest of the SC circuit is characterized by discrete-time systems modeled by difference equations. It can be shown that the step response of a single op-amp SC circuit due to step inputs applied at $t = t_1$ is

$$v_o(t-t_1) = v_o(t_1)e^{-(t-t_1)\alpha\omega_u} + v_{od}\left\{1-e^{-(t-t_1)\alpha\omega_u}\right\} \tag{85.25}$$

where v_{od} is the final output voltage, which is a function of the initial conditions, inputs, and filter architecture. α is a topology-dependent voltage divider, $0 < \alpha \le 1$, given by the following expression:

$$\alpha = \frac{\sum C_f}{\sum_i C_i} \tag{85.26}$$

where the C_f sum consists of all feedback capacitors connected directly between the op-amp output and the negative input terminal, and the C_I sum comprises overall capacitors connected to the negative op-amp terminal. The effects of the load capacitors are neglected. Note that the $\alpha\omega_u$ should be maximized for fast settling time. For the common case the output signal is sampled at the end of the clock phase, $t - t_1 = T/2$, hence the figure of merit to be maximized is $\alpha T\omega_u/2$. This means that a rule of thumb yielding reduced gain-bandwidth product effects requires that

$$\frac{\alpha T\omega_u}{2} > 5 \tag{85.27a}$$

or

$$f_u > \frac{1.6}{\alpha} f_s \tag{85.27b}$$

This rule is based on the fact that five time constants are required to obtain the steady-state response with magnitude error of less than 1%. For the multiple op-amp case the basic concept prevails. Observe

© 2003 by CRC Press LLC

that for two-clock phase SC filters the system becomes an $\mathbf{M} \times \mathbf{M}$ matrix $\mathbf{A}$ for each clock-phase, where $\mathbf{M}$ is the number of op-amps in the filter architecture. For a fixed clock frequency, $f_c = 1/T$, there are two components to be optimized: α and ω_u. The minimum ω_u effects biquadratic SC filter presented in the previous section (Fig. 85.10) has the property that $\mathbf{A}$ has been optimized. For illustration on how to determine the $\mathbf{A}$ matrix of an SC filter, the $\mathbf{A}$ matrix for the minimum ω_u effects biquadratic, Fig. 85.10, is given by

$$\mathbf{A}\Big|_{\phi_1} = \begin{bmatrix} \dfrac{1}{1+a_1+a_7} & 0 \\ 0 & 1 \end{bmatrix} \tag{85.28}$$

$$\mathbf{A}\Big|_{\phi_2} = \begin{bmatrix} 1 & \dfrac{a_2}{1+a_2+a_5+a_5'+a_8+a_9} \\ 0 & \dfrac{1+a_8}{1+a_2+a_5+a_5'+a_8+a_9} \end{bmatrix} \tag{85.29}$$

Thus, the designer should use the extra degrees of freedom to maximize the diagonal entries of $\mathbf{A}$ during all phases. Another design consideration could be to maximize ω_u. This last consideration should be carefully addressed because very large ω_u values, as it will be shown, can cause excessive phase margin degradation. Therefore, a judicious trade-off must be used in choosing the ω_u of each op-amp in the filter topology.

85.4 Noise and Clock Feedthrough

The lower range of signals that can be processed by the electronic devices is limited by several unwanted signals that appear at the output of the circuit. The rms values of these electrical signals determine the system noise level, and it represents the lowest limit for the incoming signals to be processed. The circuit cannot properly detect input signals smaller than the noise level, in most of the cases.

The most critical noise sources are those due to: (i) the employed elements (transistors, diodes, resistors, etc.); (ii) the noise induced by the clocks; (iii) the harmonic distortion components generated due to the intrinsic nonlinear characteristics of the devices; and (iv) the noise induced by the surrounding circuitry. In this section, types (i), (ii), and (iii) are considered. Using fully differential structures can further reduce the noise generated by the surrounding circuitry and coupled to the output of the switched-capacitor circuit. These structures are not treated here, but there are excellent references in the literature [2], [4], [6], [9].

Noise Due to the Op-Amp

In an MOS transistor, the noise is generated by different mechanisms but there are two dominant noise sources: channel thermal noise and $1/f$ or flicker noise. A discussion of the nature of these noise sources follows.

Thermal Noise

The flow of the carriers due to the drain-source voltage takes place on the source-drain channel, mostly like in a typical resistor. Therefore, due to the random flow of the carriers, thermal noise is generated. For an MOS transistor biased in the linear region, the spectral density of the input referred thermal noise is approximately given by [1]–[4]

$$V_{\text{eqth}}^2 = 4kTR_{\text{on}} \tag{85.30}$$

© 2003 by CRC Press LLC

where R_{on}, k, and T are the drain-source resistance of the transistor, the Boltzmann constant, and the temperature (in degrees Kelvin), respectively. In saturation region, the spectral noise density can be calculated by the same expression but with R_{on} equal to $2/3g_m$, g_m being the small-signal transconductance of the transistor.

1/*f* Noise

This type of noise is mainly due to the imperfections in the silicon–silicon oxide interface. The surface states and the traps in this interface randomly interfere with the charges flowing through the channel; hence, the generated noise is strongly dependent on the technology. The 1/f noise (or flicker noise) is also inversely proportional to the gate area because at larger areas more traps and surface states are present and some averaging occurs. The spectral density of the input referred 1/f noise is commonly characterized as

$$V_{eq1/f}^2 = \frac{k_F}{WLf} \tag{85.31}$$

where the product WL, f, and k_F are the gate area of the transistor, the frequency in hertz, and the flicker constant, respectively. The spectral noise density of the MOS transistor is composed by both components; therefore, the input referred spectral noise density of a transistor operated in its saturation region becomes

$$V_{eq}^2 = \frac{8}{3}\frac{kT}{g_m} + \frac{k_F}{WLf} \tag{85.32}$$

Op-Amp Noise Contributions

In an op-amp, the output referred noise density is composed by the noise contribution of all transistors; hence, the noise level is a function of the op-amp architecture. A typical unbuffered folded cascode op-amp (folded cascode OTA) is shown in Fig. 85.11. For the computation of the noise level, the contribution of each transistor has to be evaluated. Obtaining the OTA output current generated by the gate-referred noise of all the transistors can do this. For instance, the spectral density of the output-referred noise current due to M_1 is straightforwardly determined because the gate-referred noise is at the input of the OTA, leading to

$$i_{01}^2 = G_m^2 V_{eq1}^2 \tag{85.33}$$

where G_m (equal to g_{m1} at low frequencies) is the OTA transconductance and V_{eq1}^2 is the input-referred noise density of M_1. Similarly, the contributions of M_2 and M_5 to the spectral density of the output-referred noise current are given by

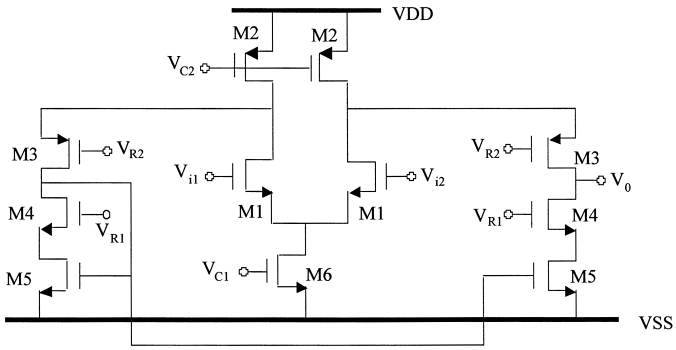

FIGURE 85.11 A folded cascode operational transconductance amplifier.

© 2003 by CRC Press LLC

$$i_{o2}^2 = g_{m2}^2 v_{\text{eq2}}^2$$
$$i_{o5}^2 = g_{m5}^2 v_{\text{eq5}}^2 \tag{85.34}$$

The noise contributions of transistors M_3 and M_4 are very small in comparison to the other components. This is because their noise drain currents, due to the source degeneration implicit in these transistors, are determined by the equivalent conductance associated with their sources instead of those by their transconductance. Since in a saturated MOS transistor the equivalent conductance is much smaller than the transistor transconductance, this noise drain current contribution can be neglected. The noise contribution of M_6 is mainly common-mode noise; therefore, it is ideally canceled at the OTA output due to the current subtraction. The spectral density of the total output-referred noise current can be calculated approximately as

$$i_o^2 = 2\left[G_m^2 V_{\text{eq1}}^2 + g_{m2}^2 v_{\text{eq2}}^2 + g_{m5}^2 v_{\text{eq5}}^2\right] \tag{85.35}$$

The factor 2 is the result of the pair of transistors M_1, M_2, and M_5. From this equation, the OTA input referred noise density becomes

$$v_{\text{OTAin}}^2 = 2v_{\text{eq1}}^2\left[1 + \frac{g_{m2}^2 v_{\text{eq2}}^2 + g_{m5}^2 v_{\text{eq5}}^2}{g_{m1}^2 v_{\text{eq1}}^2}\right] \tag{85.36}$$

According to this result, if g_{m1} is larger than g_{m2} and g_{m5}, the OTA input-referred noise density is mainly determined by the OTA input stage. In that case and using (85.32), (85.36) yields

$$v_{\text{OTAin}}^2 \cong 2v_{\text{eq1}}^2 = v_{\text{eq1}/f}^2 + 4kTR_{\text{eqth}} \tag{85.37}$$

where the factor 2 has been included in $v_{\text{eq1}/f}$ and R_{eqth}. In (85.37), $v_{\text{eq1}/f}^2$ is the equivalent $1/f$ noise density and R_{eqth} is the equivalent resistance for noise, equal to $4/3g_{m1}$.

Noise in a Switched-Capacitor Integrator

In a switched-capacitor lossless integrator, the output-referred noise density component due to the OTA is frequency limited by the gain-bandwidth product of the OTA. In order to avoid misunderstandings, in this section f_u (the unity-gain frequency of the OTA in hertz) is used instead of ω_u (in radians per second). Since f_u must be higher than the clock frequency f_c and due to the sampled nature of the SC integrator, the OTA high-frequency noise is folded back into the integrator baseband. In the case of the SC integrator and assuming that the flicker noise is not folded back, the output-referred spectral noise density becomes

$$V_{o\,\text{eq}\,1}^2 = \left[v_{\text{eq1}/f}^2 + 4KTR_{\text{eqth}}\left(1 + \frac{2f_u}{f_c}\right)\right]\left|1 + H(z)\right|^2 \tag{85.38}$$

where the folding factor is equal to f_u/f_c, and $H(z)$ is the z-domain transfer function of the integrator. The factor $2f_u/f_c$ is the result of both positive and negative folding. Typically, the frequency range of the signal to be processed is around and below the unity-gain frequency of the integrator; therefore, $|H(z)| > 1$ and (85.38) can be approximated as

$$V_{o\,\text{eq}\,1}^2 = \left[v_{\text{eq}\,1/f}^2 + 4kTR_{\text{eqth}}\left(1 + \frac{2f_u}{f_c}\right)\right]\left|H(z)\right|^2 \tag{85.39}$$

© 2003 by CRC Press LLC

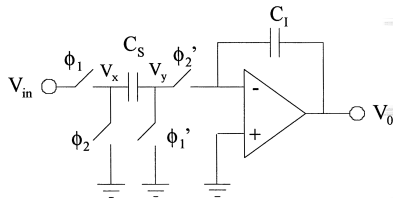

FIGURE 85.12 Typical switched-capacitor lossless integrator.

Noise Due to the Switches

In switched-capacitor networks, the switches are implemented with single or complementary MOS transistors. These transistors are biased in the cutoff and ohmic region for open and close operations, respectively. In cutoff region, the drain-source resistance of the MOS transistor is very high, then the noise contribution of the switch is confined to very low frequencies and it can be considered as dc offset. When the switch is in the on state, the transistor is biased in linear region and its spectral noise distribution is characterized by (85.30). This noise contribution is the most fundamental limit for the signal-to-noise ratio of switched-capacitor networks. The effects of these noise sources are better appreciated if a switched-capacitor integrator is considered.

Let us consider the SC integrator of Fig. 85.12 and assume that $\phi_1 = \phi_1'$ and $\phi_2 = \phi_2'$. The spectral noise density of the ϕ_1 driven switches are low-pass filtered by the on resistance of the switches R_{on} and the sampling capacitor C_s. The cutoff frequency of this continuous-time filter is given by $f_{on} = 1/(2\pi R_{on}C_s)$. Typically f_{on} is higher than the clock frequency; therefore, the high-frequency noise is folded back into the baseband of the integrator when the switched-capacitor integrator samples it. Taking into account the folding effects, the spectral noise density component of the switch-capacitor combination becomes

$$v_{eq2}^2 = 4kTR_{on}\left[1+\frac{2f_{on}}{f_c}\right] \tag{85.40}$$

with R_{on} the switch resistance. Considering that the noise bandwidth is given by $2\pi f_{on} = 1/R_{on}C_S$, then the integrated noise level yields:

$$v_{eq\text{-}integrated}^2 = \frac{kT}{C_S}\left[1+\frac{2f_{on}}{f_c}\right] \tag{85.41}$$

For the noise induced by the ϕ_2 driven switches, the situation is slightly different, but for practical purposes the same equation is used. According to (85.41), the integrated noise power is inversely proportional to C_S. Therefore, for low-noise applications it is desirable to design the integrators with large capacitors. However, the costs for the noise reduction are larger silicon area and higher power consumption. This last result is because the slew rate of the OTA is inversely proportional to the load capacitance and in order to maintain the specifications, it is necessary to increase the current drive capability of the OTA. Clearly, there is a trade-off between noise level, silicon area, and power consumption.

Clock Feedthrough

Another factor that limits the accuracy of switched-capacitor networks is the charge induced by the clocking of the switches. These charges are induced by the gate-source capacitance, the gate-drain capacitance, and the charge stored in the channel. Furthermore, some of these charges are input signal dependent and introduce distortion in the circuit. Although these errors cannot be canceled, there are some techniques that reduce these effects.

© 2003 by CRC Press LLC

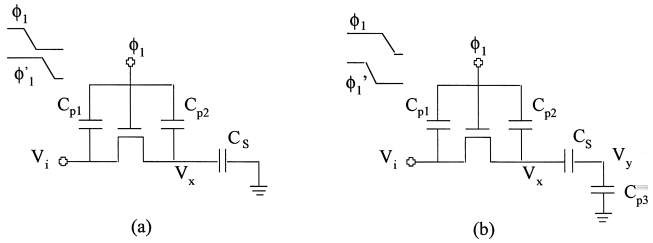

FIGURE 85.13 Charge induced due to the clocks. (a) If ϕ_1 goes down before ϕ_1' and (b) if ϕ_1' goes down before ϕ_1.

The analysis of the clock feedthrough is not straightforward because it depends on the order of the clock phases, the relative delay of the clock phases, as well as the speed of the clock transition. For instance, let us consider in Fig. 85.12 the case when ϕ_1 goes down before ϕ_1'. This situation is shown in Fig. 85.13(a).

While C_{p1} is connected between two low-impedance nodes, C_{p2} is connected between ϕ_1, a low-impedance node, and v_x. For $\phi_1 > v_i + V_T$ the transistor is on and the current injected by C_{p2} is absorbed by the drain-source resistance; then v_x remains at a voltage equal to v_i. When the transistor is turned off, $\phi_1 < v_i + V_T$, charge conservation at node v_x leads to

$$v_x = v_i + \frac{C_{p2}}{C_S + C_{p2}}\left(VSS - v_i - V_T\right) \tag{85.42}$$

where VSS is the low level of ϕ_1 and ϕ_2. During the next clock phase, the charge of C_S is injected to C_i. Thus, C_{p2} induces a charge error proportional to $C_{p2}/(C_S+C_{p2})$. In addition, an offset voltage proportional to VSS-V_T is also generated. Because the threshold voltage V_T is a nonlinear function of v_I, an additional error in the transfer function and harmonic distortion components appears at the output of the integrator. The same effect occurs when the clock phases ϕ_2 and ϕ_2' have a similar sequence.

Let us consider the case when ϕ_1' is opened before ϕ_1; the situation is shown in the Fig. 85.13(b). Before the transistors turn off, $v_x = v_i$ and $v_y = 0$. When the transistor is turned off, $VSS < \phi_1 < v_i + V_T$, the charge is recombined between C_S, C_{p2}, and C_{p3}. After the charge redistribution, the charge injected into C_s and C_{p3} is

$$Q_{Cp3} \cong \frac{C_{p2}C_{p3}}{C_{p2} + C_{p3}}\left(VSS - v_i - V_T\right) \tag{85.43}$$

Observe from (85.43) that the charge error is reduced due to the effects of C_{p3}. During the next clock phase, both capacitors C_S and C_{p3} transfer the ideal charge $C_S v_i$ and Q_{Cp3}, making the clock feedthrough-induced error smaller. The conclusion is that if the clock phase ϕ_1' is a bit delayed than ϕ_1 the clock-induced error is reduced. This is also true for the clock phases ϕ_2 and ϕ_2'.

In Fig. 85.12, the right-hand switch also introduces clock feedthrough, but unlike the clock feedthrough previously analyzed, this is input signal independent. When the clock phase ϕ_2 goes down, the gate-source overlap capacitor extracts from the summing node the following charge:

$$\Delta Q = C_{GS}\left(VSS - V_T\right) \tag{85.44}$$

In this case, V_T does not introduce distortion because v_y is almost at zero voltage for both clock phases. The main effect of this charge is to introduce an offset voltage. The same analysis reveals that the bottom right-hand switch introduces similar offset voltage. From the previous analysis it can be seen that using minimum transistor dimension can reduce the clock feedthrough. This implies minimum parasitic capacitors and minimum induced charge from the channel. If possible, the clock phases should be arranged for minimum clock feedthrough; i.e., Fig. 85.13(b).

© 2003 by CRC Press LLC

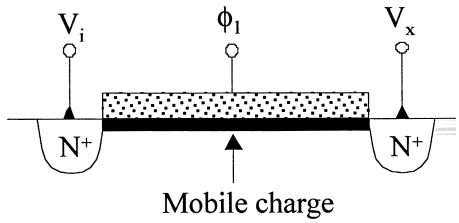

FIGURE 85.14 Cross-section of the MOS transistor showing the mobile charge.

Channel Mobile Charge

Charge injection also occurs due to the mobile charge in the channel. If the transistor is biased in linear region, the channel mobile charge can be approximated by

$$Q_{ch} = C_{GS}\left(V_{GS} - V_T\right) \tag{85.45}$$

where C_{GC} is the gate-channel capacitor; see Fig. 85.14.

When the switch is turned off this charge is released and part of it goes to the sampling capacitor. Fortunately, the previously discussed technique for the reduction of clock feedthrough also reduces the effects of the channel mobile charge injection. The mobile charge injected to the sampling capacitor is a function of several parameters; e.g., input signal, falling rate of the clock, overlap capacitors, gate capacitor, threshold voltage, integrating capacitor, and the supply voltages.

The effects of the channel mobile charges are severe when the ϕ_1-driven transistor is opened before the ϕ_1'-driven transistor. In this case, the situation is similar to that shown in Fig. 85.13(a), in which one terminal of C_S is still grounded. While ϕ_1 is higher than $v_I + V_T$ the channel resistance is small and v_I absorbs most of the channel-released charge. For $\phi_1 < v_I + V_T$, the channel resistance increases further and a substantial amount of charge released by the channel will flow through C_S, introducing a charge error. If the clock phases are arranged as those shown in Fig. 85.13(b), most of the charge released by the channel returns back to v_i. The main reason is because the equivalent capacitor seen at the right-hand side of the transistor is nearly equal to C_{p3}, if C_{p2} is neglected. Because this parasitic capacitor is smaller than the sampling capacitor, a small amount of extracted (or injected) charge will produce a huge variation on v_y, see Fig. 85.13(b), pushing back most of the mobile charges.

Dynamic Range

The dynamic range is defined as the ratio of the maximum signal that the circuit can drive without significant distortion to the noise level. The maximum distortion tolerated by the circuit depends on the application, but –60 dB is commonly used. Since the linearity of the capacitors is good enough and if the harmonic distortion components introduced by the OTA input stage are small, the major limitation for the linearity is determined by the output stage of the OTA. For the folded cascode OTA of Fig. 85.11 this limit is

$$V_{o\max} \cong V_{R2} + V_{TP3} \tag{85.46}$$

If the reference voltage V_{R2} is maximized, (85.46) yields

$$V_{o\,\max} \cong V_{DD} - 2V_{DSATP} \tag{85.47}$$

A similar expression can be obtained for the lowest limit. Assuming a symmetrical single-side output stage, from (85.47), the maximum rms value of the OTA output voltage is given by

$$V_{o\mathrm{RMS}} \cong \frac{V_{DD} - 2V_{DSATP}}{\sqrt{2}} \tag{85.48}$$

© 2003 by CRC Press LLC

If the in-band noise, integrated up to $\omega = 1/R_{int}C_I$, is considered and if the most important term of (85.41) is retained, the dynamic range of the single-ended switched-capacitor integrator becomes

$$DR \cong \frac{\left(V_{DD} - 2V_{DSATP}\right)}{\sqrt{2}\sqrt{2kT/C_S}} = \frac{\left(V_{DD} - 2V_{DSATP}\right)}{2\sqrt{kT}}\sqrt{C_S} \tag{85.49a}$$

For this equation, the alias effects have been neglected and the noise contribution of the switches driven by ϕ_1 and ϕ_2 are considered. At room temperature, this equation is reduced to the following expression:

$$DR \cong 5.6 \times 10^9 \sqrt{C_I}\left(V_{DD} - 2V_{DSATP}\right) \tag{85.49b}$$

According to this result, the dynamic range of the switched-capacitor integrator is reduced when the power supplies are scaled down and minimum capacitors are employed. Clearly, there is a compromise between power consumption, silicon area, and dynamic range. As an example, for the case of $C_S = 1.0$ pF and supply voltages of ±1.5 V and neglecting V_{DSATP}, the dynamic range of a single integrator is around 78 dB. For low-frequency applications, however, the dynamic range is lower due to the low-frequency flicker noise component.

85.5 Design Considerations for Low-Voltage Switched-Capacitor Circuits

For the typical digital supply voltages, 0–5 V, switched-capacitors achieve dynamic ranges of the order of 80 to 100 dB. As long as the power supplies are reduced, the swing of the signal decreases and the switch resistance increases further. Both effects reduce the dynamic range of the switched-capacitor networks. A discussion of these topics follows.

Low-Voltage Operational Amplifiers

The design techniques for low-voltage low-power amplifiers for switched-capacitor circuits have been addressed by several authors [4], [7]-[9], [11]. The implementation of op-amps for low-voltage applications does not seem to be a fundamental limitation as long as the transistor threshold voltage is smaller than (VDD-VSS)/2. This limitation will become clear in the design example presented in this section. The design of the operational amplifier is strongly dependent on the application. For high-frequency circuits, the folded-cascode op-amp is suitable, but the cascode transistors limit the swing of the signals at the output stage. If large output voltage swing is needed, complementary stages are desirable. To illustrate the design trade-offs involved in the design of a low-voltage OTA, let us consider the folded cascode OTA of Fig. 85.11. For low-voltage applications and small signals, the transistors have to be biased with very low V_{DSAT} ($=V_{GS} - V_T$). For ±0.75 V applications and $V_T = 0.5$ V, $V_{DSAT1} + V_{DSAT6}$ must be lower than 0.25 V, otherwise the transistor M_6 goes to the triode region. For large signals, however, the variations of the input signal produce variations at the source voltage of M_1. If an input of the OTA is grounded, it can be shown that linear range of the differential pair is of the order of ±1.44 V_{DSAT1}. Hence, for proper operation of the OTA input stage it is desirable to satisfy

$$0.25 > 2.44V_{DSAT1} + V_{DSAT6} \tag{85.50}$$

It has to be taken into account that the threshold voltage of M_1 increases if an N-well process is used, due to the body effects. In critical applications, PMOS transistors fabricated in a different well with their source tied to their own well can be used. The dimensioning of the transistors and the bias conditions are directly related to the application. For instance, if the switched-capacitor integrator must slew 1 V into 4 μs and the load capacitor is of the order of 10 pF, the OTA output current must be equal to or

© 2003 by CRC Press LLC

higher than 2.5 μA. Typically, for the folded cascode OTA the dc current of both output and input stages are the same. Therefore, the bias current for M_1, M_3, M_4, and M_5 can be equal to 2.5 μA. The bias current for M_2 and M_6 is 5 μA. If $V_{GS1} - V_{T1}$ is fixed at 100 mV, the dimensions of M_1 can be computed according to the required small signal transconductance. Similarly, the dimension of the other transistors can be calculated, most of them designed to maximize the output swing and dc gain. A very important issue in the design of low-voltage amplifiers is the reference voltage. In the folded-cascode of Fig. 85.11, the values of the reference voltages V_{R1} and V_{R2} must be optimized for maximum output swing. OTA design techniques are fully covered in Reference [11].

Analog Switches

For low-voltage applications, the highest voltage that can be processed is limited by the analog switches rather than by the op-amps [11]. For a single NMOS transistor, the switch resistance is approximately given by

$$R_{DS} = \frac{1}{\mu_n C_{OX} \frac{W}{L}\left(V_{GS} - V_T\right)} \tag{85.51}$$

where μ_n and C_{OX} are technological parameters. According to (85.51), the switch resistance increases further when V_{GS} approaches to V_T. This effect is shown in Fig. 85.15 for the case $VDD = -VSS = 0.75$ V and $V_T = 0.5$ V. From this figure, the switch resistance is higher than 300 kΩ for input signals of 0.2 V. However, for a drain-source voltage higher than $V_{GS} - V_T$ the transistor saturates and no longer behaves as a switch. This limitation clearly reduces further the dynamic range of the switched-capacitor circuits.

A solution for this drawback is to generate the clocks from higher voltage supplies. A simplified diagram of a voltage doubler is depicted in Fig. 85.16(a). During the clock phase ϕ_1, the capacitor C_1 is charged to VDD and during the next clock phase its negative plate is connected to VDD. Hence, at the beginning of ϕ_2, the voltage at the top plate of C_1 is equal to $2VDD\text{-}VSS$. After several clock cycles, if C_{LOAD} is not further discharged, the charge is recombined leading to an output voltage equal to $2\ VDD\text{-}VSS$. A practical implementation for an N-well process is shown in Fig. 85.16(b).

In this circuit, the transistors M_1, M_2, M_3, and M_4 behave as the switches S_1, S_2, S_3, and S_4 respectively, of Fig. 85.16(a). While for M_1 and M_2 the normal clocks are used, special clock phases are generated for M_3 and M_4 because they drive higher voltages. The circuit operates as follows.

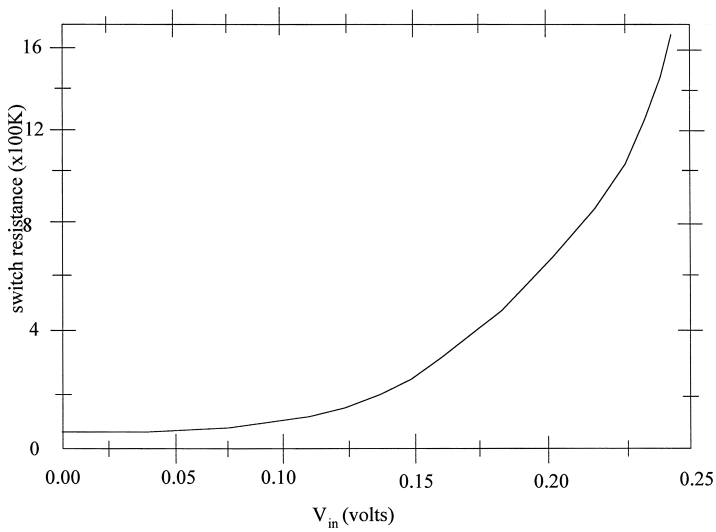

FIGURE 85.15 Typical switch resistance for an NMOS transistor.

© 2003 by CRC Press LLC

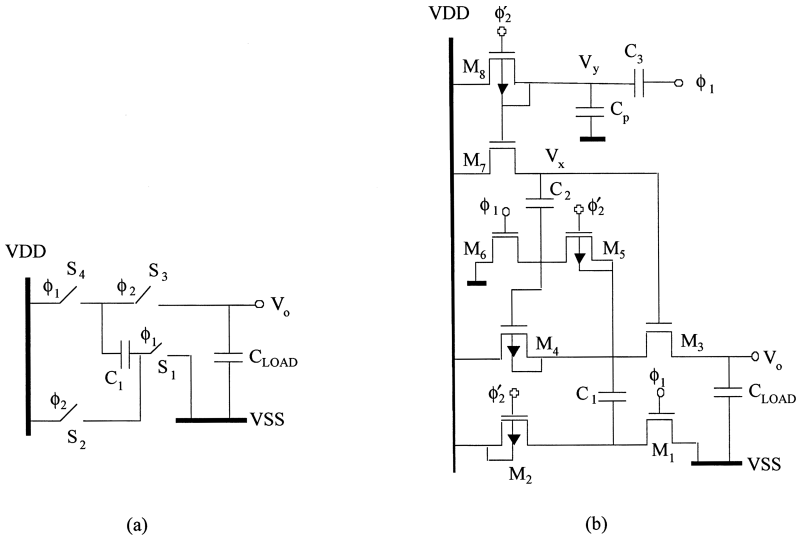

FIGURE 85.16 Voltage doubler. (a) Simplified diagram and (b) transistor level diagram.

During ϕ_1, M_8 is turned off because ϕ_2' is high. The voltage at node v_y is higher than *VDD* because the capacitors C_3 and C_p were charged to VDD during the previous clock phase ϕ_2 and, when ϕ_1 goes up, charge is injected to the node through the capacitor C_3. Since v_y is higher than *VDD*, M_7 is turned on. The bottom plate of C_2 is connected to *VSS* by M_6 and C_2 is charged to *VDD-VSS*.

During ϕ_2, the refresh clock phase, the bottom plate of C_1 is connected to *VDD* by the PMOS transistor M_2. Note that if an NMOS transistor is employed, the voltage at the bottom plate of C_1 is equal to $VDD\text{-}V_T$, resulting in lower output voltage. During ϕ_2, the voltage at its top plate is $2VDD\text{-}VSS$. The voltage at node v_x becomes close to $3VDD\text{-}2VSS$ volts, turning M_3 on and enabling the charge recombination of C_1 and C_{LOAD}. As a result, after several clock periods, the output voltage v_o becomes equal to $2VDD\text{-}VSS$. It has to be noted that v_y is precharged to VDD during this clock phase and that M_7 is turned off, keeping the voltage v_x high. Also, in order to avoid discharges the gate of M_4 is connected to the bottom plate of C_2. Thus, M_4 is turned off during the refresh phase.

Some results are shown in Fig. 85.17. In this figure, the voltage at the nodes v_x and v_o are depicted. The load current is 10 μA and 25 μA, respectively. The capacitors C_1 and C_{LOAD} are 100 pF and 10 nF, respectively. The supply voltages used are $VDD = 0.75$ V and $VSS = -0.75$ V. During ϕ_1, the peak voltage at node v_x is nearly equal to $3VDD\text{-}2VSS$; for this example it is equal to 3.75 V. Nevertheless, some losses

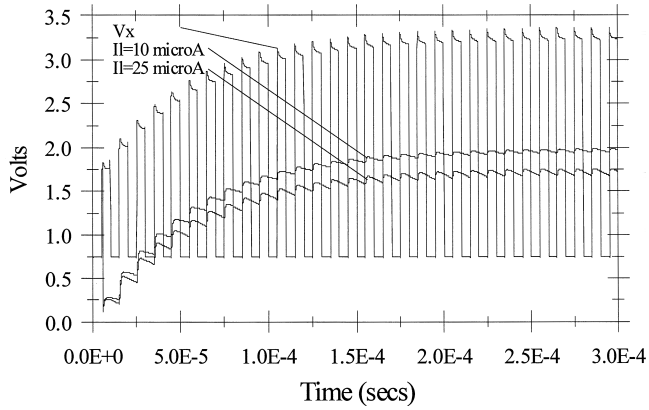

FIGURE 85.17 Time response of the voltage doubler at start up. Load currents of 10 μA and 25 μA are considered.

© 2003 by CRC Press LLC

in the circuit leads reduce it to 3.5 V. The output voltage v_o is nearly equal to $2VDD\text{-}VSS = 2.25$ V. Another technique using switched op-amps, described in Reference [12], has also been successfully used.

85.6 Design Examples

Biquadratic Filter

In this section, a second-order bandpass filter is designed. The specifications for this biquad are

Center frequency	1.63 kHz
Quality factor	16
Peak gain	10 dB
Clock frequency	8 kHz

A transfer function that realizes this filter is given by the following expression:

$$H(z) = \frac{0.1953(z-1)z}{z^2 + 0.5455z + 0.9229} \tag{85.52}$$

This transfer function can be implemented by using the biquads presented in Section 85.2. For the biquad of Fig. 85.10, and employing $a_1 = a_5 = a_9 = 0$, the circuit behaves as a bandpass filter. Equating the terms of (85.52) with the terms of (85.18), the following equations are obtained:

$$\begin{aligned} a_8 &= \frac{1}{0.9229} - 1 \\ a_5' &= \frac{0.1953}{0.9229} \\ a_2 a_7 &= 2 + a_8 - \frac{0.5455}{0.9229} \end{aligned} \tag{85.53}$$

Solving these equations, the following values are obtained: $a_8 = 0.0835$, $a_5' = 0.2116$, and $a_2 a_7 = 1.4924$. A typical design procedure employs $a_2 = 1$. For this case, the total capacitance is of the order of 32 unit capacitances. The frequency response of the filters is shown in Fig. 85.18.

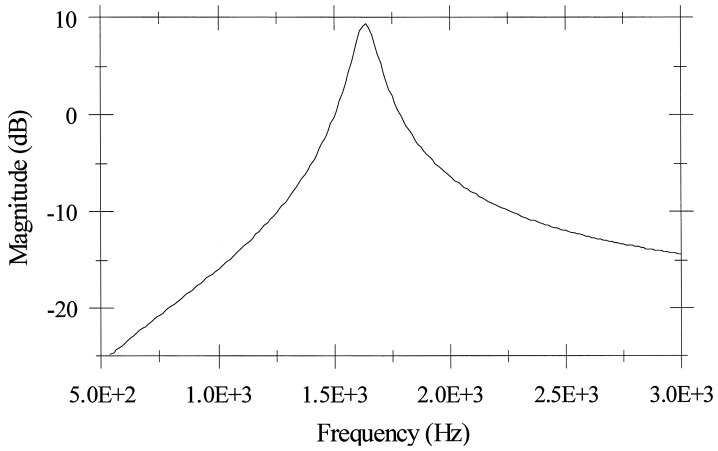

FIGURE 85.18 Frequency response of the second-order bandpass filter.

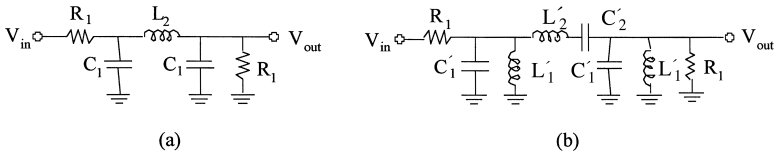

FIGURE 85.19 RLC prototypes. (a) Third-order low-pass filter and (b) sixth-order bandpass filter.

A Sixth-Order Bandpass Ladder Filter

In this section, the design procedure for a sixth-order bandpass filter based on an RLC prototype is considered. The ladder filters are very attractive because of their low passband sensitivity to tolerances in the filter components. Let us consider the following specifications:

Center frequency	100 kHz
Bandwidth	2.5 kHz
Passband ripple	<0.5 dB
Clock frequency	2 MHz

The design starts with an RLC low-pass prototype; see Fig. 85.19.

The values of the components for a prototype with 1 rad/s passband frequency can be obtained from tables or computed from well-known expressions. For this example, the passive components are $R_1 = 1\ \Omega$, $C_1 = 1.5963$ F, and $L_2 = 1.0967$ H. Using the low-pass to bandpass transformation, the capacitor C_1 is transformed in a parallel of a capacitor and an inductor. The values of the resulting components are

$$C_1' = \frac{C_1}{BW}$$
$$L_1' = \frac{1}{\omega_0^2 C'} \tag{85.54}$$

where ω_o and BW are the center frequency in radians per second and the filter bandwidth in radians per second, respectively. The inductor L_2 is transformed in a series of an inductor and a capacitor whose values become

$$L_2' = \frac{L_2}{BW}$$
$$C_2' = \frac{1}{\omega_0^2 L_2'} \tag{85.55}$$

The bandpass prototype is shown in Fig. 85.19(b). Before making the denormalizations it is desirable to transform the passive prototype to an active implementation. The grounded *LC* tank circuit can be simulated by the *RC* active implementation shown in Fig. 85.20.

The value of the simulated inductance is

$$L_1' = R_1^2 C_1' \tag{85.56}$$

It is important to note that the output of the active *RC* circuit is a low-impedance node. Therefore, the inverting input of the op-amps must be used for current injection. Similarly, the circuit shown in Fig. 85.21 can simulate a floating resonator. Obviously, this is an expensive implementation but typically several active elements can be shared in the final design. Using typical circuit analysis techniques it can be shown that i_{12} for the passive *LC* tank is related to the components by the following expression:

© 2003 by CRC Press LLC

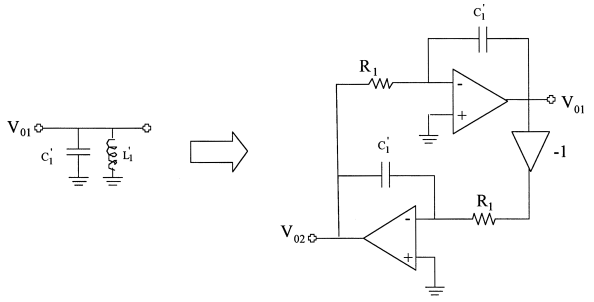

FIGURE 85.20 RC active implementation of a grounded LC tank circuit.

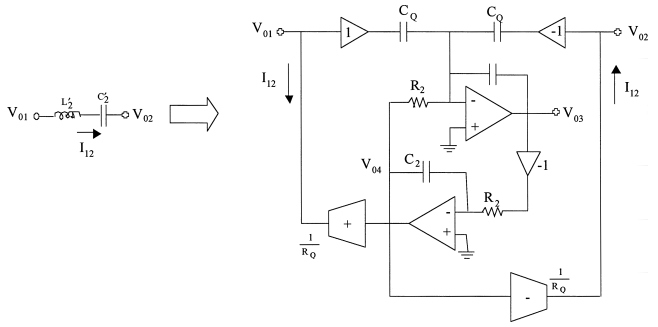

FIGURE 85.21 RC active implementation of a floating LC tank circuit.

$$i_{12} = \frac{sC_2'}{1+s^2L_2'C_2'}\left(v_{o1} - v_{o2}\right) \tag{85.57}$$

and for the active implementation

$$i_{12} = \frac{\left(\frac{R_2}{R_Q}C_Q\right)s}{1+s^2R_2^2C_2^2}\left(v_{o1} - v_{o2}\right) \tag{85.58}$$

Comparing (85.57) and (85.58), the active and passive implementations are equivalents if the following constraints are satisfied:

$$C_2' = \frac{R_2}{R_Q}C_Q \tag{85.59}$$

$$L_2'C_2' = R_2^2C_2^2 \tag{85.60}$$

Obviously, the resistors R_2 can be replaced by switched capacitor equivalents. Using these building blocks, the implementation of the sixth-order bandpass filter is straightforward. The sixth-order switched-capacitor bandpass filter is shown in Fig. 85.22. The implementation of the $L_1'C_1'$ tank circuit is straightforward from Fig. 85.20. The resonant frequency of the switched-capacitor resonator is determined by the capacitors θC_1. The node voltage v_{o1} is taken at the output of the first op-amp. The input resistor is implemented by the capacitor C_R and its associated switches. In Fig. 85.22, the resonator associated with v_{o3} and v_{o4} and the capacitors C_Q implement the $L_2'C_2'$ floating tank circuit. The final step of the design is to compute the values of the components. A simplified design follows, but more detailed procedures are presented in [1], [2], and [6].

© 2003 by CRC Press LLC

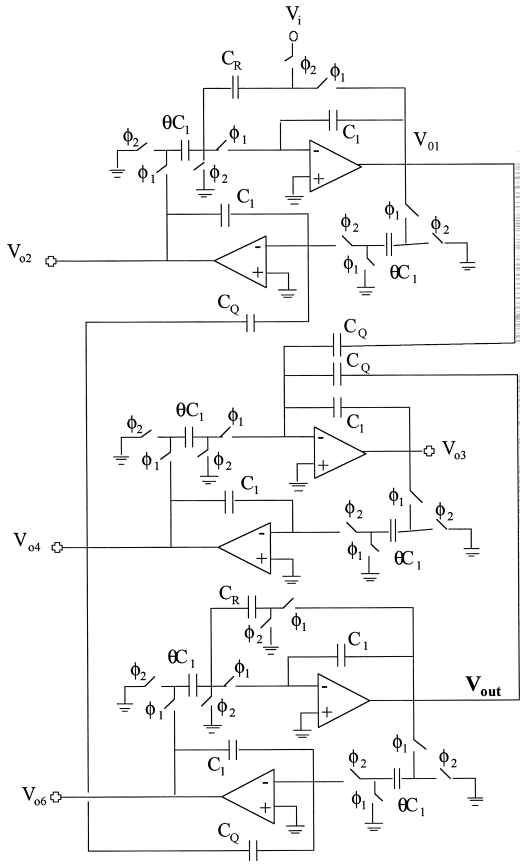

FIGURE 85.22 Sixth-order bandpass ladder filter

The loops of the switched-capacitor filter implementation are of the lossless discrete integrator (LDI) type and the resistors are of the serial type. Hence, if an LDI prewarping scheme is used, the analog center frequency of the filter should be mapped to the desired value, mainly for high-Q filters wherein the interaction between resonators is very small. Since the resistors are not LDI, a distortion in the quality factor of the filter sections occurs, and thus increases the passband ripple. The LDI transformation relates the analog and discrete frequencies by the following expression [1], [6]:

$$\omega_{\text{analog}} = 2f_c \sin\left(\frac{\omega_{\text{discrete}}}{2f_c}\right) \tag{87.61}$$

Applying the LDI transformation to the center frequency of the filter, the predistorted center frequency is equal to 99,056 kHz. Using this prewarped frequency and (85.54) through (85.60), the following component values are obtained:

$$R_1 = 1\ \Omega$$

$$C_1' = 1.01623 \times 10^{-4}\ \text{F}$$

$$\text{L}_1' = 2.51316 \times 10^{-8}\ \text{H}$$

$$C_2' = 3.65803 \times 10^{-8}\ \text{F}$$

$$L_2' = 6.98181 \times 10^{-5}\ \text{H}$$

© 2003 by CRC Press LLC

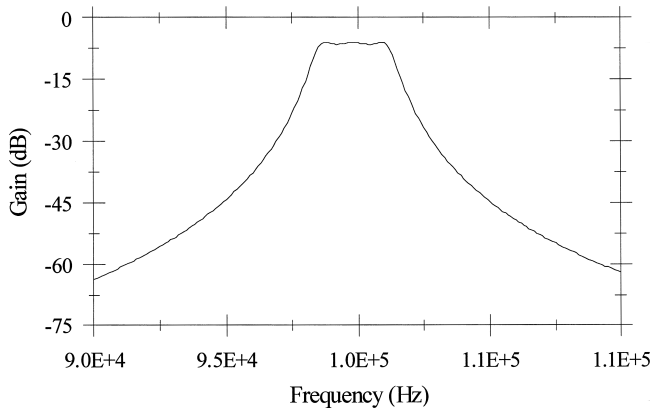

FIGURE 85.23 Frequency response for the sixth-order bandpass filter.

In addition, the continuous-time and switched-capacitor resistors are related by the following expression:

$$C_{eq} = \frac{1}{f_c R_{cont}} \tag{85.62}$$

In the switched-capacitor filter, the transconductor $1/R_Q$ is implemented by C_Q/C_1R. Hence, the final values of the capacitors are

$$C_R = 0.0738 \text{ pF}$$

$$C_1 = 15.000 \text{ pF}$$

$$\theta C_1 = 4.6900 \text{ pF}$$

$$C_Q = 0.2833 \text{ pF}$$

While the filter center frequency of this design is accurate, the passband ripple is increased to around 0.8 dB instead of 0.5 dB. This is because the resistors used in the terminals of the filter are not implemented as LDI resistors. However, this effect can be partially corrected by adjusting the resonant frequency of the second loop. If θC_1 is equal to 4.685 pF for the second resonator, the ripple is decreased to around 0.55 dB. The results for this case are shown in Fig. 85.23.

A Programmable Switched-Capacitor Filter

In most of the programmable filters, the important parameters are the resonant frequencies, the pole-quality factor, and sometimes the peak gain. Thus, programmable low-pass, bandpass, high-pass, and bump equalizers are typically designed. Nevertheless, in some applications it is more important to control the gain at the frequency bands instead of that at the resonant frequency, the quality factor, or the peak gain. A typical approach for the implementation of these systems is to employ a parallel of a low-pass, bandpass, and a high-pass filter with programmable peak gain. For a second-order system, the implementation of this approach needs at least six operational amplifiers, three capacitor banks, and the implementation of six poles. Therefore, the number of switches, the power dissipation, and the silicon area needed for these structures are considerable. Another approach follows in this section.

In order to independently control the low-, medium-, and high-frequency bands, it is required to realize the following function:

$$H(s) = \frac{K_1 s^2 + K_2 \text{BW} s + K_3 \omega_0^2}{s^2 + \text{BW} s + \omega_0^2} \tag{85.63}$$

© 2003 by CRC Press LLC

where BW and ω_o are the bandwidth and the frequency of the poles, respectively. The control of the frequency bands is carried out by the parameters K_1, K_2, and K_3. From (85.63) it is clear that the dc gain and the high-frequency gain are equal to K_3 and K_1, respectively. A disadvantage of this expression is the lack of good control in the medium frequencies. If K_1 is equal to K_3, the filter gain at the resonant frequency depends on K_2. However, for the general case it is affected by the parameters K_1 and K_3. In addition, the shape of the transfer function is not well behaved for moderate- and high-Q applications. The behavior of the transfer function is improved if the following equation is employed:

$$H(s) = K_1 \frac{s^2 + K_2 K_3 \mathrm{BW} s + K_3 \omega_0^2}{s^2 + K_1 \mathrm{BW} s + K_1 \omega_0^2} \tag{85.64}$$

For low and high frequencies, the behavior of this equation is similar to that of (85.63). At medium frequencies the behavior of the transfer function is better controlled by the parameter K_2 than for the case of (85.63). For the medium-frequency band, the gain is related to the product K_2K_3 instead of that of the absolute value of K_2. Therefore, the effect of parameter K_2 on the transfer function is linked to K_3.

A block diagram representation of (85.64) is presented in Fig. 85.24. In this figure, the filter bandwidth BW is equal to ω_o/Q, with Q equal to the quality factor of the filter. The control parameters are the gain factors K_1, K_2, and K_3. The implementation of this block diagram can be carried out by using various techniques, e.g., OTA-C, MOSFET-C, or switched-capacitor. A switched-capacitor implementation is shown in Fig. 85.25. For high sampling rate $2\pi f_c \gg \omega_o$, the capacitors θC_I are related to the pole frequency by the equation $\theta = \omega_o T$. The capacitor banks control the gain of the three frequency bands. For the computation of the total capacitance, the capacitors can be associated in the following groups: the first group (K_3 C_I, C_1), second group (θC_2, K_2C_2/Q, C_2), and third group ($\theta C_3/Q$,θC_3, C_3/K_1, C_3).

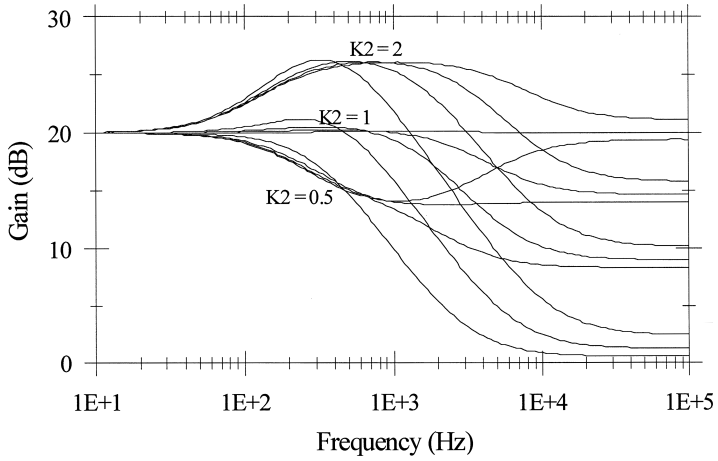

FIGURE 85.26 Effect of the parameter K_2 on the filter transfer function. For this plot K_3 = 10 and K_1 has been varied (1, 2.5, 5, and 10).

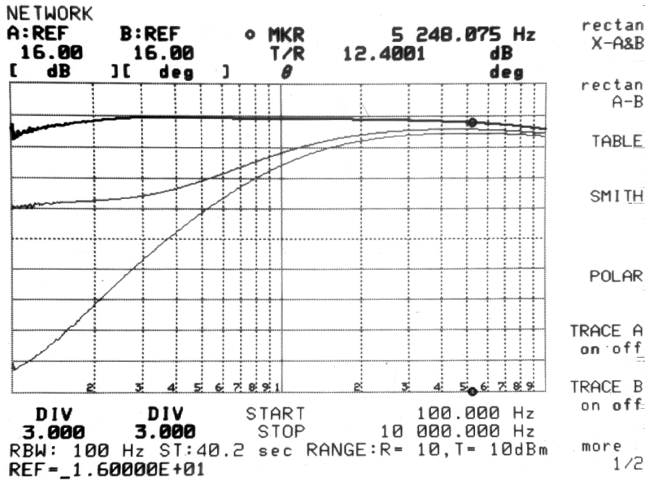

FIGURE 85.27 Experimental frequency response of the programmable SC filter.

The versatility of the topology is shown in Fig. 85.26. For these results, the following design parameters have been employed: clock frequency = 128 kHz, ω_o = 6.2832 * 350 rad/s, and Q = 0.5. For Fig. 85.26, the parameter K_3 is equal to 10, fixing the low frequency gain at 20 dB. The medium-frequency band is controlled by the parameter K_2, which corresponds to the values 0.5 (attenuation of 6 dB), 1 (0 dB attenuation), and 2 (gain of 6 dB). The high-frequency gain is controlled by the parameter K_1, which corresponds to the values 1, 2.5, 5, and 10, giving a high-frequency gain of 0, 8, 14, and 20 dB, respectively. Experimental results for a chip fabricated in a 0.8 μm CMOS process are shown Fig. 85.27. For these results, K_1 and K_2 were fixed to 10 and 1, respectively. The low-frequency gain is controlled using the parameter K_3.

86.1 Properties of FIR Filters

M. H. Er

Linear Phase Property

The finite-impulse response (FIR) filter is characterized by a unit-sample response that has a finite duration. One of the advantages of FIR filters compared to their infinite-impulse response (IIR) counterparts is that FIR filters can be designed with exactly linear phase. Linear phase response is important for applications where phase distortion due to nonlinear phase can degrade performance, such as in data transmission and television applications.

A FIR causal filter can be characterized by the transfer function [1]

$$H(z) = \sum_{n=0}^{N-1} h(nT) z^{-n} \tag{86.1}$$

where $h(nT)$ is the impulse response of the filter, N is the filter length, and T is the sampling interval. Using the relationship that

$$H(z) = \frac{Y(z)}{X(z)} \tag{86.2}$$

the difference equation of a FIR filter can be obtained by taking the inverse Z-transform of (86.1), that is

$$y(iT) = \sum_{n=0}^{N-1} h(nT) X(iT - nT) \tag{86.3}$$

which says that the current output of a FIR causal filter is the weighted sum of the current and past inputs. The weighting coefficients are given by the impulse response of the filter.

© 2003 by CRC Press LLC

From (86.1), the frequency response can be obtained by replacing $z = e^{j\omega T}$ as

$$H\left(e^{j\omega T}\right) = \sum_{n=0}^{N-1} h(nT) e^{-j\omega nT} = M(\omega) e^{j\phi(\omega)} \tag{86.4}$$

where $M(\omega)$ and $\phi(\omega)$ are the magnitude and phase responses, respectively, defined as

$$M(\omega) = \left|H\left(e^{j\omega T}\right)\right| \tag{86.5a}$$

$$\phi(\omega) = \arg\ H\left(e^{j\omega T}\right) \tag{86.5b}$$

The phase delay and group (time) delay functions of a filter are defined as

$$\tau_p = -\frac{\phi(\omega)}{\omega} \tag{86.6}$$

and

$$\tau_g = -\frac{d\phi(\omega)}{d\omega} \tag{86.7}$$

respectively. Filters for which τ_p and τ_g are independent of frequency are referred to as constant time delay or linear phase filters. Hence, the phase response of a linear phase filter is given by

$$\phi(\omega) = -\tau\omega, \qquad -\pi < \omega < \pi \tag{86.8}$$

where τ is a constant phase delay in samples.

From (86.4), (86.5b), and (86.8), the phase response can be expressed as

$$\phi(\omega) = -\tau\omega = \tan^{-1} \frac{-\sum_{n=0}^{N-1} h(nT)\sin(\omega nT)}{\sum_{n=0}^{N-1} h(nT)\cos(\omega nT)} \tag{86.9}$$

Consequently,

$$\tan(\omega\tau) = \frac{\sum_{n=0}^{N-1} h(nT)\sin(\omega nT)}{\sum_{n=0}^{N-1} h(nT)\cos(\omega nT)} \tag{86.10}$$

Using the definition $\tan(\omega\tau) = \sin(\omega\tau)/\cos(\omega\tau)$, (86.10) can be reexpressed as

$$\sum_{n=0}^{N-1} h(nT)\sin(\omega\tau - \omega nT) = 0 \tag{86.11}$$

It can be shown [1] that a solution to (86.11) is given by

$$\tau = \frac{(N-1)T}{2} \tag{86.12}$$

© 2003 by CRC Press LLC

and

$$h(nT) = h\left[(N-1-n)T\right] \qquad 0 \le n \le N-1 \tag{86.13}$$

Hence, FIR filters can be designed to have constant phase and group delays if the conditions of (86.12) and (86.13) are satisfied. The symmetry property of (86.13) can also lead to efficient filter realizations.

In applications where only constant group delay is needed, the phase response can have the form

$$\phi(\omega) = \phi_0 - \tau\omega \tag{86.14}$$

where ϕ_0 is a constant. With $\phi_0 = \pm\pi/2$, it can be shown [1] that the impulse response is of the form

$$h(nT) = -h\left[(N-1-n)T\right] \qquad 0 \le n \le N-1 \tag{86.15}$$

In this case, the impulse response exhibits antisymmetrical property.

Frequency Response of Linear Phase FIR Filters

The frequency response of a causal linear phase FIR filter can be simplified to some simple forms using (86.13) and (86.15) and the values of N as follows:

(1) ***Symmetric Impulse Response and N = Odd.*** In this case,

$$\begin{aligned} H\left(e^{j\omega T}\right) = &\sum_{n=0}^{(N-3)/2} h(nT)e^{-j\omega nT} + h\left[\frac{(N-1)T}{2}\right]e^{-j\omega(N-1)T/2} \\ &+ \sum_{n=(N+1)/2}^{N-1} h(nT)e^{-j\omega nT} \end{aligned} \tag{86.16}$$

Using (86.13), letting $m = N - 1 - n$ and changing the limits of summation, and finally letting $m = n$, the last summation in (86.16) can be reexpressed as

$$\sum_{n=(N+1)/2}^{N-1} h(nT)e^{-j\omega nT} = \sum_{n=0}^{(N-3)/2} h(nT)e^{-j\omega(N-1-n)T} \tag{86.17}$$

Substituting (86.17) into (86.16), one obtains

$$\begin{aligned} H\left(e^{j\omega T}\right) = &\sum_{n=0}^{(N-3)/2} h(nT)\left[e^{-j\omega nT} + e^{-j\omega(N-1-n)T}\right] \\ &+ h\left[\frac{(N-1)T}{2}\right]e^{-j\omega(N-1)T/2} \end{aligned} \tag{86.18}$$

Factoring $e^{-j\omega(N-1)T/2}$ in (86.18) and letting $k = (N-1)/2 - n$, (86.18) can be reexpressed as

$$\begin{aligned} H\left(e^{j\omega T}\right) = e^{-j\omega(N-1)T/2}\Bigg\{ &\sum_{k=1}^{(N-1)/2} h\left[\left(\frac{N-1}{2} - k\right)T\right]\left(e^{j\omega kT} + e^{-j\omega kT}\right) \\ &+ h\left[\frac{(N-1)T}{2}\right]\Bigg\} \end{aligned} \tag{86.19}$$

© 2003 by CRC Press LLC

Using the property that $e^{j\theta} + e^{-j\theta} = 2\cos\theta$, (86.19) can be simplified to the form

$$H\left(e^{j\omega T}\right) = e^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{(N-1)/2} 2h\left[\left(\frac{N-1}{2}-k\right)T\right]\cos(\omega kT) + h\left[\frac{(N-1)T}{2}\right]\right\} \tag{86.20}$$

Letting $a(o) = h[(N-1)\,T/2]$ and $a(k) = 2h[((N-1)/2 - k)T]$, (86.20) can be simplified further to

$$H\left(e^{j\omega T}\right) = e^{-j\omega(N-1)T/2}\left[\sum_{k=0}^{(N-1)/2} a(k)\cos(\omega kT)\right] \tag{86.21}$$

(2) ***Symmetric Impulse Response and N = Even.*** For this case, the frequency response takes the form

$$H\left(e^{j\omega T}\right) = e^{-j\omega(N-1)T/2}\left\{\sum_{k=0}^{N/2-1} 2h(kT)\cos\left[\omega\left(\frac{N}{2}-k-\frac{1}{2}\right)T\right]\right\} \tag{86.22}$$

Letting $b(k) = 2h[N/2 - k)T]$, $k = 1, 2, \ldots, N/2$, (86.22) can expressed as

$$H\left(e^{j\omega T}\right) = e^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{N/2} b(k)\cos\left[\omega\left(k-\frac{1}{2}\right)T\right]\right\} \tag{86.23}$$

An interesting feature of this frequency response is that $H(e^{j\omega T})$ is always equal to zero for $\omega = \pi$, independent of $b(k)$. This implies that high-pass filter characteristics cannot be realized with this type of filter.

(3) ***Antisymmetric Impulse Response and N = Odd.*** For this case, the derivation of the frequency response is the same as that in (1) except that the cosine summations are replaced by the sine summations multiplied by j because of (86.15). Hence, the frequency response is given by

$$H\left(e^{j\omega T}\right) = je^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{(N-1)/2} 2h\left[\left(\frac{N-1}{2}-k\right)T\right]\sin(\omega kT) + h\left[\frac{(N-1)T}{2}\right]\right\} \tag{86.24}$$

It should be noted that for odd values of N, (86.15) requires that $h[(N-1)T/2] = 0$. Letting $c(k) = 2h[((N-1)/2 - k)T]$, $k = 1, 2, \ldots, (N-1)/2$, (86.24) becomes

$$H\left(e^{j\omega T}\right) = je^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{(N-1)/2} c(k)\sin(\omega kT)\right\} \tag{86.25}$$

A notable feature of this frequency response is that at frequencies $\omega = 0$ and $\omega = \pi$, the frequency response is always zero, independent of $c(k)$.

© 2003 by CRC Press LLC

TABLE 86.1 Frequency Response of Linear Phase FIR Filters

$h(nT)$	N	$H(e^{j\omega T})$
Symmetrical	Odd	$e^{-j\omega(N-1)T/2}\sum_{k=0}^{(N-1)/2} a(k)\cos(\omega kT)$
	Even	$e^{-j\omega(N-1)T/2}\sum_{k=1}^{N/2} b(k)\cos\left[\omega\left(k-\frac{1}{2}\right)T\right]$
Antisymmetrical	Odd	$je^{-j\omega(N-1)T/2}\sum_{k=1}^{(N-1)/2} c(k)\sin(\omega kT)$
	Even	$je^{-j\omega(N-1)T/2}\sum_{k=1}^{N/2} d(k)\sin\left[\omega\left(k-\frac{1}{2}\right)T\right]$

where $a(o)=h\left[\frac{(N-1)T}{2}\right]$, $a(k)=c(k)=2h\left[\left(\frac{N-1}{2}-k\right)T\right]$, $b(k)=d(k)=2h\left[\left(\frac{N}{2}-k\right)T\right]$

(4) ***Antisymmetric Impulse Response and N = Even.*** For this case, the frequency response is the same as that in (2) except the cosine summations become sine summations multiplied by j as follows:

$$H\left(e^{j\omega T}\right)=je^{-j\omega(N-1)T/2}\left\{\sum_{k=0}^{N/2-1}2h(kT)\sin\left[\omega\left(\frac{N}{2}-k-\frac{1}{2}\right)T\right]\right\} \tag{86.26}$$

Letting $d(k) = 2h[N/2 - k)T]$, $k = 1, 2, \ldots, N/2$, (86.26) becomes

$$H\left(e^{j\omega T}\right)=je^{-j\omega(N-1)T/2}\left\{\sum_{k=1}^{N/2}d(k)\sin\left[\omega\left(k-\frac{1}{2}\right)T\right]\right\} \tag{86.27}$$

In this case, the frequency response is zero at $\omega = 0$, independent of $d(k)$.

In summary, the frequency responses of the four possible types of FIR filters with linear phase are given in Table 86.1.

Locations of Zeros of Linear Phase FIR Filters

The symmetric and antisymmetric conditions of the impulse response given by (86.13) and (86.15) impose certain constraints on the zeros of the transfer function $H(z)$ [2]. For the case where N is an odd value, $H(z)$ can be written as

$$H(z)=z^{-(N-1)/2}\sum_{k=0}^{(N-1)/2}\frac{a(k)}{2}\left(z^{k}\pm z^{-k}\right) \tag{86.28}$$

where the ± sign corresponds to symmetry and antisymmetry in the impulse response respectively, and $a(o)$ and $a(k)$ are defined in Table 86.1.

Substituting z^{-1} for z in (86.28), one obtains

$$H\left(z^{-1}\right)=z^{(N-1)/2}\sum_{k=0}^{(N-1)/2}\frac{a(k)}{2}\left(z^{-k}\pm z^{k}\right) \tag{86.29}$$

© 2003 by CRC Press LLC

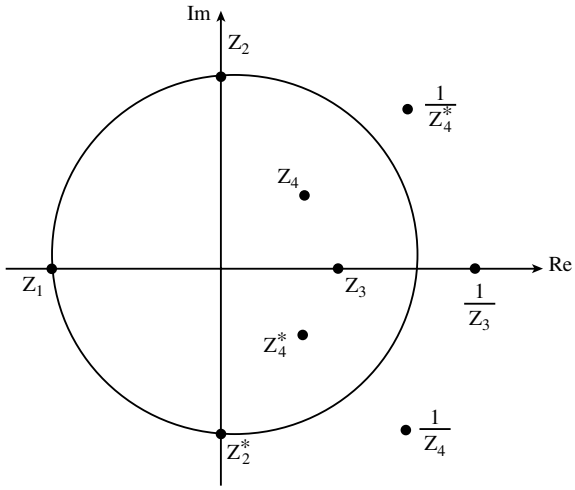

FIGURE 86.1 Typical zero positions of linear phase filters.

It follows from (86.28) and (86.29) that

$$H\left(z^{-1}\right) = \pm z^{(N-1)} H(z) \tag{86.30}$$

Equation 86.30 shows that $H(z)$ and $H(z^{-1})$ are identical to within a delay of $(N-1)$ samples and a multiplier of ± 1. Thus, the zeros of $H(z^{-1})$ are identical to the zeros of $H(z)$. Therefore, if $z_i = r_i e^{j\phi_i}$ is a zero of $H(z)$, then $z_i^{-1} = (1/r_i)e^{-j\phi_i}$ must also be a zero of $H(z)$. This has the following implications on the zero locations:

1. If $r_i = 1$ and $\phi_i = 0$ or π, then the zeros lie at either $z = +1$ or $z = -1$. In these cases, the zero is its own complex conjugate.
2. If $r_i = 1$ and $\phi_i \neq 0$ or π, then the zeros of $H(z)$ that are on the unit circle are also zeros of $H(z^{-1})$ that are on the unit circle. Hence, the zeros occur in complex conjugate pairs on the unit circle.
3. If $r_i \neq 1$ and $\phi_i = 0$ or π, then the zeros are real and occur in reciprocal pairs on the unit circle.
4. If $r_i \neq 1$ and $\phi_i \neq 0$ or π, then the zeros occur in quadruplets with complex conjugate reciprocal pairs off the unit circle.

Figure 86.1 shows the possible types of zeros for linear phase FIR filters.

86.2 Windowing Techniques

M. H. Er

Windowing is one of the earliest techniques for designing FIR filters [3], [4]. The technique is simple because the filter coefficients can be obtained in closed form without the need for solving complex optimization problems as in some other sophisticated FIR design techniques. Hence, the design time is very short and the technique remains an attractive tool for FIR filter design.

To understand the windowing technique, first consider the process of obtaining a finite-length impulse response by truncating an infinite-duration impulse response sequence. Suppose $H_d(e^{j\omega T})$ is an ideal desired low-pass response with cutoff frequency ω_c. As the frequency response of an FIR filter is a periodic function, it can be expressed as a Fourier series as

$$H_d\left(e^{j\omega T}\right) = \sum_{n=-\infty}^{\infty} h_d(nT) e^{-j\omega nT} \tag{86.31}$$

© 2003 by CRC Press LLC

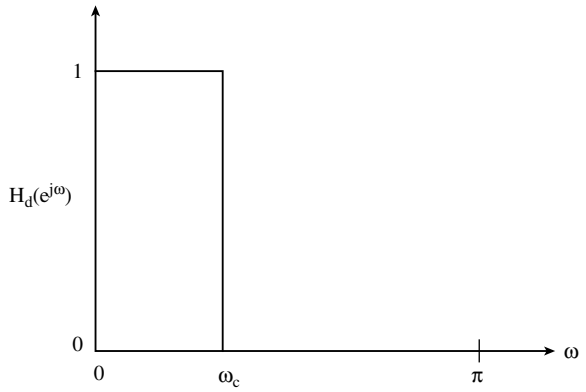

FIGURE 86.2 An ideal low-pass filter specification.

where

$$h_d(nT) = \frac{T}{2\pi}\int_{-\pi/T}^{\pi/T} H_d\left(e^{j\omega T}\right)e^{j\omega nT}d\omega \tag{86.32}$$

In general, $H_d(e^{j\omega T})$ is piecewise constant with a certain passband and stopband and with discontinuities at the boundaries between bands. Hence, the impulse sequence $h_d(nT)$ is of infinite duration. For example, for the ideal low-pass response shown in Fig. 86.2, the corresponding impulse response sequence is given by

$$h_d(nT) = \frac{\omega_c T}{\pi}\left(\frac{\sin\omega_c nT}{\omega_c nT}\right) \quad -\infty \le n \le \infty \tag{86.33}$$

It is clear that (86.33) is a noncausal IIR filter. Also it is unstable and therefore unrealizable.

The Rectangular Window. One way to obtain a finite-duration causal impulse response is to simply truncate $h_d(nT)$ and introduce sufficient delay to obtain a causal impulse response, i.e., define

$$h(nT) = \begin{cases} h'_d(nT) & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{86.34}$$

where $h'_d(nT)$ is a delay version of $h_d(nT)$.

This can be represented as the product of the desired impulse response and a finite-duration window $w_r(nT)$, i.e.,

$$h(nT) = h'_d(nT)w_r(nT) \tag{86.35}$$

where $w_r(nT)$ is the rectangular window function defined as

$$w_r(nT) = \begin{cases} 1 & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{86.36}$$

Let $\theta = \omega T$ and using the fact that multiplication of two discrete-time sequences corresponds to a convolution of their Fourier transforms. Hence,

$$H\left(e^{j\omega}\right) = \frac{1}{2\pi}\int_{-\pi}^{\pi} H'_d\left(e^{j\theta}\right)W_r\left(e^{j(\omega-\theta)}\right)d\theta \tag{86.37}$$

where $W_r(e^{j\theta})$ is the spectrum of the rectangular window.

© 2003 by CRC Press LLC

Since the two functions in the integral are periodic, a circular convolution results and the limits of integration are taken over one period. Thus the frequency response $H(e^{j\omega})$ will be a "smeared" version of the desired response $H_d'(e^{j\omega})$ and the discontinuities in the desired frequency response become transition bands of $H(e^{j\omega})$. To understand this, it is instructive to examine the frequency response for the causal rectangular window, that is,

$$W_r\left(e^{j\omega T}\right) = \sum_{n=0}^{N-1} e^{-j\omega nT} = e^{-j\omega(N-1)T/2}\frac{\sin\left(\omega NT/2\right)}{\sin\left(\omega T/2\right)} \tag{86.38}$$

The spectrum $W_r(e^{j\omega T})$ for $N = 31$ is shown in Fig. 86.3. The spectrum $W_r(e^{j\omega T})$ has two features that are worth noting, the mainlobe width and the sidelobe amplitude. The mainlobe width is defined as the distance between the two points closest to $\omega = 0$, where $W_r(e^{j\omega T})$ is zero. For a rectangular window, the mainlobe width is equal to $4\pi/N$. The maximum sidelobe amplitude for $W_r(e^{j\omega T})$ is equal to approximately –13 dB relative to the maximum value at $\omega = 0$.

Figure 86.4 shows the log–magnitude response of applying a 31-point rectangular window to approximate an ideal low-pass filter with a cutoff frequency equal to $\pi/4$. It can be seen that the sharp transition in the ideal response at $\omega = \omega_c$ has been converted into a gradual transition. Also, in the passband a series of overshoots and undershoots occur, and in the stopband, where the desired response is zero, the FIR filter has a nonzero response. These are the results of the convolution between $W_r(e^{j\omega T})$ and $H_d(e^{j\omega T})$. The mainlobe of $W_r(e^{j\omega T})$ causes the smearing of the desired response and the sidelobes of $W_r(e^{j\omega T})$ appear as overshoots and undershoots to the desired response. It is interesting to note that there will always be oscillations in the function $H(e^{j\omega T})$ in the vicinity of the steep transitions in $H_d'(e^{j\omega T})$, no matter how large the value of N as shown in Fig. 86.5 for $N = 61$. This result is known as the Gibbs phenomenon [2] in the theory of Fourier series.

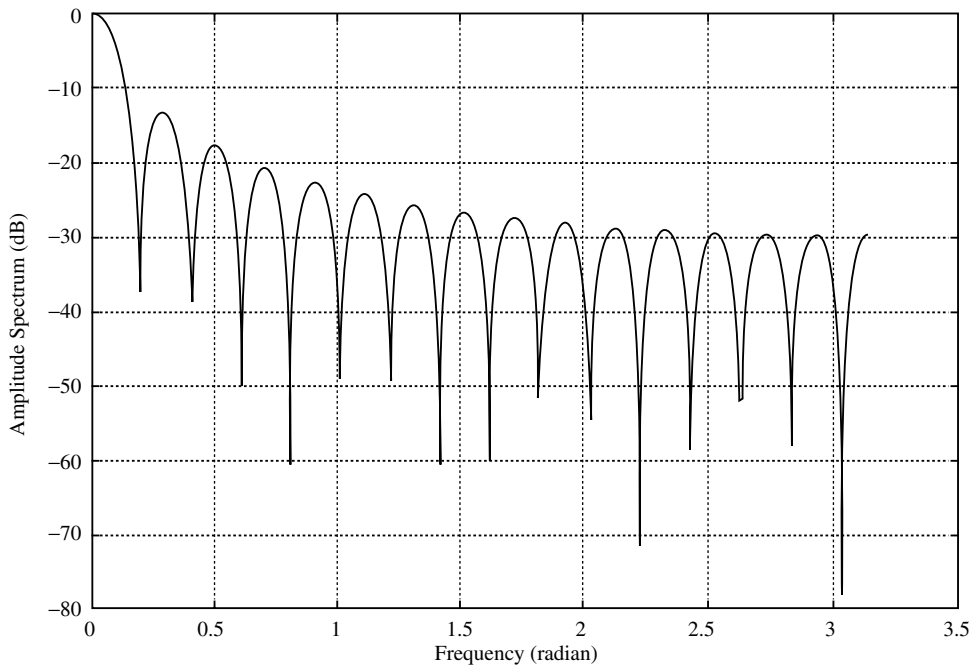

FIGURE 86.3 Fourier transform of the rectangular window.

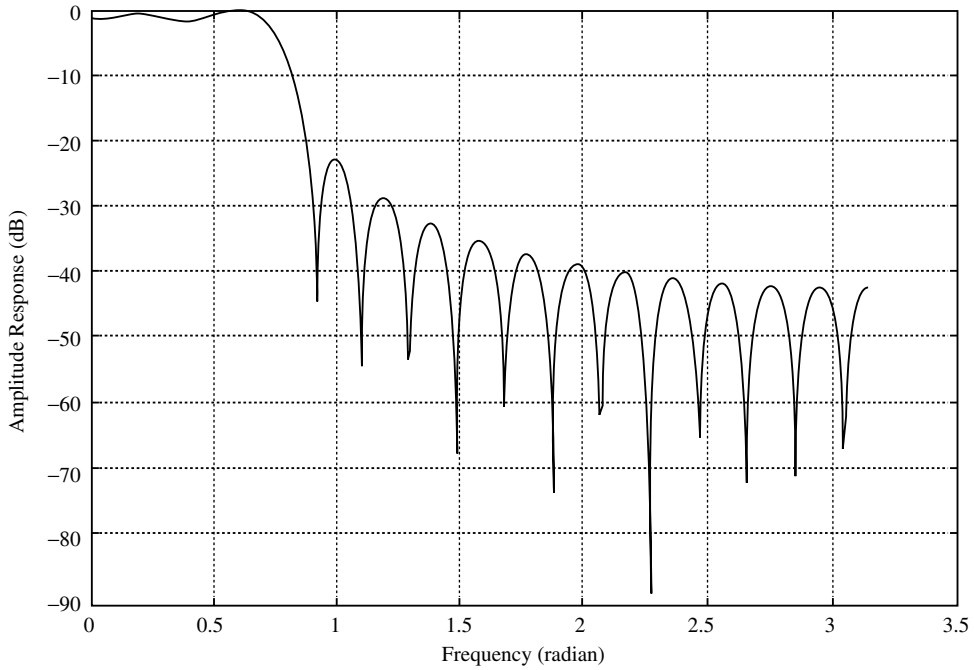

FIGURE 86.4 Magnitude response of low-pass FIR filter design using a 31-point rectangular window.

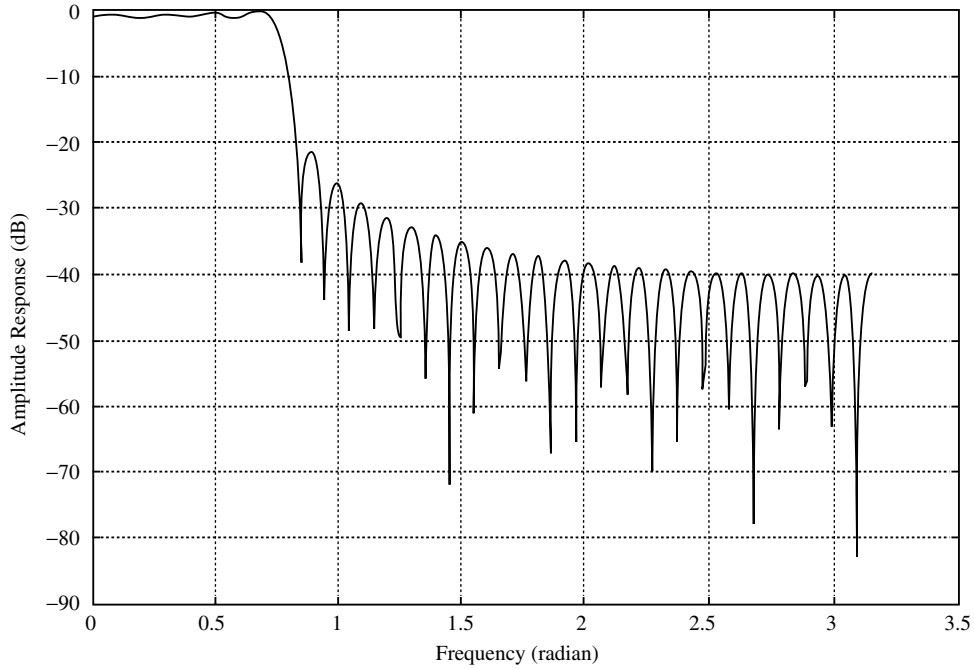

FIGURE 86.5 Magnitude response of low-pass FIR filter design using a 61-point rectangular window.

To reduce the oscillations in $H(e^{j\omega T})$, other window functions having spectra exhibiting smaller sidelobes must be used. To understand how the form of windows should be selected, it is observed that the sidelobes of the rectangular window represent the high-frequency components and are due to the sharp transitions from one to zero at the edges of the window. Therefore, the amplitudes of these sidelobes can

© 2003 by CRC Press LLC

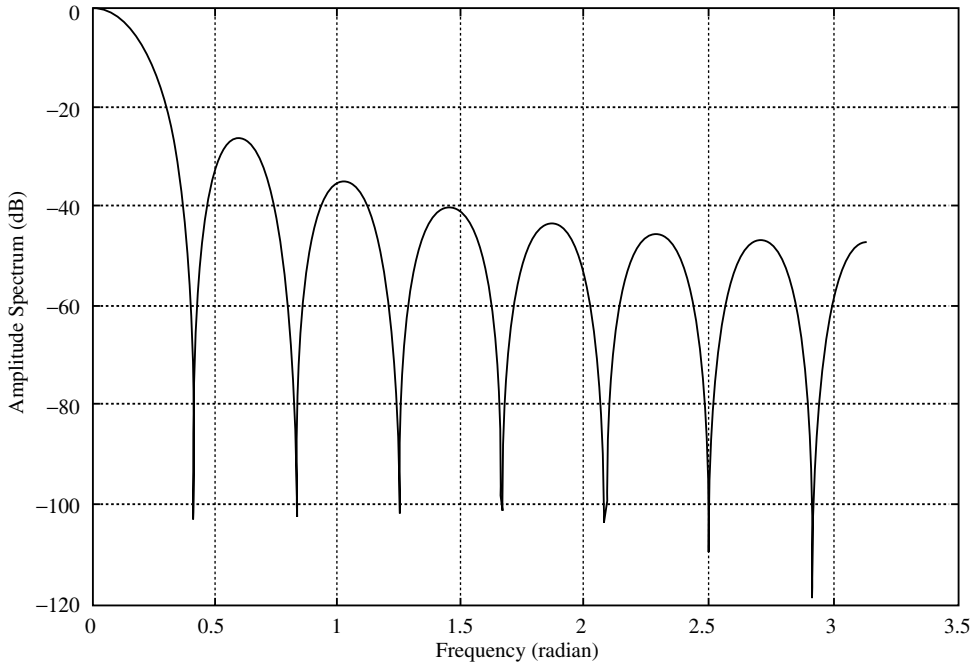

FIGURE 86.6 Fourier transform of the Bartlett window.

be reduced by replacing the sharp transitions by more gradual ones. Some of the most frequently used window functions are described below.

The Bartlett Window. The Bartlett window, also known as the triangular window, is defined as

$$w_t(nT) = \begin{cases} \dfrac{2n}{N-1} & 0 \le n \le \dfrac{N-1}{2} \\ 2 - \dfrac{2n}{N-1} & \dfrac{N-1}{2} \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{86.39}$$

The spectrum $W_t(e^{j\omega T})$ is shown in Fig. 86.6. As expected, the sidelobe level is smaller than that of the rectangular window, being reduced from –13 to –25 dB relative to the maximum. However, the mainlobe width is now $8\pi/N$, twice that of the rectangular window. Hence, there is a trade-off between mainlobe width and sidelobe level.

Figure 86.7 illustrates the FIR low-pass magnitude response obtained by using the Bartlett window. Comparing Fig. 86.7 to Fig. 86.4, it is observed that the Bartlett window produces a smoother magnitude response.

The Hanning Window. The Hanning window, also known as the raised-cosine window, is given by

$$w_c(nT) = \begin{cases} \dfrac{1}{2}\left[1 - \cos\left(\dfrac{2\pi n}{N-1}\right)\right] & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{86.40}$$

© 2003 by CRC Press LLC

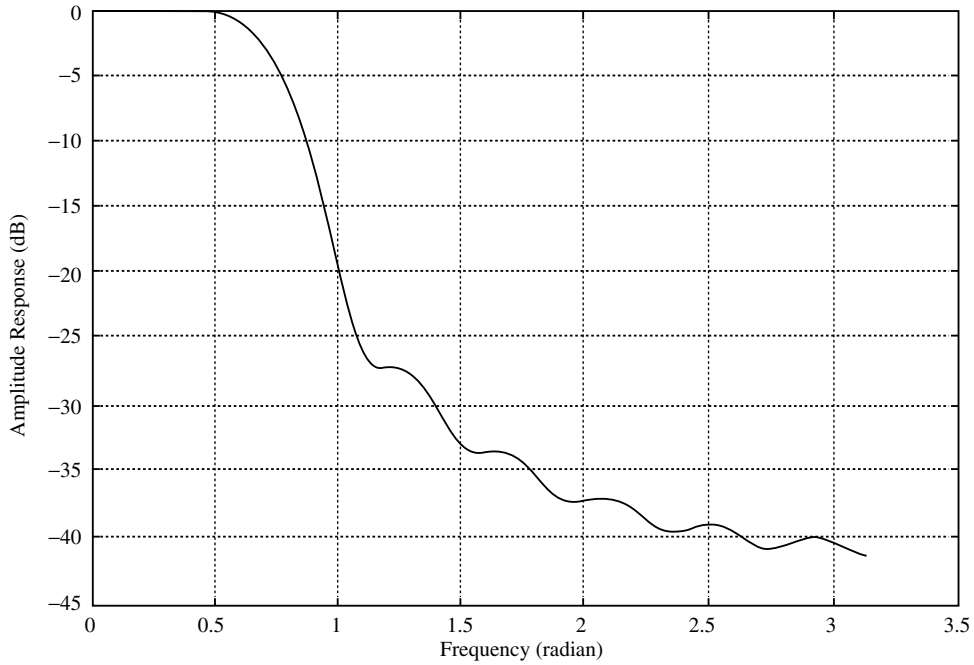

FIGURE 86.7 Magnitude response of low-pass FIR filter design using a 31-point Bartlett window.

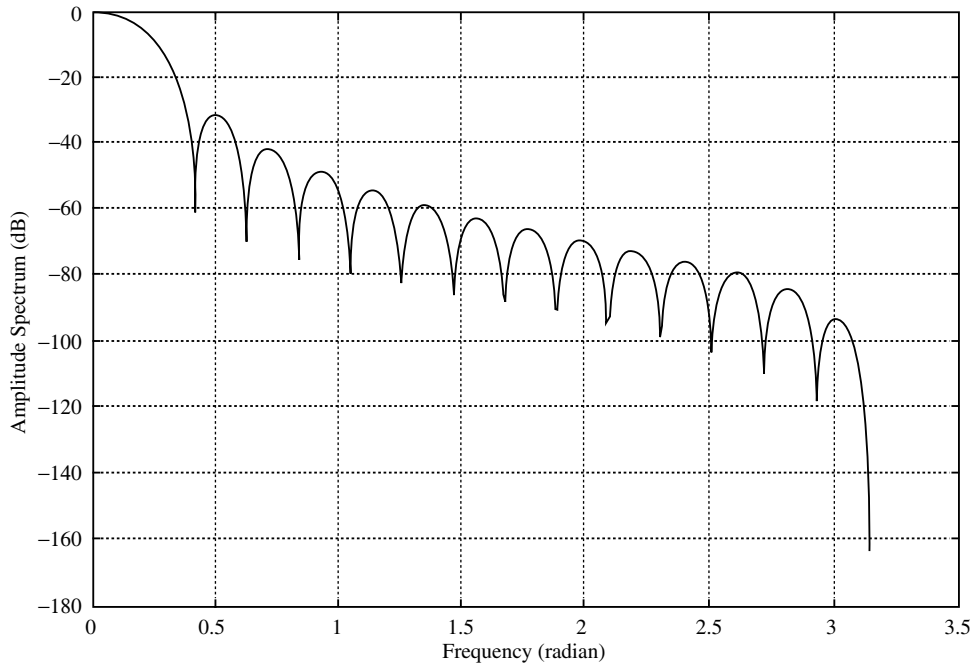

FIGURE 86.8 Fourier transform of the Hanning window.

The amplitude spectrum of this window is shown in Fig. 86.8 for $N = 31$. The magnitude of the first sidelobe level is –31 dB, down with respect to the peak value at $\omega = 0$. Comparing to the triangular window, there is an improvement of 6 dB. Since the mainlobe widths of both windows are the same, the Hanning window is preferred over the triangular one.

© 2003 by CRC Press LLC

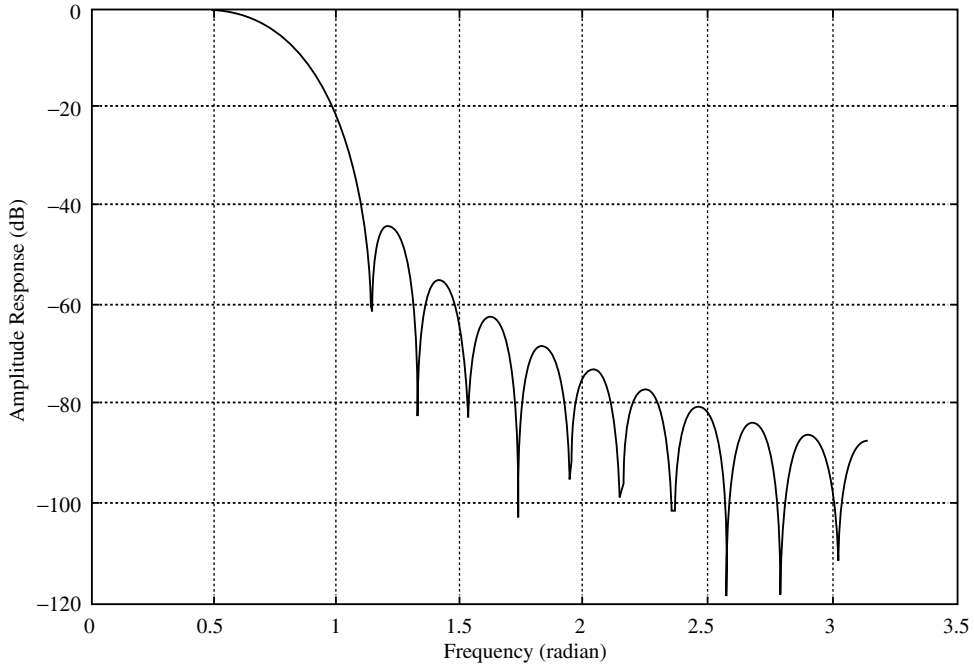

FIGURE 86.9 Magnitude response of low-pass FIR filter design using a 31-point Hanning window.

The amplitude response of the FIR low-pass filter with $\omega_{c=}\pi/4$ produced by applying the Hanning window with $N = 31$ is shown in Fig. 86.9. The largest peak in the stopband is now reduced to –44 dB relative to the passband level.

The Hamming Window. The Hamming window is given by

$$w_h(nT) = \begin{cases} 0.54 - 0.46\cos\left(\dfrac{2\pi n}{N-1}\right) & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{86.41}$$

Figure 86.10 shows the amplitude spectrum of the Hamming window, The magnitude of the highest sidelobe is about –41 dB, a reduction of 10 dB relative to the Hanning window. This reduction is achieved at the expense of higher sidelobes at the higher frequencies.

Figure 86.11 illustrates the amplitude response of the FIR low-pass filter with $\omega_c = \pi/4$ obtained by applying the Hamming window for $N = 31$. The first sidelobe peak is –51 dB, a –7 dB improvement with respect to that using the Hanning window. However, it is noted that as frequency increases, the stopband attenuation does not increase as much as that produced by using the Hanning window.

The Blackman Window. The Blackman window is given by

$$w_b(nT) = \begin{cases} 0.42 - 0.5\cos\left(\dfrac{2\pi n}{N-1}\right) + 0.08\cos\left(\dfrac{4\pi n}{N-1}\right) & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{86.42}$$

The amplitude response of the Blackman window is shown in Figure 86.12. It can be seen that it has the highest sidelobe level, down –57 dB from the mainlobe peak. However, the mainlobe width has increased to $12\pi/N$.

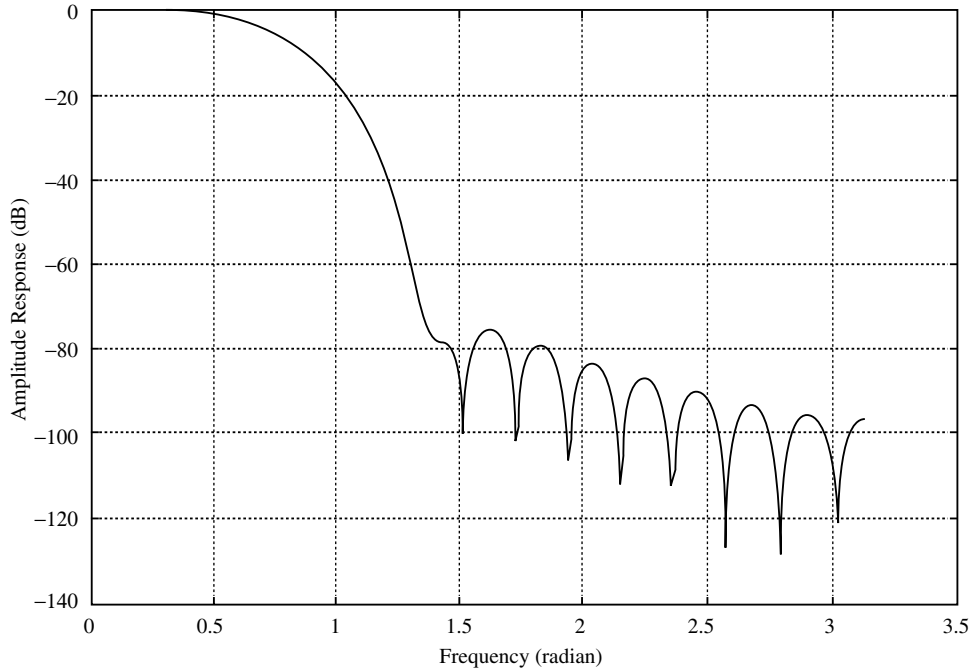

FIGURE 86.13 Magnitude response of low-pass FIR filter design using a 31-point Blackman window.

The amplitude response of the FIR low-pass filter obtained when applying the Blackman window is shown in Fig. 86.13. The minimum attenuation in the stopband is about –74 dB, but it occurs for $\omega > \pi/2$.

© 2003 by CRC Press LLC

The Kaiser Window. For the foregoing windows, the width of the mainlobe is inversely proportional to N. However, the minimum stopband attenuation is independent of the window length and is a function of the selected window. Hence, to meet a desired stopband attenuation, the designer is forced to select a window that meets the design specifications. It is worth noting that windows with low sidelobe levels have broader mainlobe widths, hence requiring an increase in the order of the filter N to achieve the desired transition width.

In 1974, Kaiser [4] introduced a new window, now known as the Kaiser window, based on discrete-time approximations of the prolate spheroidal wave functions. This window has a variable parameter β, which can be varied to control the sidelobe level with respect to the mainlobe peak. As in other windows, the mainlobe width can be adjusted by changing the length of the window, which in turn adjusts the transition width of the filter. Therefore, FIR filters can be efficiently designed using the Kaiser window.

The Kaiser windows are defined by

$$w_k(nT) = \begin{cases} \dfrac{I_0\left(2\beta\sqrt{\dfrac{n}{N-1}-\left(\dfrac{n}{N-1}\right)^2}\right)}{I_0(\beta)} & 0 \le n \le N-1 \\ 0 & \text{elsewhere} \end{cases} \tag{86.43}$$

where $I_0(x)$ is the modified zeroth-order Bessel function of the first kind. Kaiser has shown that these windows are nearly optimum in the sense of having the largest energy in the mainlobe for a given peak sidelobe amplitude.

To give an impression of the results that can be obtained by using Kaiser windows, Fig. 86.14 shows the amplitude responses of an FIR low-pass filter design with $N = 31$ and $\omega_c = \pi/4$ and with $\beta = 1$, $\beta = 6$, and $\beta = 10$. As the value of β increases, the stopband attenuation of the low-pass filter increases and the transition band widens. Proper choice of N then leads to the final design.

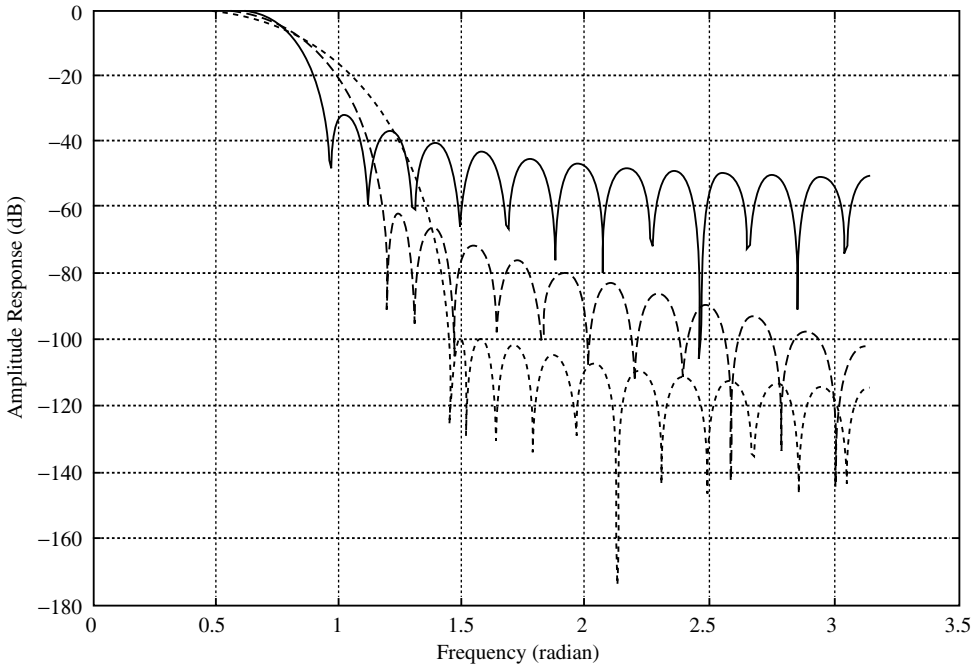

FIGURE 86.14 Magnitude responses of low-pass FIR filter design using a 31-point Kaiser window with $\beta = 1$ (solid line), $\beta = 6$ (dash line), and $\beta = 10$ (dotted line).

86.3 Design of FIR Filters by Optimization

Equiripple FIR Filters

Andreas Antoniou

The design of FIR filters can be accomplished either through noniterative or iterative methods. Noniterative methods entail the use of a small set of closed-form formulas and are, as a consequence, simple to apply. A frequently used method of this class is through the use of the Fourier series in conjunction with window functions. Iterative methods are based on the application of optimization techniques. These are characterized by a substantial increase in the computational complexity, but often lead to designs that are optimal in some respect.

This subsection deals with an iterative method for the design of FIR filters known as the *weighted-Chebyshev* method. In this approach, an error function is formulated for the desired filter in terms of a linear combination of cosine functions and is then minimized by using a very efficient multivariable optimization algorithm known as the *Remez exchange algorithm.* When convergence is achieved, the error function becomes equiripple, as in other Chebyshev solutions. The amplitude of the error in different frequency bands of interest is controlled by applying weighting to the error function.

The weighted-Chebyshev method is very flexible and can be used to obtain optimal solutions for most types of FIR filters, e.g., digital differentiators, Hilbert transformers, and low-pass, high-pass, bandpass, bandstop, and multiband filters with piecewise-constant amplitude responses. Furthermore, it can be used to design filters with arbitrary amplitude responses. Consequently, it is widely used. In common with other optimization methods, the weighted-Chebyshev method requires a large amount of computation; however, as the cost of computation is becoming progressively cheaper with time, this disadvantage is not a serious one.

The underlying principles of the weighted-Chebyshev method were proposed during the early 1970s [1]–[3] and a series of developments soon after [4]–[8] led to the well-known computer program of McClellan, Parks, and Rabiner [9]. Some more recent enhancements to the method are reported in [10] and [11]. A detailed treatment of the subject can be found in [12].

Problem Formulation

An FIR filter with a symmetrical impulse response and odd length N can be represented by the transfer function

$$H(z) = \sum_{n=0}^{N-1} h(nT) z^{-n}$$

If we assume a sampling rate $\omega_s = 2\pi$, we have $T = 2\pi/\omega_s = 1$ s, and hence the frequency response of the filter can be expressed as

$$H\left(e^{j\omega T}\right) = e^{-jc\omega} P_c(\omega)$$

where

$$P_c(\omega) = \sum_{k=0}^{c} a_k \cos k\omega \tag{86.44}$$

with

$$a_0 = h(c)$$

$$a_k = 2h(c-k) \quad \text{for } k = 1, 2, \ldots, c$$

$$c = (N-1)/2$$

For a desired frequency response $e^{-jc\omega}D(\omega)$ and a specified weighting function $W(\omega)$, an error function $E(\omega)$ can be constructed as

$$E(\omega) = W(\omega)\left[D(\omega) - P_c(\omega)\right] \tag{86.45}$$

If it were possible to minimize the magnitude of the above error such that

$$\left|E(\omega)\right| \le \delta_p$$

with respect to some compact subset of the frequency interval $[0, \pi]$, say Ω, a filter would be obtained in which

$$\left|E_0(\omega)\right| = \left|D(\omega) - P_c(\omega)\right| \le \frac{\delta_p}{\left|W(\omega)\right|} \quad \text{for } \omega \in \Omega \tag{86.46}$$

In an equiripple filter, the magnitude of the error oscillates uniformly between zero and some maximum in each passband and stopband. In a low-pass equiripple filter, the amplitude response assumes the form depicted in Fig. 86.15, where δ_p and δ_a are the amplitudes of the passband and stopband ripples, and ω_p and ω_a are the passband and stopband edges, respectively. Hence, we require

$$D(\omega) = \begin{cases} 1 & \text{for } 0 \le \omega \le \omega_p \\ 0 & \text{for } \omega_a \le \omega \le \pi \end{cases}$$

with

© 2003 by CRC Press LLC

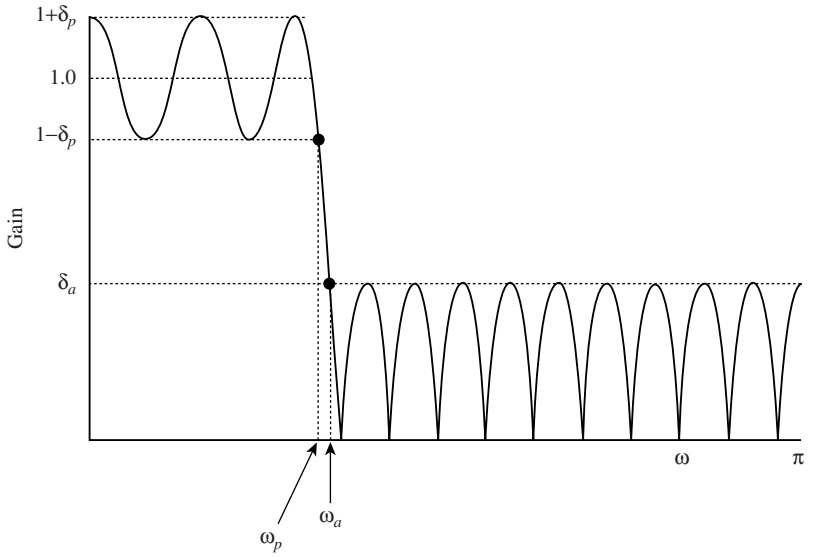

FIGURE 86.15 Amplitude response of equiripple low-pass filter. (Reproduced from A. Antoniou, *Digital Filters: Analysis, Design, and Applications.* New York: McGraw-Hill, 1993, by permission of McGraw-Hill, Inc.)

$$\left|E_0(\omega)\right| \le \begin{cases} \delta_p & \text{for } 0 \le \omega \le \omega_p \\ \delta_a & \text{for } \omega_a \le \omega \le \pi \end{cases} \tag{86.47}$$

Therefore, from (86.46) and (86.47) we deduce

$$W(\omega) = \begin{cases} 1 & \text{for } 0 \le \omega \le \omega_p \\ \delta_p/\delta_a & \text{for } \omega_a \le \omega \le \pi \end{cases}$$

Similarly, for high-pass filters, we obtain

$$D(\omega) = \begin{cases} 0 & \text{for } 0 \le \omega \le \omega_a \\ 1 & \text{for } \omega_p \le \omega \le \pi \end{cases}$$

and

$$W(\omega) = \begin{cases} \delta_p/\delta_a & \text{for } 0 \le \omega \le \omega_a \\ 1 & \text{for } \omega_p \le \omega \le \pi \end{cases}$$

Bandpass and Bandstop Filters. The above formulation can be easily extended to other types of filters. For bandpass filters, we have

$$D(\omega) = \begin{cases} 0 & \text{for } 0 \le \omega \le \omega_{a1} \\ 1 & \text{for } \omega_{p1} \le \omega \le \omega_{p2} \\ 0 & \text{for } \omega_{a2} \le \omega \le \pi \end{cases}$$

© 2003 by CRC Press LLC

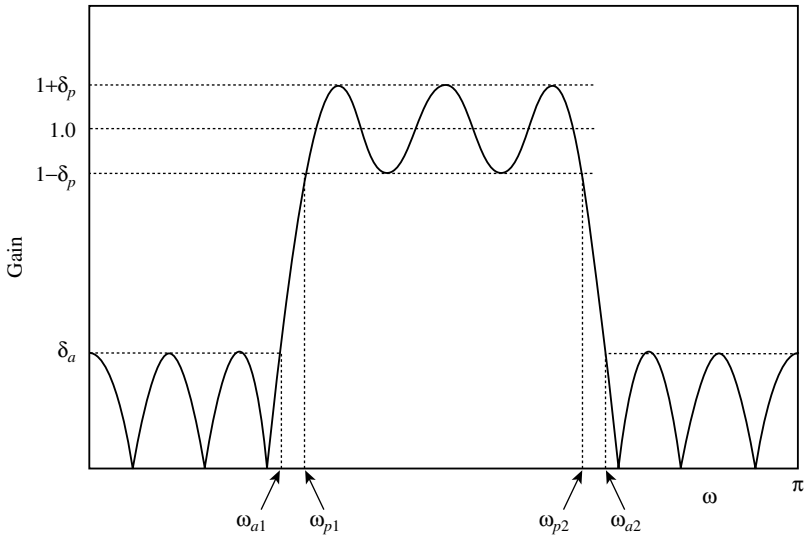

FIGURE 86.16 Amplitude response of equiripple bandpass filter. (Reproduced from A. Antoniou, *Digital Filters: Analysis, Design, and Applications.* New York: McGraw-Hill, 1993, by permission of McGraw-Hill, Inc.)

and

$$W(\omega) = \begin{cases} \delta_p/\delta_a & \text{for } 0 \le \omega \le \omega_{a1} \\ 1 & \text{for } \omega_{p1} \le \omega \le \omega_{p2} \\ \delta_p/\delta_a & \text{for } \omega_{a2} \le \omega \le \pi \end{cases}$$

where δ_p and δ_a are the passband and stopband ripples, respectively, ω_{p1} and ω_{p2} are passband edges, and ω_{a1} and ω_{a2} are stopband edges, as depicted in Fig. 86.16. On the other hand, for bandstop filters

$$D(\omega) = \begin{cases} 1 & \text{for } 0 \le \omega \le \omega_{p1} \\ 0 & \text{for } \omega_{a1} \le \omega \le \omega_{a2} \\ 1 & \text{for } \omega_{p2} \le \omega \le \pi \end{cases}$$

and

$$W(\omega) = \begin{cases} 1 & \text{for } 0 \le \omega \le \omega_{p1} \\ \delta_p/\delta_a & \text{for } \omega_{a1} \le \omega \le \omega_{a2} \\ 1 & \text{for } \omega_{p2} \le \omega \le \pi \end{cases}$$

The Alternation Theorem. An effective approach for the design of equiripple filters is to solve the minimax problem

$$\underset{x}{\text{minimize}}\left\{\max_{\omega}\left|E(\omega)\right|\right\} \tag{86.48}$$

© 2003 by CRC Press LLC

where

$$\mathrm{x} = \begin{bmatrix} a_0 & a_1 \cdots a_c \end{bmatrix}^T$$

is a column vector whose elements are the coefficients of the transfer function of the filter, which happen to be the values of the impulse response. The solution of this problem exists by virtue of the so-called *alternation theorem* [13], which is as follows.

Theorem: *If* $P_c(\omega)$ *is a linear combination of* $r = c + 1$ *cosine functions of the form*

$$P_c(\omega) = \sum_{k=0}^{c} a_k \cos k\omega$$

then a necessary and sufficient condition that $P_c(\omega)$ *be the unique, best, weighted-Chebyshev approximation to a continuous function* $D(\omega)$ *on* Ω, *where* Ω *is a compact subset of the frequency interval* $[0, \pi]$, *is that the weighted error function* $E(\omega)$ *exhibit at least* $r + 1$ *extremal frequencies in* Ω, *i.e., there must exist at least* $r + 1$ *points* $\hat{\omega}_i$ *in* Ω *such that*

$$\hat{\omega}_0 < \hat{\omega}_1 < \cdots < \hat{\omega}_r$$

$$E(\hat{\omega}_i) = -E(\hat{\omega}_{i+1}) \quad \text{for } i = 0, 1, \ldots, r-1$$

and

$$\left|E(\hat{\omega}_i)\right| = \max_{\omega \in \Omega} \left|E(\omega)\right| \quad \text{for } i = 0, 1, \ldots, r$$

From the alternation theorem and (86.45) we can write

$$E(\hat{\omega}_i) = W(\hat{\omega}_i)\left[D(\hat{\omega}_i) - P_c(\hat{\omega}_i)\right] = (-1)^i \delta \tag{86.49}$$

for $i = 0, 1, \ldots, r$, where δ is a constant. This system of equations can be put in matrix form as

$$\begin{bmatrix} 1 & \cos\hat{\omega}_0 & \cos 2\hat{\omega}_0 & \cdots & \cos c\hat{\omega}_0 & \dfrac{1}{W(\hat{\omega}_0)} \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 1 & \cos\hat{\omega}_r & \cos 2\hat{\omega}_r & \cdots & \cos c\hat{\omega}_r & \dfrac{(-1)^r}{W(\hat{\omega}_r)} \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \\ \vdots \\ a_c \\ \delta \end{bmatrix} = \begin{bmatrix} D(\hat{\omega}_0) \\ D(\hat{\omega}_1) \\ \vdots \\ D(\hat{\omega}_r) \end{bmatrix} \tag{86.50}$$

If the extremal frequencies (or extremals for short) were known, coefficients a_k and, in turn, the frequency response of the filter could be computed using (86.44). The solution of this system exists since the above $(r+1)$ x $(r+1)$ matrix is nonsingular [13].

Remez Exchange Algorithm

The Remez exchange algorithm is an *iterative multivariable* algorithm, which is naturally suited for the solution of the minimax problem stated in (86.48). It is based on the second optimization method of Remez [14] and involves the following basic steps.

© 2003 by CRC Press LLC

Algorithm 1: Basic Remez Exchange Algorithm

1. Initialize extremals $\hat{\omega}_0, \hat{\omega}_1, \ldots, \hat{\omega}_r$ ensuring that an extremal is assigned at each band edge.
2. Locate the frequencies $\hat{\omega}_0, \hat{\omega}_1, \ldots, \hat{\omega}_p$ at which $|E(\omega)|$ is maximum and $|E(\hat{\omega}_i)| \geq \delta$. These frequencies are *potential* extremals for the next iteration.
3. Compute the convergence parameter

$$Q = \frac{\max\left|E\left(\hat{\omega}_i\right)\right| - \min\left|E\left(\hat{\omega}_i\right)\right|}{\max\left|E\left(\hat{\omega}_i\right)\right|}$$

   where $i = 0, 1, \ldots, \rho$.
4. Reject $\rho - r$ *superfluous* potential extremals $\hat{\omega}_i$ according to an appropriate rejection criterion and renumber the remaining $\hat{\omega}_i$ sequentially; then set $\hat{\omega}_i = \hat{\omega}_i$ for $i = 0, 1, \ldots, r$.
5. If $Q > \varepsilon$, where ε is a convergence tolerance (say $\varepsilon = 0.01$), repeat from step 2; otherwise continue to step 6.
6. Compute $P_e(\omega)$ using the last set of extremals; then deduce $h(n)$, the impulse response of the required filter, and stop.

The amount of computation required by the algorithm tends to depend quite heavily on the initialization scheme used in step 1, on the search method used for the location of the maxima of the error function in step 2, and on the criterion used to reject superfluous frequencies $\hat{\omega}_i$ in step 4.

Initialization of Extremals. The simplest scheme for the initialization of extremals $\hat{\omega}_i$ for $i = 0, 1, \ldots, r$ is to assume that they are uniformly spaced in the frequency bands of interest. If there are J distinct bands in the required filter of widths $B_1, B_2, \ldots, B_J$ and extremals are to be located at the left-hand and right-hand band edges of each band, the sum of these bandwidths should be divided into $r + 1 - J$ intervals. Thus the average interval between adjacent extremals is

$$W_0 = \frac{1}{r+1-J}\sum_{j=1}^{J} B_j$$

Since the quantities B_j/W_0 need not be integers, the use of W_0 for the generation of the extremals will almost always result in a fractional interval in each band. This problem can be avoided by rounding the number of intervals B_j/W_0 to the nearest integer and then readjusting the frequency interval for the corresponding band accordingly. This can be achieved by letting the number of intervals in bands j and J be

$$m_j = \mathrm{Int}\left(\frac{B_j}{W_0} + 0.5\right) \qquad \text{for } j = 1,\ 2, \ldots,\ J-1$$

and

$$m_J = r - \sum_{j=1}^{J-1}\left(m_j + 1\right)$$

respectively, and then recalculating the frequency intervals for the various bands as

$$W_j = \frac{B_j}{m_j} \quad \text{for } j = 1,\ 2, \ldots,\ J$$

A more sophisticated initialization scheme, which was found to give good results, is described in [15].

Location of Maxima of the Error Function. The frequencies, $\hat{\omega}_i$, which *must include maxima at band edges if* $|E(\hat{\omega}_i| \geq |\delta|$, can be located by simply evaluating $|E(\omega)|$ over a dense set of frequencies. A reasonable number of frequency points that yields sufficient accuracy in the determination of the frequencies $\hat{\omega}_i$ is $8(N + 1)$. This corresponds to about 16 frequency points per ripple of $|E(\omega)|$. A suitable frequency interval for the jth band is $w_j = W_j/S$ with $S = 16$.

The above *exhaustive* search can be implemented in terms of Algorithm 2 below, where ω_{Lj} and ω_{Rj} are the left-hand and right-hand edges in band j; W_j is the interval between adjacent extremals and m_j is the number of intervals W_j in band j; w_j is the interval between successive samples of $|E(\omega)|$ in interval W_j and S is the number of intervals w_j in each interval W_j; N_j is the total number of intervals w_j in band j; and J is the number of bands.

Algorithm 2: Exhaustive Step-by-Step Search

1. Set $N_j = m_jS$, $w_j = B_j/N_j$ and $e = 0$.
2. For each of bands 1, 2, …, j, …, J do the following. For each of frequencies $\omega_{1j} = \omega_{Lj}$, $\omega_{2j} = \omega_{Lj} + \omega_j$, …, $\omega_{ij} = \omega_{LJ} + (i - 1)\omega_j$, …, $\omega_{Nj+1} = \omega_{Rj}$, set $\hat{\omega}_i = \omega_{ij}$ and $e = e + 1$ provided that $|E(\omega_{ij})| \geq |\delta|$ and one of the following conditions holds:
   i. Case $\omega_{ij} = \omega_{Lj}$: if $|E(\omega_{ij})|$ is maximum at $\omega_{ij} = \omega_{Lj}$ (i.e., $|E(\omega_{Lj})| > |E(\omega_{Lj} + \varepsilon)|$);
   ii. Case $\omega_{Lj} < \omega_{ij} < \omega_{Rj}$: if $|E(\omega)|$ is maximum at $\omega = \omega_{ij}$ (i.e., $|E(\omega_{ij} - \omega_j)| < |E(\omega_{ij})| > |E(\omega_{ij} + \omega_j)|$)
   iii. Case $\omega_{ij} = \omega_{Rj}$: if $|E(\omega_{ij})|$ is maximum at $\omega_{ij} = \omega_{Rj}$ (i.e., $|E(\omega_{Rj})| > |E(\omega_{Rj} - \varepsilon)|$).

The parameter ε in steps i and iii is a small positive constant and a value $10^{-2}w_j$ yields satisfactory results.

In practice, $|E(\omega)|$ is maximum at an interior left-hand band edge[1] if its first derivative at the band edge is negative, and a mirror-image situation applies at an interior right-hand band edge. In such cases, $|E(\omega)|$ has a zero immediately to the right or left of the band edge and the inequality in step i or iii may sometimes fail to identify a maximum. However, the problem can be avoided by using the inequality $|E(\omega_{Li} - \varepsilon)| > |E(\omega_{Li})|$ in step i and $|E(\omega_{Ri})| < |E(\omega_{Ri} + \varepsilon)|$ in step iii for interior band edges.

In rare circumstances, a maximum of $|E(\omega)|$ may occur between a band edge and the first sample point. Such a maximum may be missed by Algorithm 2, but the problem can be easily identified since the number of potential extremals will then be less than the minimum. The remedy is to check the number of potential extremals at the end of each iteration and if it is found to be less than $r + 1$, the density of sample points, i.e., S, is doubled and the iteration is repeated. If the problem persists, the process is repeated until the required number of potential extremals is obtained. If a value of S equal to or less than 256 does not resolve the problem, the loss of potential extremals is most likely due to some other reason.

An important precaution in the implementation of the preceding search method is to ensure that extremals belong to the dense set of frequency points to avoid numerical ill-conditioning in the computation of $E(\omega)$ [see (86.49) and (86.51)]. In addition, the condition $|E(\omega)| \leq |\delta|$ should be replaced by $|E(\omega)| > |\delta| - \varepsilon_1$, where ε_1 is a small positive constant, say 10^{-6}, to ensure that no maxima are missed owing to roundoff errors.

The search method is very reliable and its use in Algorithm 1 leads to a *robust* algorithm since the entire frequency axis is searched using a dense set of frequency points. Its disadvantage is that it requires a considerable amount of computation and is, therefore, inefficient.

A more efficient version of Algorithm 2 is obtained by maintaining all the interior band edges as extremals throughout the optimization independently of the behavior of the error function at the band edges. However, the algorithm obtained tends to be somewhat less robust, i.e., it tends to fail more frequently than Algorithm 2.

Computation of $|E(\omega)|$ and $P_e(\omega)$. In steps 2 and 6 of the basic Remez algorithm (Algorithm 1), $|E(\omega)|$ and $P_e(\omega)$ need to be evaluated. This can be done by determining coefficients a_k by inverting the matrix

[1]An interior band edge is one in the range $0 < \omega < \pi$, i.e., not at $\omega = 0$ or π.

© 2003 by CRC Press LLC

in Eq. (86.50). This approach is inefficient and may be subject to numerical ill-conditioning, in particular, if δ is small and N is large. An alternative and more efficient approach is to deduce δ analytically and then interpolate $P_c(\omega)$ on the r frequency points using the *barycentric* form of the *Lagrange interpolation* formula. The necessary formulation is as follows.

Parameter δ can be deduced as

$$\delta = \frac{\sum_{k=0}^{r} \alpha_k D(\hat{\omega}_k)}{\sum_{k=0}^{r} \frac{(-1)^k \alpha_k}{W(\hat{\omega}_k)}}$$

and $P_c(\omega)$ is given by

$$P_c(\omega) = \begin{cases} C_k & \text{for } \omega = \hat{\omega}_0,\ \hat{\omega}_1, \ldots, \hat{\omega}_{r-1} \\ \dfrac{\sum_{k=0}^{r-1} \frac{\beta_k C_k}{x - x_k}}{\sum_{k=0}^{r-1} \frac{\beta_k}{x - x_k}} & \text{otherwise} \end{cases} \tag{86.51}$$

where

$$\alpha_k = \prod_{i=0,\, i\neq k}^{r} \frac{1}{x_k - x_i}$$

$$C_k = D(\hat{\omega}_k) - (-1)^k \frac{\delta}{W(\hat{\omega}_k)}$$

$$\beta_k = \prod_{i=0,\, i\neq k}^{r-1} \frac{1}{x_k - x_i}$$

with

$$x = \cos\omega \quad \text{and} \quad x_i = \cos\hat{\omega}_i \quad \text{for } i = 0,\ 1,\ 2, \ldots,\ r$$

In step 2 of the Remez algorithm, $|E(\omega)|$ often needs to be evaluated at a frequency that was an extremal during the previous iteration. For these cases, the magnitude of the error function is simply $|\delta|$, according to (86.49), and need not be evaluated. This would reduce the amount of computation to some extent.

An alternative formulation that simplifies the implementation of the Remez exchange algorithm can be found in [12].

Rejection of Superfluous Potential Extremals. The solution of (86.50) can be obtained only if *precisely* $r + 1$ extremals are available. By differentiating $E(\omega)$, one can show that in a filter with one frequency band of interest (e.g., a digital differentiator) the number of maxima in $|E(\omega)|$ (potential extremals in step 2 of Algorithm 1) can be as high as $r + 1$. In the weighted-Chebyshev method, band edges at which $|E(\omega)|$ is maximum or $|E(\omega)| \geq |\delta|$ are treated as potential extremals (see Algorithm 2). Therefore, whenever the number of frequency bands is increased by one, the number of potential extremals is increased by 2, i.e., for a filter with J bands there can be as many as $r + 2J - 1$ frequencies $\hat{\omega}_i$ and a maximum of $2J - 2$ superfluous $\hat{\omega}_i$ may occur. This problem is overcome by rejecting $\rho - r$ of the potential extremals $\hat{\omega}_i$, if $p > r$, in step 4 of the algorithm.

© 2003 by CRC Press LLC

A simple rejection scheme is to reject the $p - r$ frequencies $\hat{\omega}_i$ that yield the lowest $|E(\hat{\omega}_i)|$ and then renumber the remaining $\hat{\omega}_i$ from 0 to r [8]. This strategy is based on the well-known fact that the magnitude of the error in a given band is inversely related to the density of extremals in that band, i.e., a low density of extremals results in a large error and a high density results in a small error. Conversely, a low band error is indicative of a high density of extremals, and rejecting superfluous $\hat{\omega}_i$ in such a band is the appropriate course of action.

A problem with the scheme just described is that whenever a frequency remains an extremal in two successive iterations, $|E(\omega)|$ assumes the value of $|\delta|$ in the second iteration by virtue of (86.49). In practice, there are almost always several frequencies that remain extremals from one iteration to the next, and the value of $|E(\omega)|$ at these frequencies will be the same. Consequently, the rejection of potential extremals on the basis of the magnitude of the error can become arbitrary and may lead to the rejection of potential extremals in bands where the density of extremals is low. This tends to increase the number of iterations, and it may even prevent the algorithm from converging on occasion. This problem can to some extent be alleviated by rejecting only potential extremals that are not band edges.

An alternative rejection scheme based on the aforementioned strategy, which gives excellent results for two-band and three-band filters, involves ranking the frequency bands in the order of lowest average band error, dropping the band with the highest average error from the list, and then rejecting potential extremals, one per band, in a cyclic manner starting with the band with the lowest average error [11]. The steps involved are as follows.

Algorithm 3: Rejection of Superfluous Potential Externals

1. Compute the average band errors

$$E_j = \frac{1}{v_j} \sum_{\hat{\omega}_i \in \Omega_j} \left| E\left(\hat{\omega}\right) \right| \quad \text{for } j = 1, 2, \ldots, J$$

   where Ω_j is the set of potential externals in band j given by

$$\Omega_j = \left\{ \hat{\omega}_j : \omega_{Lj} \le \hat{\omega}_j \le \omega_{Rj} \right\}$$

   v_j is the number of potential externals in band j, and J is the number of bands.
2. Rank the J bands in the order of lowest average error and let $l_1, l_2, \ldots, l_1$ be the ranked list obtained, i.e., l_1 and l_j are the bands with the lowest and highest average errors, respectively.
3. Reject one $\hat{\omega}_i$ in each of bands $l_1, l_2, \ldots, l_{1-1}, l_1, l_2, \ldots, l_1$ until $\rho - r$ superfluous $\hat{\omega}_i$ are rejected. In each case, reject the $\hat{\omega}_i$, other than a band edge, that yields the lowest $|E(\hat{\omega}_i)|$ in the band.

For example, if $J = 3$, $\rho - r = 3$, and the average errors for bands 1, 2, and 3 are, respectively, 0.05, 0.08, and 0.02, then $\hat{\omega}_i$ are rejected in bands 3, 1, and 3. Note that potential extremals are not rejected in band 2, which is the band of highest average error.

Computation of Impulse Response. The impulse response in step 6 of Algorithm 1 can be determined by noting that function $P_c(\omega)$ is the frequency response of a noncausal version of the required filter. The impulse response of this filter, represented by $h_0(n)$ for $-c \le n \le c$, can be determined by computing $P_c(k\Omega)$ for $k = 0, 1, 2, \ldots, c$, where $\Omega = 2\pi/N$, and then using the *inverse discrete Fourier transform*. It can be shown that

$$h_0(n) = h_0(-n) = \frac{1}{N}\left[P_c(0) + \sum_{k=1}^{c} 2P_c(k\Omega)\cos\left(\frac{2\pi kn}{N}\right) \right]$$

© 2003 by CRC Press LLC

for $n = 0, 1, 2, \ldots, c$. Therefore, the impulse response of the required causal filter is given by

$$h(n) = h_0(n - c)$$

for $n = 0, 1, 2, \ldots, N - 1$.

Improved Search Methods

For a filter of length N, with the number of intervals w_j in each internal W_j equal to S, the exhaustive step-by-step search described (Algorithm 2) requires about $S \times (N + 1)/2$ function evaluations, where each function evaluation entails $N - 1$ additions, $(N + 1)/2$ multiplications, and $(N + 1)/2$ divisions [see (86.51)].

A Remez optimization usually requires four to eight iterations for low-pass or high-pass filters, four to ten iterations for bandpass filters, and four to 12 iterations for bandstop filters. Further, if prescribed specifications are to be achieved and the appropriate value of N is unknown, typically two to four Remez optimizations have to be performed.[2] Thus, if $N = 101$, $S = 16$, number of Remez optimizations = 4, iterations per optimization = 6, the design would entail 24 iterations, 19,200 function evaluations, 1.92×10^6 additions, 0.979×10^6 multiplications, and 0.979×10^6 divisions. This is in addition to the computation required for the evaluation of δ and coefficients α_k, C_k, and β_k once per iteration. In effect, the amount of computation required to complete a design is quite substantial.

The bulk of the computation in Algorithm 2 is carried out to locate the maxima of $|E(\omega)|$, and the large amount of computation is a consequence of the exhaustive character of the search. Therefore, any attempt to reduce the computational complexity of the Remez exchange algorithm must of necessity involve a more efficient search for the maxima of $|E(\omega)|$.

The error function in the weighted-Chebyshev method is well behaved in practice, and is normally unimodal between successive zeros, as can be seen in Figs. 86.15 and 86.16. Hence, the maxima of $|E(\omega)|$ can be located through more sophisticated search methods that utilize gradient information. Two such methods are the so-called *selective step-by-step search* and *cubic-interpolation search* reported in [10] and [11]. Collectively, the two search methods can reduce the amount of computation to about one fifth the amount required by the exhaustive search.

Selective Step-by-Step Search. The underlying principle in the development of the selective step-by-step search is that normally there is strict alternation between the maxima and the zeros of $|E(\omega)|$. In a given iteration, the maxima of $|E(\omega)|$ are either old maxima from the previous iteration that have moved or new maxima introduced at band edges. New interior maxima may also arise, in theory, but such occurrences are quite rare in practice.

The selective step-by-step search involves three distinct parts as follows.

1. Maxima that correspond to previous maxima are located by searching in the neighborhoods of the most recent set of extremals in a step-by-step fashion using the first derivative of $|E(\omega)|$. If the first derivative is positive at an extremal, the search is carried out to the right of the extremal; otherwise, the search is carried out to the left of the extremal.
2. New maxima at band edges can be located by noting the circumstances under which new maxima can arise. These are as follows:
   - To the right of $\omega = 0$ (first band), if there is an extremal and $|E(\omega)|$ has a minimum at $\omega = 0$.
   - To the left of $\omega = \pi$ (last band), if there is an extremal and $|E(\omega)|$ has a minimum at $\omega = \pi$.
   - At $\omega = 0$, if there is no extremal at $\omega = 0$.
   - At $\omega = \pi$, if there is no extremal at $\omega = \pi$.

[2] See subsection on prescribed specifications.

© 2003 by CRC Press LLC

- To the right of an interior left-hand edge.
- To the left of an interior right-hand edge.
- At $\omega = \omega_{Lj}$, if there is no extremal at $\omega = \omega_{Lj}$.
- At $\omega = \omega_{Rj}$, if there is no extremal at $\omega = \omega_{Rj}$.

3. New interior maxima, which cannot be located by the checks in (1) and (2), can be found by noting the presence of large gaps in the set of potential extremals identified in (1) and (2). If the difference between two consecutive potential extremals exceeds 1.5 to 2 times the initial interval between extremals (i.e., W_j), then the interval is checked for additional maxima.

If a selective step-by-step search based on the above principles is used in Algorithm 1, then at the start of the optimization the distance between a typical extremal $\hat{\omega}_i$ and the nearby maximum point $\hat{\omega}_i$ will be less than half the period of the corresponding ripple of $|E(\omega)|$, owing to the relative symmetry of the ripples of the error function. In effect, during the first iteration less than half of the combined width of the different bands needs to be searched. Thus the number of function evaluations required would be reduced from about 16 to less than 8 per extremal in practice. This will reduce the number of function evaluations by more than 50 percent relative to that required by the exhaustive search of Algorithm 1 without degrading the accuracy of the optimization in any way. As the optimization progresses and the solution is approached, extremal $\hat{\omega}_i$ and maximum point $\hat{\omega}_i$ tend to coincide and, therefore, the cumulative length of the frequency range that has to be searched is progressively reduced, thereby resulting in further economies in the number of function evaluations. In the last iteration, only two or three function evaluations are needed (including derivatives) per ripple. As a result, the total number of function evaluations can be reduced by 65 to 70 percent relative to that required by the exhaustive search [10], [11].

Cubic-Interpolation Search. The maxima in item (1) of the above method can also be found through the use of one stage of polynomial interpolation. Either quadratic or cubic interpolation can be used. In these methods, a polynomial approximation is obtained for the magnitude of the error function in the neighborhood of a given extremal and the location of the maximum is determined by finding the point at which the first derivative is zero. Although cubic interpolation entails a more complicated formulation than quadratic interpolation, it leads to improved accuracy, which tends to translate into improved efficiency.

Several choices are possible in setting up a cubic-interpolation search for the problem at hand. One that was found to work well in practice entails evaluating $|E(\omega)|$ at three frequency points and its derivative at one point. Choosing the extremal itself as one of the points reduces the computation further since the value of $|E(\omega)|$ is known to be $|\delta|$ from the previous iteration. Thus this scheme entails three function evaluations per extremal.

The computational complexity of the cubic-interpolation search described remains constant from iteration to iteration since the number of function evaluations required to perform an interpolation is constant. At the start of the optimization, the cubic-interpolation search is more efficient than the selective step-by-step search. However, as the solution is approached the number of function evaluations required by the selective search is progressively reduced, as was stated earlier, and at some point the selective search becomes more efficient. A prudent strategy under the circumstances is to use the cubic-interpolation search at the start of the optimization and switch over to the selective step-by-step search when some suitable criterion is satisfied. Extensive experimentation has shown that computational advantage can be gained by using the cubic-interpolation search if parameter Q (see Algorithm 1) is greater than about 0.65 and the selective search otherwise. The use of the cubic-interpolation search along with the selective step-by-step search of the preceding section can reduce the number of function evaluations by 70 to 85 percent relative to that required by the exhaustive search [10], [11].

More information, including the necessary formulation as well as a practical and efficient implementation of the Remez exchange algorithm in terms of the above search methods, can be found in [12].

© 2003 by CRC Press LLC

Example 1. The Remez algorithm was used with (1) the exhaustive search, (2) the selective step-by-step search, and (3) the selective search in conjunction with the cubic-interpolation search to design an FIR equiripple high-pass filter satisfying the following specifications:

Filter length N: 23;
Passband edge ω_p: 2.0 rad/s;
Stopband edge ω_a: 1.0 rad/s;
Ratio δ_p/δ_a: 15.0;
Sampling frequency ω_s: 2π rad/s.

The progress of the design is illustrated in Table 86.3. As can be seen, the exhaustive and selective search methods required six iterations each, whereas the selective search in conjunction with cubic interpolation required seven iterations. However, the number of function evaluations (evaluations of $P_c(\omega)$ using Eq. (86.51) plus evaluations of its first or second derivative) decreased from 1013 in the first method to 350 in the second method to 259 in the third method. In the Remez algorithm, approximately 80 to 90% of the computational effort involves function evaluations. In effect, relative to that required by the exhaustive search, the use of the selective step-by-step search reduced the amount of computation by about 65.4 percent, and the use of the selective step-by-step search in conjunction with the cubic-interpolation search reduced the amount of computation by about 74.4%.

The three methods resulted in approximately the same impulse responses, as can be seen in Table 86.4, and the passband ripple and minimum stopband attenuation obtained in each case were 0.043 and 75.7 dB, respectively. The amplitude response of the filter is illustrated in Fig. 86.17.

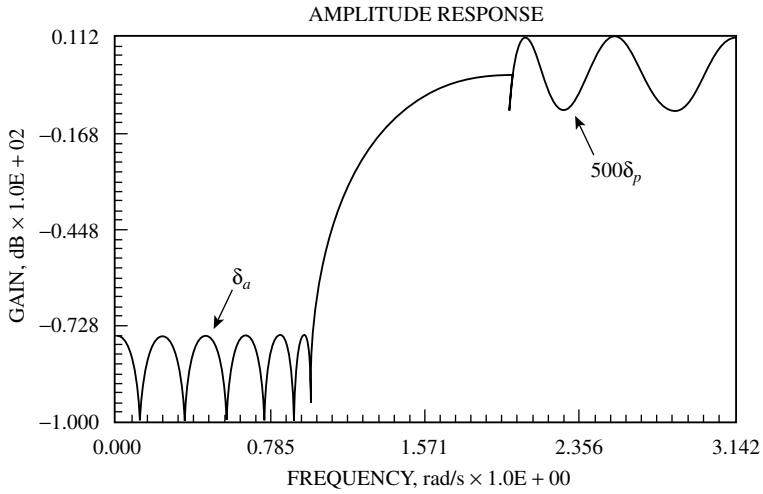

FIGURE 86.17 Amplitude response of equiripple high-pass filter (Example 1).

Example 2. In this example, the Remez algorithm was used with (1) the exhaustive search, (2) the selective step-by-step search, and (3) the selective step-by-step search in conjunction with the cubic-interpolation search to design an FIR equiripple bandstop filter satisfying the following specifications:

Filter length N: 29;
Lower passband edge ω_{p1}: 0.8 rad/s;
Upper passband edge ω_{p2}: 2.1 rad/s;
Lower stopband edge ω_{a1}: 1.1 rad/s;
Upper stopband edge ω_{a2}: 0.8 rad/s;
Ratio δ_{p1}/δ_a: 5.0;
Ratio δ_{p1}/δ_{p2}: 2.0;
Sampling frequency ω_s: 2π rad/s.

The progress of the design is illustrated in Table 86.5. In this example, each of the three methods required four iterations. The number of function evaluations decreased from 804 in the first method to 190 in the second method to 131 in the third method. In effect, the use of the selective step-by-step search reduced the amount of computation by about 76.4 percent, and the use of the selective step-by-step search in conjunction with the cubic-interpolation search reduced the amount of computation by about 83.7%, relative to that required by the exhaustive search.

The three methods resulted in approximately the same impulse responses, as can be seen in Table 86.6. The amplitude response of the filter is illustrated in Fig. 86.18; the passband ripples obtained for the two passbands were 1.78 and 0.89 dB, respectively, and the minimum stopband attenuation was 33.79 dB.

Prescribed Specifications

Given a filter length N, a set of passband and stopband edges, and a ratio δ_p/δ_a, an FIR filter with approximately piecewise-constant amplitude-response specifications can be readily designed. While the filter obtained will have passband and stopband edges at the correct locations and the ratio δ_p/δ_a will be as required, the amplitudes of the passband and stopband ripples are highly unlikely to be precisely as specified. An acceptable design can be obtained by predicting the value of N on the basis of the required specifications and then designing filters for increasing or decreasing values of N until the lowest value of N that satisfies the specifications is found.

A reasonably accurate *empirical* formula for the prediction of N for the case of low-pass and high-pass filters, due to Hermann, Rabiner, and Chan [16], is

$$N = \text{Int}\left[\frac{\left(D - FB^2\right)}{B} + 1.5\right] \tag{86.52}$$

© 2003 by CRC Press LLC

where

$$B = \left|\omega_a - \omega_p\right| / 2\pi$$

$$D = \left[0.005309\left(\log \delta_p\right)^2 + 0.07114 \log \delta_p - 0.4761\right] \log \delta_a$$

$$- \left[0.00266\left(\log \delta_p\right)^2 + 0.5941 \log \delta_p + 0.4278\right]$$

$$F = 0.51244\left(\log \delta_p - \log \delta_a\right) + 11.012$$

This formula can also be used to predict the filter length in the design of bandpass, bandstop, and multiband filters in general. In these filters, a value of N is computed for each transition band between a passband and stopband or a stopband and passband using (86.52) and the largest value of N so obtained is taken to be the predicted filter length. *Prescribed specifications* can be achieved by using the following design algorithm.

Algorithm 4: Design of Filters Satisfying Prescribed Specifications

1. Compute N using (86.52); if N is even, set $N = N + 1$.
2. Design a filter of length N and determine the minimum value of δ, say $\overset{\cup}{\delta}$.
   i. If $\overset{\cup}{\delta} > \delta_p$, then do the following:
      a. Set $N = N + 2$, design a filter of length N, and find $\overset{\cup}{\delta}$;
      b. If $\overset{\cup}{\delta} \le \delta_p$, then go to step 3; else, go to step 2ia.
   ii. If $\overset{\cup}{\delta} < \delta_p$, then do the following:
      a. Set $N = N - 2$, design a filter of length N, and find $\overset{\cup}{\delta}$;
      b. If $\overset{\cup}{\delta} > \delta_\pi$, then go to step 4; else, go to step 2iia.
3. Use the last set of extremals and the corresponding value of N to obtain the impulse response of the required filter and stop.
4. Use the last but one set of extremals and the corresponding value of N to obtain the impulse response of the required filter and stop.

Example 3. Algorithm 4 was used to design an FIR equiripple bandpass filter that would satisfy the following specifications:

Odd filter length;
Maximum passband ripple A_p: 0.5 dB;
Minimum stopband attenuation A_{a1}: 50.0 dB;
Minimum stopband attenuation A_{a2}: 30.0 dB;
Lower passband edge ω_{p1}: 1.2 rad/s;
Upper passband edge ω_{p2}: 1.8 rad/s;
Lower stopband edge ω_{a1}: 0.9 rad/s;
Upper stopband edge ω_{a2}: 2.1 rad/s;
Sampling frequency ω_s: 2π rad/s.

The progress of the design is illustrated in Table 86.7. As can be seen, a filter of length 41 was initially predicted, which was found to have a passband ripple of 0.47 dB, a minimum stopband attenuation of 50.4 in the lower stopband, and 30.4 dB in the upper stopband, i.e., the required specifications were satisfied. Then a filter length of 39 was tried and found to violate the specifications. Hence the first design is the required filter. The impulse response is given in Table 86.8. The corresponding amplitude response is depicted in Fig. 86.19.

Generalization

There are four types of constant-delay FIR filters. The impulse response can be *symmetrical* or *antisymmetrical*, and the filter length can be *odd* or *even*. In the preceding subsections, we considered the design of filters with symmetrical impulse response and odd length. In this subsection, we show that the Remez algorithm can also be applied for the design of other types of filters.

Antisymmetrical Impulse Response and Odd Filter Length. Assuming that $\omega_s = 2\pi$, the frequency response of an FIR filter with *antisymmetrical* impulse and *odd* length can be expressed as

$$H\left(e^{j\omega T}\right) = e^{-jc\omega} jP_c'(\omega)$$

© 2003 by CRC Press LLC

where

$$P_c'(\omega) = \sum_{k=1}^{c} a_k \sin\, k\omega \tag{86.53}$$

$$a_k = 2h(c-k) \qquad \text{for } k = 1, 2, \ldots, c$$
$$c = (N-1)/2$$

A filter with a desired frequency response $e^{-jc\omega}\, jD(\omega)$ can be designed by constructing the error function

$$E(\omega) = W(\omega)\left[D(\omega) - P_c'(\omega)\right] \tag{86.54}$$

and then minimizing $|E(\omega)|$ with respect to some compact subset of the frequency interval $[0, \pi]$. From (86.53), $P_c'(\omega)$ can be expressed as [6]

$$P_c'(\omega) = \sin\omega\, P_{c-1}(\omega) \tag{86.55}$$

where

$$P_{c-1}(\omega) = \sum_{k=0}^{c-1} \tilde{c}_k \cos\, k\omega$$

and

$$a_1 = \tilde{c}_0 - \frac{1}{2}\tilde{c}_2$$

$$a_k = \frac{1}{2}(\tilde{c}_{k-1} - \tilde{c}_{k+1}) \qquad \text{for } k = 2, 3, \ldots, c-2$$

$$a_{c-1} = \frac{1}{2}\tilde{c}_{c-2}$$

$$a_c = \frac{1}{2}\tilde{c}_{c-1}$$

Hence (86.54) can be put in the form

$$E(\omega) = \tilde{W}(\omega)\left[\tilde{D}(\omega) - \tilde{P}(\omega)\right] \tag{86.56}$$

where

$$\tilde{W}(\omega) = Q(\omega)W(\omega)$$
$$\tilde{D}(\omega) = D(\omega)/Q(\omega)$$
$$\tilde{P}(\omega) = P_{c-1}(\omega)$$
$$Q(\omega) = \sin\, \omega$$

© 2003 by CRC Press LLC

Evidently, (86.56) is of the same form as (86.45), and upon proceeding as in the subsection on problem formulation, one can obtain the system of equations

$$\begin{bmatrix} 1 & \cos\hat{\omega}_0 & \cos 2\hat{\omega}_0 & \cdots & \cos(c-1)\hat{\omega}_0 & \dfrac{1}{\tilde{W}(\hat{\omega}_0)} \\ 1 & \cos\hat{\omega}_1 & \cos 2\hat{\omega}_1 & \cdots & \cos(c-1)\hat{\omega}_1 & \dfrac{-1}{\tilde{W}(\hat{\omega}_1)} \\ \vdots & \vdots & \vdots & & \vdots & \vdots \\ 1 & \cos\hat{\omega}_r & \cos 2\hat{\omega}_r & \cdots & \cos(c-1)\hat{\omega}_r & \dfrac{(-1)^r}{\tilde{W}(\hat{\omega}_r)} \end{bmatrix} \begin{bmatrix} a_0 \\ a_1 \\ \vdots \\ a_{c-1} \\ \delta \end{bmatrix} = \begin{bmatrix} \tilde{D}(\hat{\omega}_0) \\ \tilde{D}(\hat{\omega}_1) \\ \vdots \\ \tilde{D}(\hat{\omega}_r) \end{bmatrix}$$

where $r = c$ is the number of cosine functions in $P_{c-1}(\omega)$. The above system is the same as that in (86.50) except that the number of extremals has been reduced from $c + 2$ to $c + 1$; therefore, the application of the Remez algorithm follows the methodology detailed in the subsections on problem formulation and the Remez exchange algorithm.

The use of Algorithm 1 yields the optimum $P_{c-1}(\omega)$ and from (86.55), the cosine function $P'_c(\omega)$ can be formed. Now $jP'_c(\omega)$ is the frequency response of a noncausal version of the required filter. The impulse response of this filter can be obtained as

$$h_0(n) = -h_0(-n) = -\frac{1}{N}\left[\sum_{k=1}^{c} 2P'_c(k\Omega)\ \sin\left(\frac{2\pi kn}{N}\right)\right]$$

for $n = 0, 1, 2, \ldots, c$, where $\Omega = 2\pi/N$, by using the inverse discrete Fourier transform. The impulse response of the corresponding causal filter is given by

$$h(n) = h_0(n-c)$$

for $n = 0, 1, 2, \ldots, N - 1$.

The Remez algorithm can also be applied for the design of filters with symmetrical or antisymmetrical impulse response and even N. However, these filters are used less frequently. The reader is referred to [6] and [12] for more details.

Digital Differentiators

The Remez algorithm can be easily applied for the design of *equiripple digital differentiators*. The ideal frequency response of a causal differentiator is of the form $e^{-jc\omega}jD(\omega)$, where

$$D(\omega) = \omega \qquad \text{for } 0 < |\omega| < \pi \tag{86.57}$$

and $c = (N - 1)/2$. Since the frequency response is antisymmetrical, differentiators can be designed in terms of filters with antisymmetrical impulse response of either odd or even length.

Problem Formulation. Assuming odd filter length, (86.54) and (86.57) give the error function

$$E(\omega) = W(\omega)\left[\omega - P'_c(\omega)\right] \qquad \text{for } 0 < \omega \le \omega_p$$

where ω_P is the required bandwidth. Equiripple absolute or relative error may be required, depending on the application at hand. Hence, $W(\omega)$ can be chosen to be either unity or $1/\omega$. In the latter case, which is the more meaningful of the two in practice, $E(\omega)$ can be expressed as

© 2003 by CRC Press LLC

$$E(\omega) = 1 - \frac{1}{\omega} P_c'(\omega) \qquad \text{for } 0 < \omega \le \omega_p$$

and from (86.55)

$$E(\omega) = 1 - \frac{\sin\omega}{\omega} P_{c-1}(\omega) \quad \text{for } 0 < \omega \le \omega_p \tag{86.58}$$

Therefore, the error function can be expressed as in (86.56) with

$$\tilde{W}(\omega) = \frac{1}{\tilde{D}(\omega)} = \frac{\sin\omega}{\omega}$$

$$\tilde{P}(\omega) = P_{c-1}(\omega)$$

Prescribed Specifications. A digital differentiator is fully specified by the constraint

$$\left|E(\omega)\right| \le \delta_p \quad \text{for } 0 < \omega \le \omega_p$$

where δ_p is the maximum passband error and ω_p is the bandwidth of the differentiator.

The differentiator length N that will just satisfy the required specifications is not normally known *a priori* and, although it may be determined on a hit-or-miss basis, a large number of designs may need to be carried out. In filters with approximately piecewise-constant amplitude responses, N can be predicted using the empirical formula of (86.52). In the case of differentiators, N can be predicted by noting a useful property of digital differentiators. If δ and δ_1 are the maximum passband errors in differentiators of lengths N and N_1, respectively, then the quantity $\ln(\delta/\delta_1)$ is *approximately linear* with respect to $N - N_1$ for a wide range of values of N_1 and ω_p. Assuming linearity, we can show that [17]

$$N = N_1 + \frac{\ln(\delta/\delta_1)}{\ln(\delta_2/\delta_1)}(N_2 - N_1) \tag{86.59}$$

where δ_2 is the maximum passband error in a differentiator of length N_2.

By designing two low-order differentiators, a fairly accurate prediction of the required value of N can be obtained by using (86.59). Once a filter order is predicted a series of differentiators can be designed with increasing or decreasing N until a design that just satisfies the specifications is obtained.

Example 4. The selective step-by-step search with cubic interpolation was used in Algorithm 4 to design a digital differentiator that should satisfy the following specifications:

Odd differentiator length;
Bandwidth ω_p: 2.75 rad/s;
Maximum passband ripple δ_P: 1.0×10^{-5}
Sampling frequency ω_s: 2π rad/s.

The progress of the design is illustrated in Table 86.9. First, differentiators of lengths 21 and 23 were designed and the required N to satisfy the specifications was predicted to be 55 using (86.59). This differentiator length was found to satisfy the specifications, and a design for length 53 was then carried out. The second design was found to violate the specifications and hence the first design is the required differentiator. The impulse response of this differentiator is given in Table 86.10. The amplitude response and passband relative error of the differentiator are plotted in Fig. 86.20(a) and (b).

Arbitrary Amplitude Responses

Very frequently FIR filters are required whose amplitude responses cannot be described by analytical functions. For example, in the design of two-dimensional filters through the singular-value decomposition [18], [19], the required two-dimensional filter is obtained by designing a set of one-dimensional digital filters whose amplitude responses turn out to have arbitrary shapes. In these applications, the desired amplitude response $D(\omega)$ is specified in terms of a table that lists a prescribed set of frequencies and the corresponding values of the required filter gain. Filters of this class can be readily designed by employing some interpolation scheme that can be used to evaluate $D(\omega)$ and its first derivative with respect to ω at any ω. A suitable scheme is to fit a set of third-order polynomials to the prescribed amplitude response.

© 2003 by CRC Press LLC

Multiband Filters

The algorithms presented in the previous subsections can also be used to design *multiband* filters. While there is no theoretical upper limit on the number of bands, in practice, the design tends to become more and more difficult as the number of bands is increased. The reason is that the difference between the number of possible maxima in the error function and the number of extremals increases linearly with the number of bands, e.g., if the number of bands is 8, then the difference is 14. As a consequence, the number of potential extremals that needs to be rejected is large and the available rejection techniques become inefficient. The end result is that the number of iterations is increased quite significantly, and convergence is slow and sometimes impossible.

In mathematical terms, the above difficulty is attributed to the fact that, in the weighted-Chebyshev methods considered here, the approximating polynomial becomes seriously *under-determined* if the number of bands exceeds three. The problem can be overcome by using the generalized Remez method described in [15]. This approach was found to yield better results for filters with more than five bands.

Least Squares and Related Techniques

L. Montgomery Smith and Bruce W. Bomar

Introduction and Statement of the Problem

One optimal method of FIR filter design is based upon the approach of minimizing — in some specified manner — the mean square error between the transfer function of the filter and the frequency characteristics of a desired filter response. In a manner similar to the methods discussed in previous subsections, the mathematical objective of least-squares filter design is to determine the values for $N + 1$ impulse response samples

$$h(0), h(1), h(1), \ldots, h(N) \tag{86.60}$$

so that the transfer function of the filter, which is given by the Fourier transform of the impulse response samples,

$$H\left(e^{j\omega}\right) = \sum_{n=0}^{N} h(n) e^{-j\omega n} \tag{86.61}$$

approximates a desired response $H_d(e^{j\omega})$ in a least-squares sense. The impulse response sequence values can be found from $H(e^{j\omega})$ by means of the inverse Fourier transform given by

$$h(n) = \frac{1}{2\pi} \int_{-\pi}^{\pi} H\left(e^{j\omega}\right) e^{j\omega n} \, d\omega \tag{86.62}$$

In this presentation, attention is restricted to causal FIR filters, so that impulse response samples outside the range $(0, N)$ are assumed to be identically zero. This specified region of support is not a limitation to the methods discussed here, but is used since it is the more common application encountered in practice.

In the subsections that follow, four approaches that fall into the category of least-squares FIR filter design are presented: unweighted least squares, frequency sampling, weighted least squares, and eigenfilter methods. These techniques differ in the specific optimization criteria chosen, as well as sometimes in the overall design approach. All methods have been tested effective, and for the most part can claim computational efficiency as contrasted with minimax designs, which are by their nature iterative.

Unweighted Least-Squares Designs

In unweighted least-square filter designs, the error in no particular frequency band is emphasized over that in any other [15]. Such filters minimize the output error variance for a white noise input signal. Interestingly, an optimal unweighted-mean-square design is equivalent to a rectangular window design. To show this, define the mean-square error between the realized and desired frequency responses by

$$\in = \frac{1}{2\pi} \int_{-\pi}^{\pi} \left| H\left(e^{j\omega}\right) - H_d\left(e^{j\omega}\right) \right|^2 d\omega \tag{86.63}$$

By Parseval's relation, this is equal to

$$\begin{aligned} \in &= \sum_{n=-\infty}^{\infty} \left| h(n) - h_d(n) \right|^2 \\ &= \sum_{n=-\infty}^{-1} \left| h_d(n) \right|^2 + \sum_{n=0}^{N} \left| h(n) - h_d(n) \right|^2 + \sum_{n=N+1}^{\infty} \left| h_d(n) \right|^2 \end{aligned} \tag{86.64}$$

© 2003 by CRC Press LLC

where $h_d(n)$ is the impulse response corresponding to the desired frequency response $H_d(e^{j\omega})$ found by means of the inverse Fourier transform given in (86.62). Since $h(n)$ is restricted by design to be zero for $n \le -1$ and $n \le N+1$, summations over those indexes involve only the squared magnitude of the desired impulse response samples, and thus cannot be reduced by any choice of $h(n)$. In the region $0 \le n \le N$, the sum of squares can be made zero by choosing $h(n)$ equal to $h_d(n)$. Thus, the unweighted least-squares filter is given by

$$h(n) = \begin{cases} h_d(n) & \text{for } 0 \le n \le N \\ 0 & \text{otherwise} \end{cases} \tag{86.65}$$

with $h_d(n)$ as determined from $H_d(e^{j\omega})$ using (86.62). In some cases, the desired impulse response coefficients can be calculated in closed form from the inverse Fourier transform. In other cases, a numerical approximation to the integral must be performed, perhaps utilizing the discrete Fourier transform (DFT).

This is, of course, the same result as that obtained by the windowing method using the rectangular window function. While it does optimize the specified criterion, it suffers from the same disadvantages discussed earlier. Specifically, for frequency selective filters (e.g., low-pass, high-pass, bandpass, and bandstop), the frequency response near band edges deviates greatly from that desired, although in other regions, it approximates it with high fidelity. Since this property introduces the largest errors near the critical design frequencies, filters designed in this manner are usually undesirable. This is not always the case, however, For example, deconvolution or *D/A* conversion compensation filters often have smooth responses with no particular weighting associated with any frequency band, and so this method may be applicable there.

Example. Consider the design of a *N*th-order (*N* even) linear phase low-pass filter with the following desired frequency response:

$$H_d\left(e^{j\omega}\right) = \begin{cases} e^{-j\omega N/2} & \text{for } |\omega| \le \omega_c \\ 0 & \text{otherwise} \end{cases}$$

The impulse response for this transfer function is given by

$$\begin{aligned} h_d(n) &= \frac{1}{2\pi}\int_{-\omega_c}^{\omega_c} e^{j\omega(n-N/2)}d\omega \\ &= \frac{\sin\left[\omega_c(n-N/2)\right]}{\pi(n-N/2)} \end{aligned}$$

The impulse response coefficients for the actual *N*th-order FIR filter are those for the filter above in the range $0 \le n \le N$.

As a specific numerical example, let $N = 12$ and $\omega_c = 0.35\pi$. The impulse response coefficients are given in the UWLS column of Table 86.11. The magnitude frequency response for this filter is shown in Fig. 86.21. Note the large deviations from the ideal in the region near the cutoff frequency.

Frequency Sampling Methods

Another method for FIR filter design utilizes linear algebraic methods. In this approach, the desired frequency response $H_d(e^{j\omega})$ is specified at $N+1$ discrete frequencies $\{\omega_0, \omega_1, \omega_2, \ldots, \omega_N\}$. Then, the filter impulse response coefficients are chosen so that the transfer function $H(e^{j\omega})$ is equal to the desired response at those particular frequencies. Since the transfer function at any given frequency as given by

(86.60) is a sum of products involving the impulse response coefficients, this procedure can be written in matrix-vector form as

$$\begin{bmatrix} 1 & e^{-j\omega_0} & e^{-j2\omega_0} & \cdots & e^{-jN\omega_0} \\ 1 & e^{-j\omega_1} & e^{-j2\omega_1} & \cdots & e^{-jN\omega_1} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 1 & e^{-j\omega_N} & e^{-j2\omega_N} & \cdots & e^{-jN\omega_N} \end{bmatrix} \begin{bmatrix} h(0) \\ h(1) \\ \vdots \\ h(N) \end{bmatrix} = \begin{bmatrix} H_d\left(e^{j\omega_0}\right) \\ H_d\left(e^{j\omega_1}\right) \\ \vdots \\ H_d\left(e^{j\omega_N}\right) \end{bmatrix} \tag{86.66}$$

In more compact form, this can be written

$$\mathbf{Qh} = \mathbf{H}_d \tag{86.67}$$

where the definitions for the matrix $\mathbf{Q}$ and vectors $\mathbf{h}$ and $\mathbf{H}_d$ should be apparent from (86.66). The impulse response coefficients are found simply by solving

$$\mathbf{h} = \mathbf{Q}^{-1}\mathbf{H}_d \tag{86.68}$$

This method guarantees that the frequency response of the filter exactly matches that of the desired response at the selected discrete frequencies. As such, it implicitly allows for frequency band weighting, since the specified frequencies do not have to be uniformly spaced over normalized frequency space. By

© 2003 by CRC Press LLC

clustering more of the selected frequencies in a given band, the response in that band is usually closer to the desired response, while the response in other regions where the frequency grid is more sparse will have larger deviations.

However, a problem may arise at frequencies other than the selected discrete set. The response at these other frequencies is not controlled in the design algorithm and often deviates greatly from the desired response. The result is often a filter design with unacceptable ripple in both the passbands and stopbands. In some cases, this ripple behavior can be quite severe.

To alleviate this problem, a least-squares solution [2] can be obtained by specifying the desired response at $M + 1$ discrete frequencies, where $M > N$ (often $M \gg N$). In this case, the matrix-vector formulation of (86.66) and (86.67) is still applicable, however, the matrix $\mathbf{Q}$ is $M + 1$ rows by $N + 1$ columns and the $\mathbf{H}_d$ vector consists of $M + 1$ elements. With the mean-square error criterion defined as

$$\in = \left(\Theta\boldsymbol{\eta} - \mathbf{H}_d\right)^{\dagger}\left(\Theta\boldsymbol{\eta} - \mathbf{H}_d\right) \tag{86.69}$$

the least-square (or pseudo-inverse) solution is then given by

$$\mathbf{h} = \left(\mathbf{Q}^{\dagger}\mathbf{Q}\right)^{-1}\left(\mathbf{Q}^{\dagger}\mathbf{H}_d\right) \tag{86.70}$$

In this case, the response at the selected discrete frequencies is not constrained to be exactly that of the desired response. However, the overall deviations at those selected frequencies is minimized in a mean-square sense. This helps to ensure that deviations from the desired response are kept under control.

Although clustering of discrete frequency locations in the selected grid is one way of effectively performing frequency band weighting, a more direct manner is to assign specific weights to the desired response. In this case, the error criterion is defined as

$$\in = \left(\mathbf{Qh} - \mathbf{H}_d\right)^{\dagger}\mathbf{W}\left(\mathbf{Qh} - \mathbf{H}_d\right) \tag{86.71}$$

where $\mathbf{W}$ is a positive definite diagonal weighting matrix whose mth element represents the weighting assigned to the desired frequency response sample $H_d(e^{j\omega_m})$. The least-squares solution in this case is given by

$$\mathbf{h} = \left(\mathbf{Q}^{\dagger}\mathbf{WQ}\right)^{-1}\mathbf{Q}^{\dagger}\mathbf{WH}_d \tag{86.72}$$

By means of the weighting assigned to each frequency sample, the achieved response can be made to approach the desired response as closely as the designer wishes.

Computational complexity in all the previously discussed frequency sampling design algorithms can often be reduced by exploiting symmetry constraints in the impulse response. Usually, FIR filters are desired to be linear phase. This property can be ensured in the design by constraining $h(n) = h(N - n)$ or $h(n) = -h(N - n)$, so that $H(e^{j\omega}) = A(e^{j\omega}) = e^{-j\omega N/2}$ or $H(e^{j\omega}) = jA\ (e^{j\omega})\ e^{-j\omega N/2}$, respectively, where $A(e^{j\omega})$ is a purely real function. (Other symmetry constraints, such as those for Hilbert transformers, are also possible. However, the basic principle is illustrated by these two more common cases.) Under these constraints, only $N/2 + 1$ (for N even) or $(N + 1)/2$ (for N odd) distinct impulse response samples exist, so that the order of the system of linear design equations is approximately halved. In addition, the complex phase factor $e^{-j\omega N/2}$ can be eliminated in the design process, so that the defining equations become purely real, and thus the elements in the design matrix and vectors are also real. This further reduces computational loading over that that is implicit in the previously presented general design equations.

Frequency sampling design methods have the advantages of being applicable to a wide range of filter classes and easily programmed for numerical implementation. In some cases, where the response at

© 2003 by CRC Press LLC

certain specific frequencies is of extreme importance, they can be the methods of choice. However, some ambiguity exists in the choice of the discrete frequency grid, and different grids will produce different results. Selecting the grid thus becomes something of an ad hoc process. Another disadvantage is associated with the lack of design constraints to frequencies between those selected. As mentioned earlier, the response between the specified frequencies can sometimes deviate significantly from the desired response, yielding unsatisfactory results.

Example. Consider the design of a N th-order (N even) linear phase low-pass filter with the same desired frequency characteristics as in the previous example. The linear phase property can be guaranteed by constraining $h(n) = h(N - n)$ and for N even, the resulting transfer function written

$$H\left(e^{j\omega}\right) = \left[h\left(N/2\right) + 2\sum_{n=1}^{N/2} h\left(n + N/2\right)\cos\left(\omega n\right)\right] e^{-j\omega N/2}$$

The design problem is thus that of finding coefficients $\{h(N/2), h(N/2 + 1), \ldots, h(N)\}$ so that

$$h\left(N/2\right) + 2\sum_{n=1}^{N/2} h\left(n + N/2\right)\cos\left(\omega n\right) \cong \begin{cases} 1 & \text{for } |\omega| \le \omega_c \\ 0 & \text{otherwise} \end{cases}$$

If the desired response is specified on a $M + 1$-point frequency grid where $M > N$ and appropriate weighting is given to each frequency sample, the least-squares (pseudo-inverse) solution of linear equations such as that in (86.70) or (86.72) must be used.

As a specific numerical example, let $N = 12$ and $\omega_c = 0.35\pi$ as in the previous case. For illustration, let the desired response be specified on a $M + 1 = 11$-point grid defined by $\{0, 0.1\pi, 2.0\pi, \ldots, \pi\}$. (Note that the response is not specified in the range $0.3\pi < |\omega| < 0.4\pi$ around the cutoff frequency.) Solving the least-squares (pseudo-inverse) solution of linear equations yields the impulse response coefficients in the FSLS column of Table 86.11. The magnitude frequency response for this filter is shown in Fig. 86.22. Note that although the result is quite similar to that obtained in the previous example, deviations from the desired response at the specified grid points are lower.

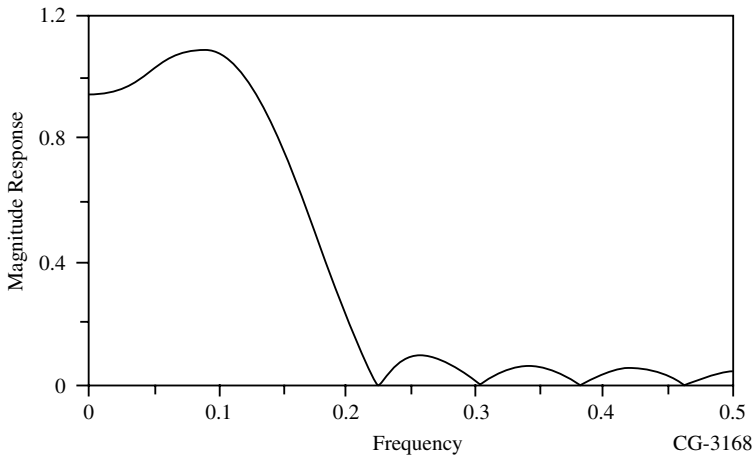

FIGURE 86.22 Magnitude frequency response for a 12th-order lowpass filter designed using the unweighted least-squares method plotted vs. frequency f where $\omega = 2\pi f$.

Weighted Least-Squares Methods

For cases where filter approximation over a continuous range of frequencies is desired inclusive of weighting, an approach resulting in a linear algebraic design method can be employed [1], [3], [6], [7], [14]. In this technique, the error criterion is a weighted mean-square error defined by

$$\epsilon = \frac{1}{2\pi}\int_{-\pi}^{\pi} W\left(e^{j\omega}\right)\left|H\left(e^{j\omega}\right) - H_d\left(e^{j\omega}\right)\right|^2 d\omega \tag{86.73}$$

where $W(e^{j\omega})$ is a real nonnegative symmetric weighting function [$W(e^{j\omega}) \le 0$, $W(e^{j\omega}) = W(e^{-j\omega})$] used to emphasize specified frequency components or bands. Setting $W(e^{j\omega}) = 0$ in a given region specifies a transition, or "don't care" band.

Substituting the expression for $H(e^{j\omega})$ given in (86.67) into (86.73) above, and evaluating $\partial\epsilon/\partial h(m) = 0$ for $m = 0, 1, 2, \ldots, N$ yields, for each m,

$$\sum_{n=0}^{N}\left[\frac{1}{2\pi}\int_{-\pi}^{\pi} W\left(e^{j\omega}\right)e^{j\omega(m-n)}d\omega\right]h(n) = \frac{1}{2\pi}\int_{-\pi}^{\pi} W\left(e^{j\omega}\right)H_d\left(e^{j\omega}\right)e^{j\omega m}d\omega \tag{86.74}$$

By defining the product function $G(e^{j\omega}) = W(e^{j\omega})H_d(e^{j\omega})$, and recognizing the integral expressions as inverse Fourier transforms, (86.74) can be written

$$\sum_{n=0}^{N} h(n)w(m-n) = g(m) \tag{86.75}$$

for $m = 0, 1, 2, \ldots, N$, where $w(n)$ and $g(n)$ are the inverse Fourier transforms of the functions $W(e^{j\omega})$ and $G(e^{j\omega})$, respectively. The real and symmetric constraints on the frequency domain weighting function $W(e^{j\omega})$ force the sequence $w(n)$ also to be real and symmetric, so the design equations can be written in matrix-vector form as

$$\begin{bmatrix} w(0) & w(1) & \cdots & w(N) \\ w(1) & w(0) & \cdots & w(N-1) \\ \vdots & \vdots & \ddots & \vdots \\ w(N) & w(N-1) & \cdots & w(0) \end{bmatrix}\begin{bmatrix} h(0) \\ h(1) \\ \vdots \\ h(N) \end{bmatrix} = \begin{bmatrix} g(0) \\ g(1) \\ \vdots \\ g(N) \end{bmatrix} \tag{86.76}$$

or more compactly,

$$\mathbf{Wh} = \mathbf{g}, \quad \mathbf{h} = \mathbf{W}^{-1}\mathbf{g} \tag{86.77}$$

In this way, it can be seen that the matrix **W** is Toeplitz, a property that can be exploited to reduce computation in the actual design procedure. (The **W** matrix in (86.76) should not be confused with the diagonal weighting matrix used in frequency sampling design methods.) If, in addition, symmetry constraints are also imposed on the impulse response coefficients, computation can be further reduced by the method described in [8].

Provided that the sequences $w(n)$ and $g(n)$ can be evaluated in closed form, this approach has the advantage over frequency sampling methods of minimizing the weighted mean-square error over every point in frequency space. For frequency selective multiband filters, closed-form expressions involving the band weights and the sinc function ($\mathrm{sinc}(x) = \sin(x)/x$) can be found. In cases where closed-form expressions cannot be obtained, numerical approximations can be used. However, if a DFT or rectangular

© 2003 by CRC Press LLC

rule integration is employed to estimate $w(n)$ and $g(n)$, it can be shown that the results are identical to those obtained by frequency sampling methods with the same frequency grid.

Example. Again, consider the design of a Nth-order (N even) linear phase low-pass filter with the same desired frequency characteristics as in the previous examples. Let the weighting function be specified as

$$W\left(e^{j\omega}\right) = \begin{cases} 1 & \text{for } |\omega| \le \omega_p \\ 0 & \text{for } \omega_p < |\omega| < \omega_S \\ 1 & \text{for } \omega_s \le |\omega| \le \pi \end{cases}$$

where ω_p and ω_s are the passband and stopband edges, respectively, chosen so that $\omega_p < \omega_c < \omega_s$. Note that the response is given zero weighting in the range $\omega_p < |\omega| < \omega_s$ around the cutoff frequency. However, unlike the previous example, all points in the stopband and passband are taken into consideration, rather than discrete points on a finite grid. In this example, the sequences $w(n)$ and $g(n)$ as defined above can be found in closed form and are given by

$$w(n) = \delta(n) + \frac{\sin(\omega_p n)}{\pi n} - \frac{\sin(\omega_s n)}{\pi n}$$

$$g(n) = \frac{\sin\left[\omega_p (n - N/2)\right]}{\pi (n - N/2)}$$

These expressions can be used to form the **W** matrix and **g** vector for use in the design equation (86.77).

As a specific numerical case, let $N = 12$ as in the previous examples with $\omega_p = 0.3\pi$ and $\omega_s = 0.4\pi$. Solving the solution of linear equations yields the impulse response coefficients in the WLS column of Table 86.11. The magnitude frequency response for this filter is shown in Fig. 86.23. Note that both the passband and stopband ripple have been reduced from the previous examples by utilizing a "don't care" transition band, and placing equal weighting on all other points in frequency space.

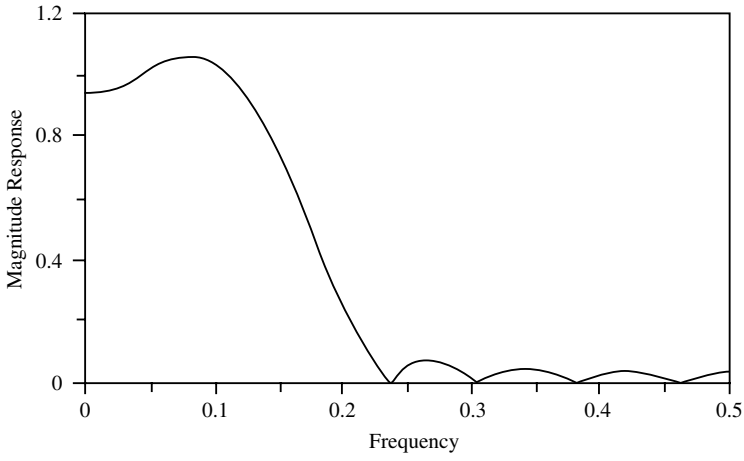

FIGURE 86.23 Magnitude frequency response for a 12th-order lowpass filter designed using the unweighted least-squares method plotted vs. frequency f where $\omega = 2\pi f$.

Eigenfilter Method

With this method the least-squares design problem is reformulated such that the impulse response samples can be obtained by finding the eigenvector of a matrix [9], [12], [13], [16]. This can be done by defining the vectors

$$\begin{aligned}\mathbf{h} &= \left[h(0) \quad h(1) \quad h(2) \cdots h(N)\right]^t \\ \mathbf{c}\left(e^{j\omega}\right) &= \left[1 \quad e^{-j\omega} \quad e^{-j2\omega} \cdots e^{-jN\omega}\right]^t\end{aligned} \tag{86.78}$$

so that

$$H\left(e^{j\omega}\right) = \mathbf{h}^t \mathbf{c}\left(e^{j\omega}\right) \tag{86.79}$$

Then, if the least-squares error can be defined in the form

$$\in = \mathbf{h}^t \mathbf{P} \mathbf{h} \tag{86.80}$$

by Rayleigh's principle [10] the solution for **h** will be the eigenvector of **P** corresponding to its minimum eigenvalue. Since only a single eigenvector is needed, it can be efficiently found using the iterative power method [5].

In the stopband(s) the desired response is zero so the error can be defined as

$$\begin{aligned}\in_s &= \int_{R_s} \left|H\left(e^{j\omega}\right)\right|^2 d\omega \\ &= \int_{R_s} \mathbf{h}^t \mathbf{c}\left(e^{j\omega}\right)\left[\mathbf{h}^t \mathbf{c}\left(e^{j\omega}\right)\right]^\dagger d\omega \\ &= \mathbf{h}^t \left[\int_{R_s} \mathbf{c}\left(e^{j\omega}\right)\mathbf{c}^\dagger\left(e^{j\omega}\right) d\omega\right]\mathbf{h} \\ &= \mathbf{h}^t \mathbf{P}_s \mathbf{h}\end{aligned} \tag{86.81}$$

where R_s is the portion of $-\pi \le \omega \le \pi$ containing stopbands. Likewise, in the passband(s) the error can be defined as

$$\begin{aligned}\in_p &= \int_{R_p} \left|\frac{H\left(e^{j\omega_0}\right)}{H_d\left(e^{j\omega_0}\right)} H_d\left(e^{j\omega}\right) - H\left(e^{j\omega}\right)\right|^2 d\omega \\ &= \mathbf{h}^t \left\{\int_{R_p} \left[\frac{H_d\left(e^{j\omega}\right)}{H_d\left(e^{j\omega_0}\right)} \mathbf{c}\left(\mathrm{e}^{j\omega_0}\right) - \mathbf{c}\left(e^{j\omega}\right)\right]\left[\frac{H_d^*\left(e^{j\omega}\right)}{H_d^*\left(e^{j\omega_0}\right)} \mathbf{c}^\dagger\left(e^{j\omega_0}\right) - \mathbf{c}^\dagger\left(e^{j\omega}\right)\right] d\omega\right\} \mathbf{h} \\ &= \mathbf{h}^t \mathbf{P}_p \mathbf{h}\end{aligned} \tag{86.82}$$

where ω_0 is a convenient reference frequency in the passband for which $H_d(e^{j\omega_0}) \neq 0$ and R_p is the portion of $-\pi \le \omega \le \pi$ containing passbands. The reason for including the reference frequency ratio $H(e^{j\omega_0})/H_d(e^{j\omega_0})$ is to bring **h** into the equation leading to the eigenformulation.

© 2003 by CRC Press LLC

Given $\mathbf{P}_s$ and $\mathbf{P}_p$, the total error can be defined as

$$\mathbf{P} = (1-\alpha)\mathbf{P}_p + \alpha\mathbf{P}_s \tag{86.83}$$

where α controls the relative accuracy of approximation in the passband and stopband. If desired, a continuous weighting function like that used with the weighted least-squares method can be incorporated into the eigenformulation as discussed in [9]. Equation (86.83) is easily extended to the case of filters with multiple passbands and stopbands where individual band weighting is desired.

Example. As an example of this approach, consider again designing a *N*th-order (*N* even) linear phase low-pass filter with the same frequency specifications as in the previous examples. Then, in the stopband ($\omega_c < \omega_s \le |\omega| < \pi$),

$$\mathbf{P}_s = \int_{-\pi}^{-\omega_s} \mathbf{c}\left(e^{j\omega}\right)\mathbf{c}^{\dagger}\left(e^{j\omega}\right)d\omega + \int_{\omega_s}^{\pi} \mathbf{c}\left(e^{j\omega}\right)\mathbf{c}^{\dagger}\left(e^{j\omega}\right)d\omega$$

so that the elements of P_s are then given by

$$\begin{aligned}\left[\mathbf{P}_s\right]_{mn} &= 2\int_{\omega_s}^{\pi} \cos\left[(m-n)\omega\right]d\omega \\ &= 2\frac{\sin\left[(m-n)\pi\right]}{(m-n)} - 2\frac{\sin\left[(m-n)\omega_s\right]}{(m-n)}\end{aligned}$$

where $m, n = 0, 1, \ldots, N$.

In the passband ($|\omega| \le \omega_p < \omega_c$), it is convenient to choose a reference frequency of $\omega_0 = 0$ giving

$$\mathbf{c}\left(e^{j\omega_0}\right) = \left[1 \quad 1\cdots 1\right] = \mathbf{1}$$

so that

$$\mathbf{P}_p = \int_{-\omega_p}^{\omega_p} \left[e^{-j\omega N/2}\mathbf{1} - \mathbf{c}\left(e^{j\omega}\right)\right]\left[\left(e^{j\omega N/2}\mathbf{1}^t - \mathbf{c}^{\dagger}\left(e^{j\omega}\right)\right]d\omega$$

The elements of $\mathbf{P}_p$ are thus

$$\left[\mathbf{P}_p\right]_{mn} = 2\omega_p + 2\frac{\sin\left[(m-n)\omega_p\right]}{m-n} - 2\frac{\sin\left[(m-N/2)\omega_p\right]}{n-N/2} - 2\frac{\sin\left[(n-N/2)\omega_p\right]}{n-N/2}$$

Choosing $N = 12$ and $\alpha = 0.5$ gives a filter comparable to that of the previous examples. Since most computer programs for finding eigenvectors return a normalized eigenvector with $\mathbf{h}^t\mathbf{h} = 1$, it is necessary to scale the eigenvector for the desired passband amplitude. In this example, the coefficients were scaled so that $h(6) = 0.35$ to simplify comparison of the results with the previous examples. The resulting coefficients are given in the EF column of Table 86.11. The magnitude frequency response of this filter is given in Fig. 86.24. Notice the similarity to the response obtained by the weighted least-squares method shown in Fig. 86.23.

Linear Programming (LP) and Mixed Integer Linear Programming (MILP) Design of FIR Filters

Y. C. Lim

Linear Programming [1]

Linear programming is an optimization problem that deals with the maximization or minimization of a linear function called the objective function subject to linear constraints. The problem expressed in (86.84a)–(86.84f) is a linear programming problem with J variables and K constraints. The objective function is

$$f = \mathbf{c}^T \mathbf{X} \tag{86.84a}$$

and the constraints are

$$\mathbf{AX} \le \mathbf{b} \tag{86.84b}$$

where

$$\mathbf{A} = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1J} \\ a_{21} & \ddots & & \vdots \\ \vdots & & \ddots & \vdots \\ a_{K1} & \cdots & \cdots & a_{KJ} \end{bmatrix} \tag{86.84c}$$

$$\mathbf{X} = \begin{bmatrix} x_1 & x_2 & \cdots & x_J \end{bmatrix}^T \tag{86.84d}$$

$$\mathbf{b} = \begin{bmatrix} b_1 & b_2 & \cdots & b_K \end{bmatrix}^T \tag{86.84e}$$

$$\mathbf{c} = \begin{bmatrix} c_1 & c_2 & \cdots & c_J \end{bmatrix}^T \tag{86.84f}$$

Formulation of the Linear Phase FIR Filter Design Problem as an LP Program [2], [3]

We shall choose the design of a low-pass filter as shown in Fig. 86.25 as an example to illustrate the formulation of a filter design problem as an LP problem. Let the peak stopband ripple be δ_s, the peak passband ripple be δ_p and the passband gain be d. Let ω_1 and ω_2 be the passband edge and stopband edge, respectively. Let

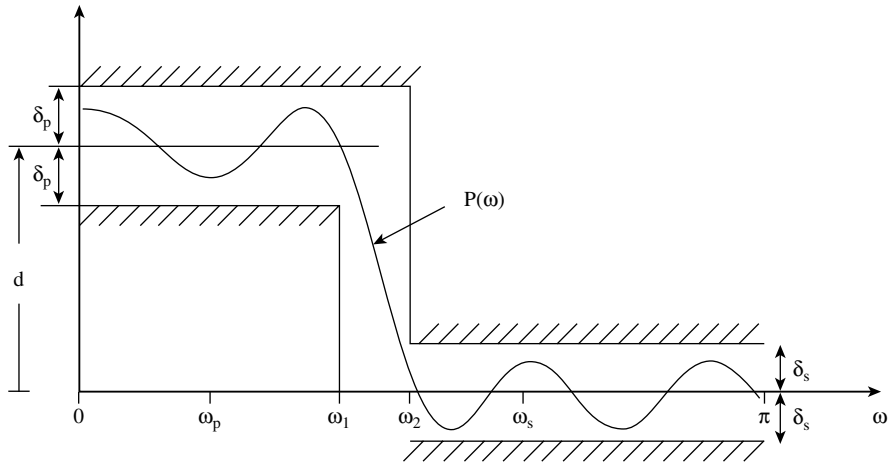

FIGURE 86.25 The frequency response of a low-pass filter.

$$0 \le \omega_p \le \omega_1 \tag{86.85a}$$

$$\omega_2 \le \omega_s \le \pi \tag{86.85b}$$

Let the frequency response of the filter be given by

$$H\left(e^{j\omega T}\right) = e^{-j\alpha\omega} P(\omega)$$

where α is a constant and $P(\omega)$ is a trigonometrical function (see Table 86.1). From 86.25, we have

$$P\left(\omega_p\right) \le d + \delta_p \tag{86.86a}$$

$$P\left(\omega_p\right) \ge d - \delta_p \tag{86.86b}$$

$$P\left(\omega_s\right) \le \delta_s \tag{86.86c}$$

$$P\left(\omega_s\right) \ge -\delta_s \tag{86.86d}$$

The set of constraints in (86.86a)–(86.86d) can be generalized to (86.87a)–(86.87f).

$$P(\omega) \le G(\omega) \times d + k(\omega) \times \delta \tag{86.87a}$$

$$P(\omega) \ge G(\omega) \times d - k(\omega) \times \delta \tag{86.87b}$$

where

$$G\left(\omega_p\right) = 1 \tag{86.87c}$$

$$G\left(\omega_s\right) = 0 \tag{86.87d}$$

$$k\left(\omega_p\right) \times \delta = \delta_p \tag{86.87e}$$

© 2003 by CRC Press LLC

$$k(\omega_s) \times \delta = \delta_s \tag{86.87f}$$

$G(\omega)$ is the gain weighting function and $k(\omega)$ is the ripple weighting function. By using suitable function values for $G(\omega)$ and $k(\omega)$, (86.87a) and (86.87b) may be used to describe arbitrary frequency response requirements for a filter.

A set of inequalities can be obtained by evaluating (86.87a) and (86.87b) on a dense grid of frequencies along the ω axis. Minimizing δ (or maximizing $-\delta$) subject to this set of constraints is a linear programming problem. The method can be easily extended to the design of 2-D FIR filters by taking $P(\omega)$ to be the frequency response of a 2-D filter.

It should be noted that the density of the frequency grid points where the inequalities of (86.87a) and (86.87b) are evaluated must be sufficiently high so that the frequency response of the filter does not violate implied specifications at frequencies between the frequency grid points. If $\hat{\delta}$ is the actual peak ripple magnitude, a misleading factor J given by

$$J = \left(\hat{\delta} - \delta\right) \Big/ \hat{\delta} \tag{86.88}$$

may be defined. The higher the grid density used, the smaller the value of J. In [4] a grid spacing of λ given by

$$\lambda = \frac{0.5 - \sum_i \Delta_i}{kN} \tag{86.89}$$

was proposed where Δ_i is the ith normalized transition width, N is the filter length, and k is a constant. $\Sigma_i \Delta_i$ is the sum of all the transition widths. The relationship between k and the mean value of J denoted by $\bar{J}$ for 1-D and 2-D FIR linear phase filters is shown in Figs. 86.26 and 86.27, respectively.

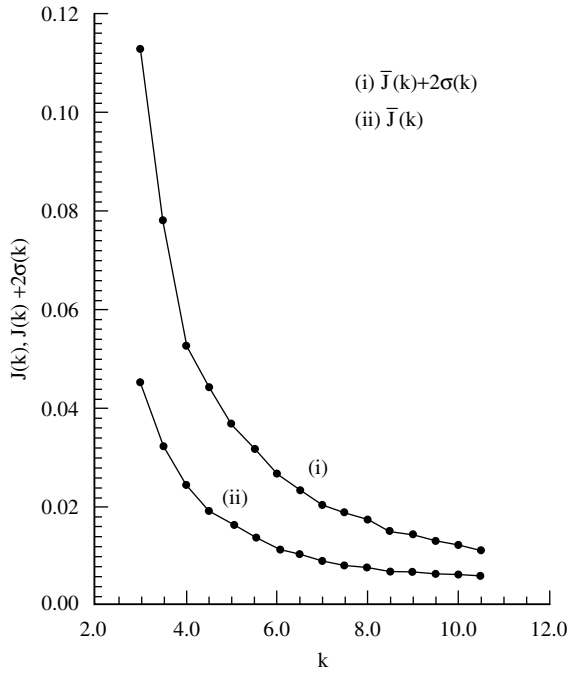

FIGURE 86.26 $\bar{J}(k)$ vs. k plots for 1-D linear phase FIR filters. σ is the standard deviation [4].

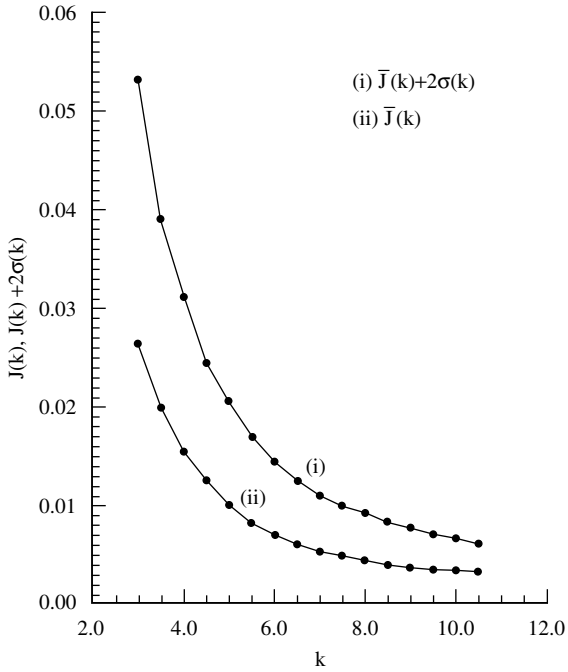

FIGURE 86.27 $\bar{J}(k)$ vs. k plots for 2-D linear phase FIR filters. σ is the standard deviation [4].

Linear Programming Design of Nonlinear Phase FIR Filters [5]

Let the desired frequency response at ω be $d(\omega)e^{j\Phi(\omega)}$, where d(ω) and $e^{j\Phi(\omega)}$ are the desired magnitude and phase responses, respectively. The frequency response ripple $E(\omega)e^{j\psi(\omega)}$ is thus given by

$$E(\omega)e^{j\psi(\omega)} = H\left(e^{j\omega}\right) - d(\omega)e^{j\Phi(\omega)} \tag{86.90}$$

where E (ω) and ψ(ω) are the magnitude and phase of the frequency response ripple. It is desired to minimize a weighted version of $E(\omega)$. This can be achieved by minimizing the weighted version of $\mathrm{Re}\{E(\omega)e^{j\psi(\omega)}\, e^{j\theta}\}$ on a dense grid of θ ranging from θ = 0 through θ = π, where Re{x} denotes the real part of x. If θ is uniformly distributed with spacing Δθ, then

$$E(\omega) \le \max_{\theta}\left|\mathrm{Re}\left\{E(\omega)e^{j\psi(\omega)}e^{j\theta}\right\}\right| \tag{86.91}$$

where $\max_{\theta}|x(\theta)|$ denotes the maximum value of $|x(\theta)|$ for all values of θ. If $h(n)$ is the nth impulse response of the FIR filter under consideration, then

$$H\left(e^{j\omega}\right) = \sum_{n} h(n)e^{-j\omega n} \tag{86.92}$$

The real part of $E(\omega)\, e^{j\psi(\omega)}\, e^{j\theta}$ is given by

$$\begin{aligned}\mathrm{Re}\left\{E(\omega)e^{j\psi(\omega)}e^{j\theta}\right\} = \sum_{n} h(n)\left\{\cos(\omega n)\cos(\theta) + \sin(\omega n)\sin(\theta)\right\} \\ - d(\omega)\left\{\cos\left[\Phi(\omega)\right]\cos(\theta) - \sin\left[\Phi(\omega)\right]\sin(\theta)\right\}\end{aligned} \tag{86.93}$$

© 2003 by CRC Press LLC

The linear programming problem for the design of nonlinear phase FIR filters can now be formulated as follows:

$$\text{minimize } \delta \tag{86.94a}$$

subject to

$$\mathrm{Re}\left\{E(\omega)e^{j\psi(\omega)}e^{j\theta}\right\} \le k(\omega)\times\delta \tag{86.94b}$$

$$\mathrm{Re}\left\{E(\omega)e^{j\psi(\omega)}e^{j\theta}\right\} \ge -k(\omega)\times\delta \tag{86.94c}$$

Design of FIR Filters with Discrete-Value Coefficients [6]–[10]

In a full custom hardware implementation, the coefficient multiplier is the most expensive and the most important speed-determining component. Consequently, the primary concern in the design of filters for hardware implementation is to reduce the multiplier complexity. If a fixed point hardware multiplier is employed, all the coefficient values will have the same quantization step size. In this case, if the gain of the filter d is scaled by a factor of 1/(coefficient quantization step size), all the coefficient values are integers. Such a filter with integer coefficient values can be optimized by using a mixed integer linear programming (MILP) algorithm. MILP is LP with integer constraints imposed on the LP variables corresponding to the filter's coefficient values.

In binary arithmetic, multiplying a number by an integer power of two is a very simple process; it is only a matter of shifting the bit position of the number. A full fletch multiplier is not needed. Hence, if each coefficient value of the filter is a sum of a limited number of signed power-of-two (SPT) terms, the filter can be implemented without using multipliers. MILP may also be used to optimize such filters.

The passband gain of an infinite-precision-coefficient-value filter may be arbitrarily scaled by scaling its coefficient values. Scaling the coefficient values corresponds to scaling the passband gain and peak ripple magnitude of the filter by the same scaling constant. Hence, the normalized peak ripple magnitude, i.e., peak ripple magnitude divided by passband gain, remains unchanged. However, this is not the case in the design of discrete-coefficient-value filters; the coefficient values cannot be arbitrarily scaled and still maintain their discrete nature. Thus, it is necessary to reoptimize the coefficient values when the passband gain is scaled. As a consequence, the normalized peak ripple magnitude, (weighted peak ripple magnitude/passband gain) changes as the passband gain changes.

If d is the passband gain of the filter, it may be allowed to vary within predetermined bounds in such a way that δ/d is minimized. This can be achieved by minimizing the objective function $\delta - \beta d$, where β is a constant to be updated iteratively using the following algorithm [10].

1. Round the coefficient values of the optimum infinite-precision-coefficient-value filter to the nearest discrete values. Let β be the value of δ/d of this rounded coefficient value filter. Set upper and lower bounds for d.
2. Perform an MILP run minimizing $\delta - \beta d$. Let β_2 be equal to δ/d of the optimum solution of the MILP run.
3. If $\beta = \beta_2$, this is the desired solution; stop. If $\beta \neq \beta_2$, let $\beta = \beta_2$ and go to step 2.

The design of a one-dimensional low-pass filter satisfying the following set of specifications is used to illustrate the above method: filter length = 20; passband edge = 0.1× sampling frequency; stopband edge = 0.2× sampling frequency; each coefficient value is a sum or difference of not more than two power-of-two terms; the peak ripple magnitude is to be minimized. Without imposing discrete constraints on the coefficient values, the peak ripple magnitude is 0.01245. Rounding each coefficient value to the nearest sum or difference of two power-of-two terms yields a design with normalized peak ripple magnitude equal to 0.05134. Letting $\beta = 0.05134$ produces a design with normalized peak ripple magnitude equal to 0.01299. Letting $\beta = 0.01299$ produces the same solution. Hence, the solution with $\beta = 0.01299$ is the optimum solution.

Design of Computationally Efficient FIR Filters Using Periodic Subfilters as Building Blocks

Tapio Saramäki

For many digital signal processing applications, FIR filters are preferred over their IIR counterparts as the former can be designed with exactly linear phase and they are free of stability problems and limit cycle oscillations. The major drawback of FIR filters is that they require, especially in applications demanding narrow transition bands, considerably more arithmetic operations and hardware components than do comparable IIR filters. Ignoring the correction term for very low-order filters, the minimum order of an optimum linear-phase low-pass FIR filter can be approximated [1] by

$$N \approx \Phi\left(\delta_p, \delta_s\right) \Big/ \left(\omega_s - \omega_p\right) \tag{86.95a}$$

where

$$\begin{aligned}\Phi\left(\delta_p, \delta_s\right) = {} & 2\pi\left[0.005\,309\left(\log_{10}\delta_p\right)^2 + 0.071\,14\log_{10}\delta_p - 0.4761\right]\log_{10}\delta_s \\ & - 2\pi\left[0.002\,66\left(\log_{10}\delta_p\right)^2 + 0.5941\log_{10}\delta_p + 0.4278\right]\end{aligned} \tag{86.95b}$$

Here, ω_p and ω_s are the passband and stopband edge angles, whereas δ_p and δ_s are the passband and stopband ripple magnitudes. From the above estimate, it is seen that as the transition bandwidth $\omega_s - \omega_p$ is made smaller, the required filter order increases inversely proportionally to it. Since the direct-form implementation exploiting the coefficient symmetry requires approximately $N/2$ multipliers, this kind of implementation becomes very costly if the transition bandwidth is small.

The cost of implementation of a narrow transition-band FIR filter can be significantly reduced by using multiplier-efficient realizations, fast convolution algorithms, or multirate filtering. This section

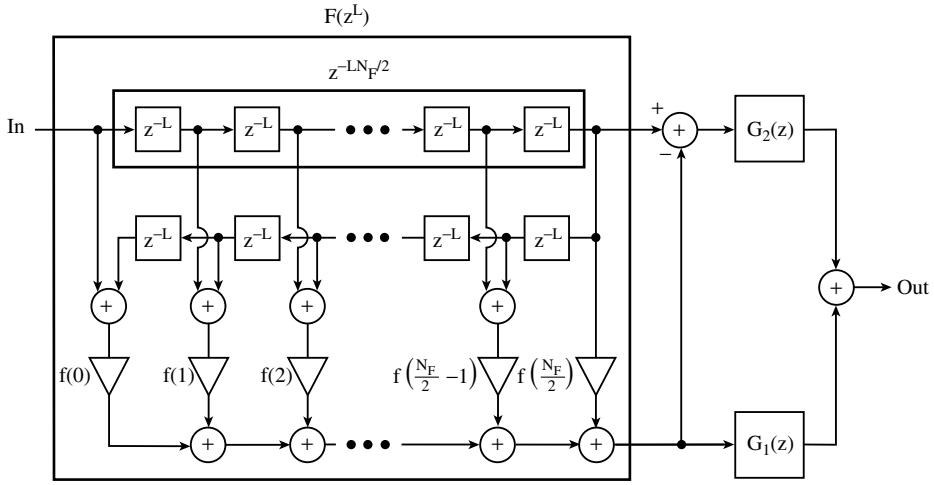

FIGURE 86.28 An efficient implementation for a filter synthesized using the frequency-response masking approach.

considers those multiplier-efficient realizations that use as basic building blocks the transfer functions obtained by replacing each unit delay in a conventional transfer function by multiple delays. We concentrate on the synthesis techniques described in [2]–[4], [6], and [8]–[10].

Frequency-Response Masking Approach

A very elegant approach to significantly reducing the implementation cost of an FIR filter has been proposed by Lim [3]. In this approach, the overall transfer function is constructed as

$$H(z) = F\left(z^L\right)G_1(z) + \left[z^{-LN_F/2} - F\left(z^L\right)\right]G_2(z) \tag{86.96a}$$

where

$$F\left(z^L\right) = \sum_{n=0}^{N_F} f(n)z^{-nL}, \qquad f\left(N_F - n\right) = f(n) \tag{86.96b}$$

$$G_1(z) = z^{-M_1}\sum_{n=0}^{N_1} g_1(n)z^{-n}, \qquad g_1\left(N_1 - n\right) = g_1(n) \tag{86.96c}$$

and

$$G_2(z) = z^{-M_2}\sum_{n=0}^{N_2} g_2(n)z^{-n}, \qquad g_2\left(N_2 - n\right) = g_2(n) \tag{86.96d}$$

Here, N_F is even, whereas both N_1 and N_2 are either even or odd. For $N_1 \le N_2$, $M_1 = 0$ and $M_2 = (N_1 - N_2)/2$, whereas for $N_1 < N_2$, $M_1 = (N_2 - N_1)/2$ and $M_2 = 0$. These selections guarantee that the delays of both of the terms of $H(z)$ are equal. An efficient implementation for the overall filter is depicted in Fig. 86.28, where the delay term $z^{-LN_F/2}$ is shared with $F(z^L)$. Also, $G_1(z)$ and $G_2(z)$ can share their delays if a transposed direct-form implementation (exploiting the coefficient symmetry) is used.

The frequency response of the overall filter can be written as

$$H\left(e^{j\omega}\right) = H(\omega)e^{-j\left(LN_F + \max\left[N_1, N_2\right]\right)\omega/2} \tag{86.97}$$

© 2003 by CRC Press LLC

where $H(\omega)$ denotes the *zero-phase frequency response* of $H(z)$ and can be expressed as

$$H(\omega) = H_1(\omega) + H_2(\omega) \tag{86.98a}$$

where

$$H_1(\omega) = F(L\omega)G_1(\omega) \tag{86.98b}$$

and

$$H_2(\omega) = \left[1 - F(L\omega)\right]G_2(\omega) \tag{86.98c}$$

with

$$F(\omega) = f\left(N_F/2\right) + 2\sum_{n=1}^{N_F/2} f\left(N_F/2 - n\right)\cos n\omega \tag{86.98d}$$

and

$$G_k(\omega) = \begin{cases} g_k\left(N_k/2\right) + 2\displaystyle\sum_{n=1}^{N_k/2} g_k\left(N_k/2 - n\right)\cos n\omega & N_k \text{ even} \\ 2\displaystyle\sum_{n=0}^{(N_k-1)/2} g_k\left[\left(N_k-1\right)/2 - n\right]\cos\left[\left(n+1/2\right)\omega\right] & N_k \text{ odd} \end{cases} \tag{86.98e}$$

for $k = 1, 2$.

The efficiency as well as the synthesis of $H(z)$ are based on the properties of the pair of transfer functions $F(z^L)$ and $z^{-LN_F/2} - F(z^L)$, which can be generated from the pair of *prototype* transfer functions

$$F(z) = \sum_{n=0}^{N_F} f(n)z^{-n} \tag{86.99}$$

and $z^{-N_F/2} - F(z)$ by replacing z^{-1} by z^{-L}, that is, by substituting for each unit delay L unit delays. The order of the resulting filters is increased to LN_F, but since only every Lth impulse response value is nonzero, the filter complexity (number of adders and multipliers) remains the same. The above prototype pair forms a *complementary* filter pair since their zero-phase frequency responses, $F(\omega)$ and $1 - F(\omega)$ with $F(\omega)$ given by (86.98d), add up to unity. Figure 86.29(a) illustrates the relations between these responses in the case where $F(z)$ and $z^{-N_F/2} - F(z)$ is a low-pass–high-pass filter pair with edges at θ and ϕ.

The substitution $z^{-L} \mapsto z^{-1}$ preserves the complementary property resulting in the *periodic* responses $F(L\omega)$ and $1 - F(L\omega)$, which are frequency-axis compressed versions of the prototype responses such that the interval $[0, L\pi]$ is shrunk onto $[0, \pi]$ [see Fig. 86.29(b)]. Since the periodicity of the prototype responses is 2π, the peridiocity of the resulting responses is $2\pi/L$ and they contain several passband and stopband regions in the interval $[0, \pi]$.

For a low-pass filter $H(z)$, one of the transition bands provided by $F(z^L)$ or $z^{-LN_F/2} - F(z^L)$ is used as that of the overall filter. In the first case, denoted by Case A, the edges are given by (see Fig. 86.30)

$$\omega_p = \left(2l\pi + \theta\right)/L \quad \text{and} \quad \omega_s = \left(2l\pi + \phi\right)/L \tag{86.100}$$

where l is a fixed integer, and in the second case, referred to as Case B, by (see Fig. 86.31)

$$\omega_p = \left(2l\pi - \phi\right)/L \quad \text{and} \quad \omega_s = \left(2l\pi - \theta\right)/L \tag{86.101}$$

The widths of these transition bands are $(\phi - \theta)/L$, which is only $1/L$th of that of the prototype filters. Since the filter order is roughly inversely proportional to the transition bandwidth, this means that the

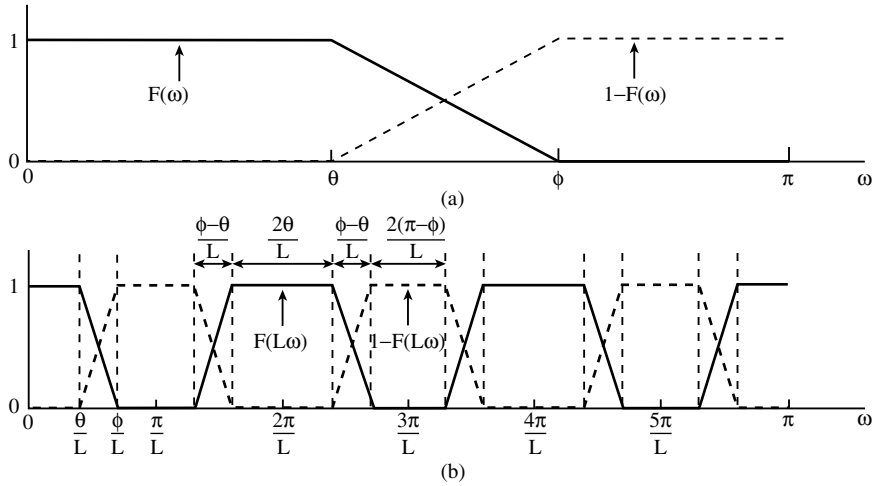

FIGURE 86.29 Generation of a complementary periodic filter pair by starting with a low-pass–high-pass complementary pair. (a) Prototype filter responses $F(\omega)$ and $1 - F(\omega)$. (b) Periodic responses $F(L\omega)$ and $1 - F(L\omega)$ for $L = 6$.

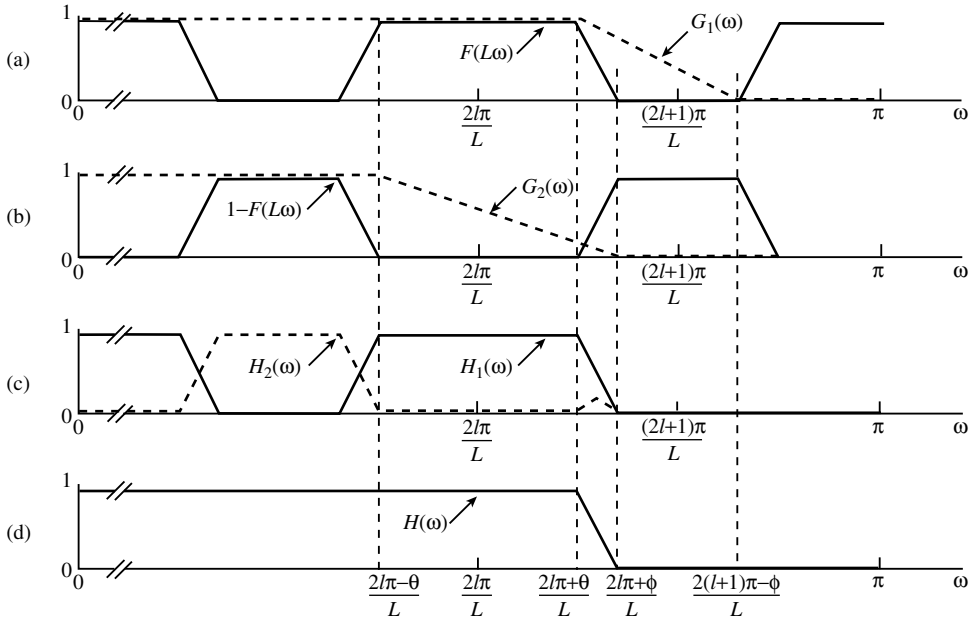

FIGURE 86.30 Case A design of a low-pass filter using the frequency-response masking technique.

arithmetic complexity of the periodic transfer functions to provide one of the transition bands is only $1/L$th of that of a conventional nonperiodic filter. Note that the orders of both the periodic filters and the corresponding nonperiodic filters are approximately the same, but the conventional filter does not contain zero-valued impulse response samples.

In order to exploit the attractive properties of the periodic transfer functions, the two low-order masking filters $G_1(z)$ and $G_2(z)$ are designed such that the subresponses $H_1(\omega)$ and $H_2(\omega)$ as given by (86.98b) and (86.98c) approximate in the passband $F(L\omega)$ and $1 - F(L\omega)$, respectively, so that their sum approximates unity, as is desired. In the filter stopband, the role of the masking filters is to attenuate the extra unwanted passbands and transition bands of the periodic responses. In Case A, this is achieved by selecting the edges of $G_1(z)$ and $G_2(z)$ as (see Fig. 86.30)

© 2003 by CRC Press LLC

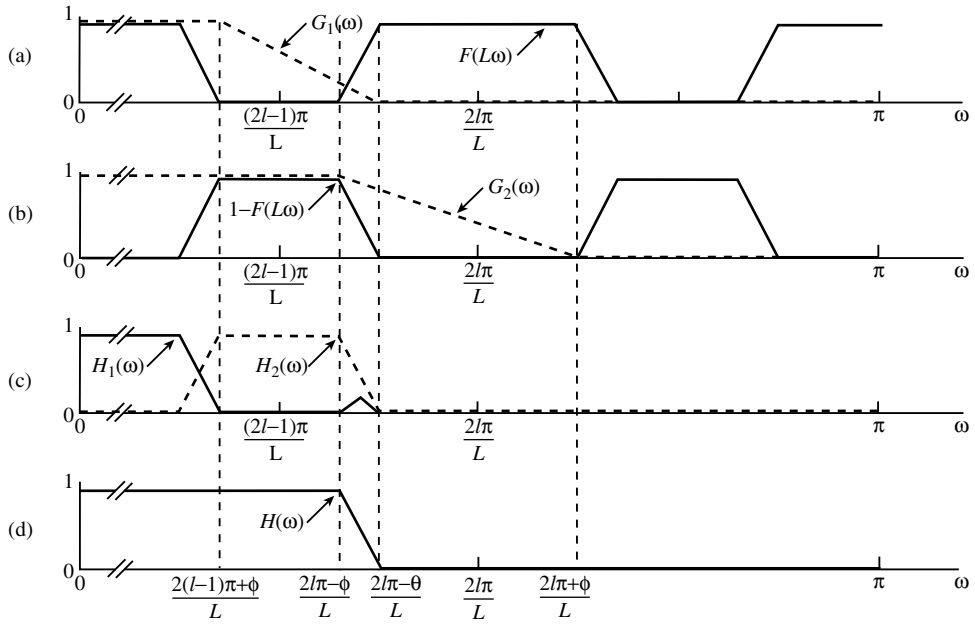

FIGURE 86.31 Case B design of a low-pass filter using the frequency-response masking technique.

$$\omega_p^{(G_1)} = \omega_p = \left[2l\pi + \theta\right]/L \quad \text{and} \quad \omega_s^{(G_1)} = \left[2(l+1)\pi - \phi\right]/L \tag{86.102a}$$

$$\omega_p^{(G_2)} = \left[2l\pi - \theta\right]/L \quad \text{and} \quad \omega_s^{(G_2)} = \omega_s = \left[2l\pi + \phi\right]/L \tag{86.102b}$$

Since $F(L\omega) \approx 0$ on $[\omega_s, \omega_s^{(G_1)}]$, the stopband region of $G_1(z)$ can start at $\omega = \omega_s^{(G_1)}$, instead of $\omega = \omega_s$. Similarly, since $H_1(\omega) \approx F(L\omega) \approx 1$ and $[1 - F(L\omega)] \approx 0$ on $[\omega_p^{(G_2)}, \omega_p]$, the passband region of $G_2(z)$ can start at $\omega = \omega_p^{(G_2)}$, instead of $\omega = \omega_p$.

For Case B designs, the required edges of the two masking filters, $G_1(z)$ and $G_2(z)$ are (see Fig. 86.31)

$$\omega_p^{(G_1)} = \left[2(l-1)\pi + \phi\right]/L \quad \text{and} \quad \omega_s^{(G_1)} = \omega_s = \left[2l\pi - \theta\right]/L \tag{86.103a}$$

$$\omega_p^{(G_2)} = \omega_p = \left[2l\pi - \phi\right]/L \quad \text{and} \quad \omega_s^{(G_2)} = \left[2l\pi + \theta\right]/L \tag{86.103b}$$

The effects of the ripples of the subresponses on the ripples of the overall response $H(\omega)$ have been studied carefully in [3]. Based on these observations, the design of $H(z)$ with passband and stopband ripples of δ_p and δ_s can be accomplished for both Case A and Case B in the following two steps:

1. Design $G_k(z)$ for $k = 1, 2$ using either the Remez algorithm or linear programming such that $G_k(\omega)$ approximates unity on $[0, \omega_p^{(G_k)}]$ with tolerance $0.85\delta_p \cdots 0.9\delta_p$ and zero on $[\omega_s^{(G_k)}, \pi]$ with tolerance $0.85\delta_s \cdots 0.9\delta_s$.
2. Design $F(L\omega)$ such that the overall response $H(\omega)$ approximates unity on

$$\Omega_p^{(F)} = \begin{cases} \left[\omega_p^{(G_2)}, \omega_p\right] = \left[\left[2l\pi - \theta\right]/L, \left[2l\pi + \theta\right]/L\right] & \text{for Case A} \\ \left[\omega_p^{(G_1)}, \omega_p\right] = \left[\left[2(l-1)\pi + \phi\right]/L, \left[2l\pi - \phi\right]/L\right] & \text{for Case B} \end{cases} \tag{86.104a}$$

with tolerance δ_p and approximates zero on

TABLE 86.12 Error Function for Designing $F(\omega)$ Using the Remez Algorithm

$$E_F(\omega) = W_F(\omega)\,[F(\omega) - D_F(\omega)],$$

where

$$D_F(\omega) = \left[u(\omega) + l(\omega)\right]/2,\ W_F(\omega) = 2/\left[u(\omega) - l(\omega)\right]$$

with

$$u(\omega) = \min\left(\Psi_1(\omega) + \psi_1(\omega),\ \Psi_2(\omega) + \psi_2(\omega)\right)$$

$$l(\omega) = \max\left(\Psi_1(\omega) - \psi_1(\omega),\ \Psi_2(\omega) - \psi_2(\omega)\right)$$

$$\Psi_k(\omega) = \frac{D_H\left[h_k(\omega)\right] - G_2\left[h_k(\omega)\right]}{G_1\left[h_k(\omega)\right] - G_2\left[h_k(\omega)\right]},\quad k = 1, 2$$

$$\psi_k(\omega) = \frac{1/W_H\left[h_k(\omega)\right]}{\left|G_1\left[h_k(\omega)\right] - G_2\left[h_k(\omega)\right]\right|},\quad k = 1, 2$$

and

$$h_1(\omega) = (2l\pi + \omega)/L,\quad h_2(\omega) = \begin{cases} (2l\pi - \omega)/L & \text{for } \omega \in [0, \theta] \\ \left[2(l+1)\pi - \omega\right]/L & \text{for } \omega \in [\phi, \pi] \end{cases}$$

for Case A and

$$h_1(\omega) = (2l\pi - \omega)/L,\quad h_2(\omega) = \begin{cases} (2l\pi + \omega)/L & \text{for } \omega \in [0, \theta] \\ \left[2(l-1)\pi + \omega\right]/L & \text{for } \omega \in [\phi, \pi] \end{cases}$$

for Case B.

$$\Omega_s^{(F)} = \begin{cases} \left[\omega_s, \omega_s^{(G_1)}\right] = \left[\left[2l\pi + \phi\right]/L,\ \left[2(l+1)\pi - \phi\right]/L\right] & \text{for Case A} \\ \left[\omega_s, \omega_s^{(G_2)}\right] = \left[\left[2l\pi - \theta\right]/L,\ \left[2l\pi + \theta\right]/L\right] & \text{for Case B} \end{cases} \tag{86.104b}$$

with tolerance δ_s.

The design of $F(L\omega)$ can be performed conveniently using linear programming [3]. Another, computationally more efficient, alternative is to use the Remez algorithm [10]. Its use is based on the fact that

$$\left|E_H(\omega)\right| \le 1 \quad \text{for } \omega \in \Omega_p^{(F)} \cup \Omega_s^{(F)} \tag{86.105a}$$

where

$$E_H(\omega) = W_H(\omega)\left[H(\omega) - D_H(\omega)\right] \tag{86.105b}$$

is satisfied when $F(\omega)$ is designed such that the maximum absolute value of the error function given in Table 86.12 becomes less than or equal to unity on $[0, \theta] \cup [\phi, \pi]$.

For Step 2 of the above algorithm, $D_H(\omega) = 1$ and $W_H(\omega) = 1/\delta_p$ on $\Omega_p^{(F)}$, whereas $D_H(\omega) = 0$ and $W_H(\omega) = 1/\delta_s$ on $\Omega_s^{(F)}$, giving for $k = 1, 2$

$$D_H\left[h_k(\omega)\right] = \begin{cases} 1 & \text{for } \omega \in [0, \theta] \\ 0 & \text{for } \omega \in [\phi, \pi] \end{cases} \quad \text{and} \quad W_H\left[h_k(\omega)\right] = \begin{cases} 1/\delta_p & \text{for } \omega \in [0, \theta] \\ 1/\delta_s & \text{for } \omega \in [\phi, \pi] \end{cases} \tag{86.106a}$$

for Case A and

$$D_H\left[h_k(\omega)\right]=\begin{cases}1 & \text{for } \omega \in [0,\theta] \\ 0 & \text{for } \omega \in [\phi,\pi]\end{cases} \quad \text{and} \quad W_H\left[h_k(\omega)\right]=\begin{cases}1/\delta_s & \text{for } \omega \in [0,\theta] \\ 1/\delta_p & \text{for } \omega \in [\phi,\pi]\end{cases} \tag{86.106b}$$

for Case B. Even though the resulting error function looks very complicated, it is straightforward to use the subroutines EFF and WATE in the Remez algorithm described in [5] for optimally designing $F(z)$.

The order of $G_1(z)$ can be considerably reduced by allowing larger ripples on those regions of $G_1(z)$ where $F(L\omega)$ has one of its stopbands. As a rule of thumb, the ripples on these regions can be selected to be 10 times larger [3]. Similarly, the order $G_2(z)$ can be decreased by allowing (ten times) larger ripples on those regions where $F(L\omega)$ has one of its passbands.

In practical filter synthesis problems, ω_p and ω_s are given and l, L, θ, and ϕ must be determined. To ensure that (86.100) yields a desired solution with $0 \le \theta < \phi \le \pi$, it is required that (see Fig. 86.30)

$$\frac{2l\pi}{L} \le \omega_p \quad \text{and} \quad \omega_s \le \frac{(2l+1)\pi}{L} \tag{86.107a}$$

for some positive integer l, giving

$$l=\left\lfloor L\omega_p/(2\pi)\right\rfloor, \qquad \theta = L\omega_p - 2l\pi, \quad \text{and} \quad \phi = L\omega_s - 2l\pi \tag{86.107b}$$

where $\lfloor x \rfloor$ stands for the largest integer that is smaller than or equal to x. Similarly, to ensure that (86.101) yields a desired solution with $0 \le \theta < \phi \le \pi$, it is required that (see Fig. 86.31)

$$\frac{(2l-1)\pi}{L} \le \omega_p \quad \text{and} \quad \omega_s \le \frac{2l\pi}{L} \tag{86.108a}$$

for some positive integer l, giving

$$l=\left\lceil L\omega_s/(2\pi)\right\rceil, \qquad \theta = 2l\pi - L\omega_s, \quad \text{and} \quad \phi = 2l\pi - L\omega_p \tag{86.108b}$$

where $\lceil x \rceil$ stands for the smallest integer that is larger than or equal to x. For any set of ω_p, ω_s, and L, either (86.107b) or (86.108b) (not both) will yield the desired θ and ϕ, provided that L is not too large. If $\theta = 0$ or $\phi = \pi$, then the resulting specifications for $F(\omega)$ are meaningless and the corresponding value of L cannot be used.

The remaining problem is to determine L to minimize the number of multipliers, which is $N_F/2 + 1 + \lfloor (N_1 + 2)/2 \rfloor + \lfloor (N_2 + 2)/2 \rfloor$ or $N_F + N_1 + N_2 + 3$ depending on whether the symmetries in the filter coefficients are exploited or not. Hence, in both cases, a good measure of the filter complexity is the sum of the orders of the subfilters. Instead of determining the actual minimum filter orders for various values of L, the computational workload can be significantly reduced based on the use of the estimation formula given by (86.95a) and (86.95b). Since the widths of transition bands of $F(z)$, $G_1(z)$, and $G_2(z)$ are $\phi - \theta$, $(2\pi - \phi - \theta)/L$ and $(\phi + \theta)/L$, respectively, good estimates for the corresponding filter orders are

$$N_F \approx \frac{\Phi(\delta_p,\delta_s)}{\phi-\theta}, \qquad N_1 \approx \frac{L\Phi(\delta_p,\delta_s)}{2\pi-\phi-\theta}, \quad \text{and} \quad N_2 \approx \frac{L\Phi(\delta_p,\delta_s)}{\phi+\theta} \tag{86.109}$$

For the optimum nonperiodic direct-form design, the transition bandwidth is $\omega_s - \omega_p = (\phi - \theta)/L$, giving

$$N_{\text{opt}} \approx \frac{L\Phi(\delta_p,\delta_s)}{\phi-\theta} \tag{86.110}$$

© 2003 by CRC Press LLC

The sum of the subfilter orders can be expressed in terms of N_{opt} as follows:

$$N_{ove} = N_{opt}\left[\frac{1}{L} + \frac{\phi - \theta}{2\pi - \phi - \theta} + \frac{\phi - \theta}{\phi + \theta}\right] \tag{86.111}$$

The smallest values of N_{ove} are typically obtained at those values of L for which $\theta + \phi \approx \pi$ and, correspondingly, $2\pi - \theta - \phi \approx \pi$. In this case, $N_1 \approx N_2$ and (86.111) reduces, after substituting $\phi - \theta = L(\omega_s - \omega_p)$, to

$$N_{ove} = N_{opt}\left[\frac{1}{L} + 2L\left(\omega_s - \omega_p\right)/\pi\right] \tag{86.112}$$

At these values of L, N_F decreases and $N_1 \approx N_2$ increases inversely proportionally to L with the minimum of N_{ove} given by

$$N_{ove} = 2N_{opt}\sqrt{\frac{2\left(\omega_s - \omega_p\right)}{\pi}} \tag{86.113}$$

taking place at

$$L_{opt} = 1\Big/\sqrt{\frac{2\left(\omega_s - \omega_p\right)}{\pi}} \tag{86.114}$$

If for $L = L_{opt}$, $\theta + \phi$ is not approximately equal to π, then L minimizing the filter complexity can be found in the near vicinity of L_{opt}. The following example illustrates the use of the above estimation formulas.

Example 1. Consider the specifications: $\omega_p = 0.4\pi$, $\omega_s = 0.402\pi$, $\delta_p = 0.01$, and $\delta_s = 0.001$. For the optimum conventional direct-form design, $N_{opt} = 2541$, requiring 1271 multipliers when the coefficient symmetry is exploited. Equation (86.114) gives $L_{opt} = 16$. Table 86.13 shows, for the admissible values of L in the vicinity of this value, l, θ, ϕ, the estimated orders for the subfilters, and the sum of the subfilter orders as well as whether the overall filter is a Case A or Case B design. For N_F, the minimum even order larger than or equal to the estimated order is used, whereas N_2 is forced to be even (odd) if N_1 is even (odd).

Also with the estimated filter orders of Table 86.13, $L = 16$ gives the best result. The actual filter orders are $N_F = 162$, $N_1 = 70$, $N_2 = 98$. The responses of the subfilters as well as that of the overall design are depicted in Fig. 86.32. The overall number of multipliers and adders for this design are 168 and 330,

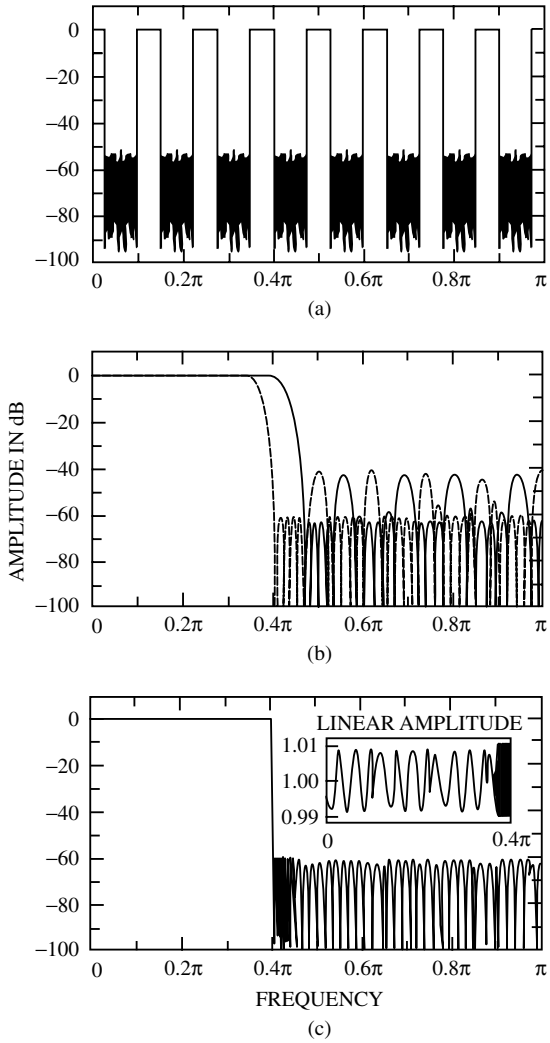

FIGURE 86.32 Amplitude responses for a filter synthesized using the frequency-response masking approach. (a) Periodic response $F(L\omega)$. (b) Responses $G_1(\omega)$ (solid line) and $G_2(\omega)$ (dashed line). (c) Overall response.

respectively, which are 13 percent of those required by an equivalent conventional direct-form design (1271 and 2541). The overall filter order is 2690, which is only 6 percent higher than that of the direct-form design (2541).

Multistage Frequency-Response Masking Approach

If the order of $F(z)$ is too high, its complexity can be reduced by implementing it using the frequency-response masking technique. Extending this to an arbitrary number of stages results in the multistage frequency-response masking approach [3], [4], where $H(z)$ is generated iteratively as

$$H(z) \equiv F^{(0)}(z) = F^{(1)}\left(z^{L_1}\right)G_1^{(1)}(z) + \left[z^{-L_1 N_F^{(1)}/2} - F^{(1)}\left(z^{L_1}\right)\right]G_2^{(1)}(z) \tag{86.115a}$$

© 2003 by CRC Press LLC

$$F^{(1)}(z) = F^{(2)}\left(z^{L_2}\right)G_1^{(2)}(z) + \left[z^{-L_2 N_F^{(2)}/2} - F^{(2)}\left(z^{L_2}\right)\right]G_2^{(2)}(z) \tag{86.115b}$$

$$\vdots \quad \vdots \quad \vdots$$

$$F^{(R-1)}(z) = F^{(R)}\left(z^{L_R}\right)G_1^{(R)}(z) + \left[z^{-L_R N_F^{(R)}/2} - F^{(R)}\left(z^{L_R}\right)\right]G_2^{(R)}(z) \tag{86.115c}$$

Here, the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s for $r = 1, 2, \ldots, R$ as well as $F^{(R)}(z)$ are the filters to be designed. For implementation purposes, $H(z)$ can be expressed in the form shown in Table 86.14. Fig. 86.33 shows an efficient implementation for a three-stage filter, where the delay terms z^{-M_3}, z^{-m_2}, and z^{-m_1}, can be shared with $F^{(3)}(z^{\hat{L}_3})$. In order to obtain a desired overall solution, the orders of the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s for $r = 2, 3, \ldots, R$, denoted by $N_1^{(r)}$ and $N_2^{(r)}$ in Table 86.14, have to be even.

TABLE 86.14 Implementation Form for the Transfer Function in the Multistage Frequency-Response Masking Approach

$$H(z) \equiv F^{(0)}\left(z^{\hat{L}_0}\right) = F^{(1)}\left(z^{\hat{L}_1}\right)G_1^{(1)}\left(z^{\hat{L}_0}\right) + \left[z^{-M_1} - F^{(1)}\left(z^{\hat{L}_1}\right)\right]G_2^{(1)}\left(z^{\hat{L}_0}\right)$$

$$F^{(1)}\left(z^{\hat{L}_1}\right) = F^{(2)}\left(z^{\hat{L}_2}\right)G_1^{(2)}\left(z^{\hat{L}_1}\right) + \left[z^{-M_2} - F^{(2)}\left(z^{\hat{L}_2}\right)\right]G_2^{(2)}\left(z^{\hat{L}_1}\right)$$

$$\vdots \quad \vdots \quad \vdots$$

$$F^{(R-1)}\left(z^{\hat{L}_{R-1}}\right) = F^{(R)}\left(z^{\hat{L}_R}\right)G_1^{(R)}\left(z^{\hat{L}_{R-1}}\right) + \left[z^{-M_R} - F^{(R)}\left(z^{\hat{L}_R}\right)\right]G_2^{(R)}\left(z^{\hat{L}_{R-1}}\right),$$

where

$$\hat{L}_0 = 1, \qquad \hat{L}_r = \prod_{k=1}^{r} L_k, \qquad r = 1, 2, \cdots, R$$

$$M_R = \hat{L}_R N_F^{(R)}/2, \qquad M_{R-r} = M_{R-r+1} + m_{R-r}, \quad r = 1, 2, \cdots, R-1$$

$$m_{R-r} = \hat{L}_{R-r} \max\left\{N_1^{(R-r+1)}, N_2^{(R-r+1)}\right\}/2, \qquad r = 1, 2, \cdots, R-1$$

$N_F^{(R)}$ is the order of $F^{(R)}(z)$.

$N_1^{(r)}$ and $N_2^{(r)}$ are the orders of $G_1^{(r)}(z)$ and $G_2^{(r)}(z)$, respectively.

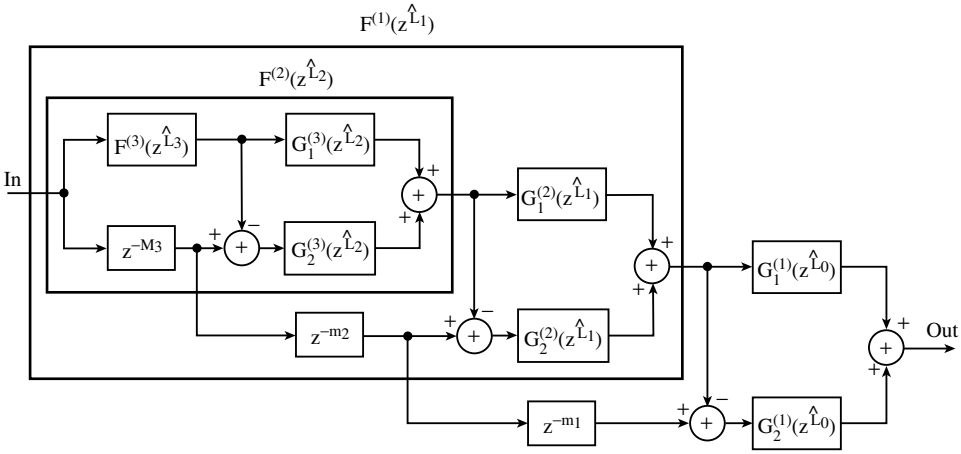

FIGURE 86.33 An implementation for a filter synthesized using the three-stage frequency-response masking approach.

© 2003 by CRC Press LLC

Given the filter specifications and the L_r's for $r = 1, 2, \cdots, R$, the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s as well as $F^{(R)}(z)$ can be synthesized in the following steps:

1. Set $r = 1$, $L = L_1$, and

$$D_H(\omega) = \begin{cases} 1 & \text{for } \omega \in [0,\ \omega_p] \\ 0 & \text{for } \omega \in [\omega_s,\ \pi] \end{cases} \qquad W_H(\omega) = \begin{cases} 1/\delta_p & \text{for } \omega \in [0,\ \omega_p] \\ 1/\delta_s & \text{for } \omega \in [\omega_s,\ \pi] \end{cases} \tag{86.116}$$

2. Determine whether $F^{(r-1)}(z)$ is a Case A or Case B design as well as θ, ϕ, and l for $F^{(r)}(z)$ according to (86.107b) or (86.108b). Also, determine $\omega_p^{(G_k)}$ and $\omega_s^{(G_k)}$ for $k = 1, 2$ from (86.102a) and (86.102b) or (86.103a) and (86.103b).
3. Design $G_k^{(r)}(z)$ for $k = 1, 2$, using either the Remez algorithm or linear programming, in such a way that

$$\max_{\omega \in \left[0,\ \omega_p^{(G_k)}\right] \cup \left[\omega_s^{(G_k)},\ \pi\right]} \left| W_H(\omega) \left[G_k^{(r)}(\omega) - D_H(\omega) \right] \right| \le 0.9 \tag{86.117}$$

4. Determine $W_F(\omega)$ and $D_F(\omega)$ from Table 86.12.
5. If $r = R$, then go to the next step. Otherwise, set $r = r + 1$, $L = L_r$, $W_H(\omega) = W_F(\omega)$, $D_H(\omega) = D_F(\omega)$, $\omega_p = \theta$, $\omega_s = \phi$, and go to Step 2.
6. Design $F^{(R)}(z)$, using either the Remez algorithm or linear programming, in such a way that

$$\max_{\omega \in [0,\theta] \cup [\phi,\pi]} \left| W_F(\omega) \left[F^{(R)}(\omega) - D_F(\omega) \right] \right| \le 1 \tag{86.118}$$

In the above algorithm, $G_1^{(1)}(z)$ and $G_2^{(1)}(z)$ are determined like in the one-stage frequency-response masking technique. The remaining filter part as given by (86.115b) has then to be designed such that the maximum absolute value of the error function given in Table 86.12 becomes less than or equal to unity on $[0, \theta] \cup [\phi, \pi]$. Using the substitutions $\omega_p = \theta$ and $\omega_s = \phi$, the synthesis problem for $F^{(1)}(z)$ becomes the same as for the overall filter with the only exception that the desired function $D_F(\omega)$ and the weighting function $W_F(\omega)$ are not constants in the passband and stopband regions. Therefore, the following $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s can be designed in the same manner. Finally, $F^{(R)}(z)$ is determined at Step 6 like $F(z)$ in one-stage designs.

Given the filter specifications, the remaining problem is to select R as well as the L_r's to minimize the filter complexity. This problem has been considered in [4]. Assuming that for all the selected L_r's, $\theta + \phi \approx \pi$, the sum of the estimated orders of $F^{(R)}(z)$ and the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s becomes

$$N_{\text{ove}}(R) = \left[1 \Big/ \prod_{r=1}^{R} L_r + \left[2(\omega_s - \omega_p)/\pi \right] \sum_{r=1}^{R} L_r \right] N_{\text{opt}} \tag{86.119}$$

The minimum of $N_{\text{ove}}(R)$ taking place at

$$L_1 = L_2 = \cdots = L_R = L_{\text{opt}}(R) = \left[\frac{2(\omega_s - \omega_p)}{\pi} \right]^{-1/(R+1)} \tag{86.120}$$

is

$$N_{\text{ove}}(R) = (R+1) \left[\frac{(2\omega_s - \omega_p)}{\pi} \right]^{R/(R+1)} N_{\text{opt}} \tag{86.121}$$

© 2003 by CRC Press LLC

The derivation of the above formula is based on the assumption that the orders of all the $G_1^{(r)}(z)$'s and $G_2^{(r)}(z)$'s for $r = 1, 2, \cdots, R$ are equal, which is seldom true. Therefore, in order to minimize the overall filter complexity, the values of the L_r's should be varied in the vicinity of $L_{\text{opt}}(R)$. Given ω_p, ω_s, and R, good values for the L_r's can be obtained by the following procedure:

1. Set $r = 1$.
2. Determine $L = L_{\text{opt}}(R + 1 - r)$ from (86.120).
3. For values of $\tilde{L}_r$ in the vicinity of L determine $\theta(\tilde{L}_r)$ and $\phi(\tilde{L}_r)$.
4. If $r = R$, then go to Step 7. Otherwise, go to the next step.
5. Determine $L_r = \tilde{L}_r$ minimizing

$$(R+1-r)\left[\frac{2\left[\phi\left(\tilde{L}_r\right)-\theta\left(\tilde{L}_r\right)\right]}{\pi}\right]^{(R-r)/(R+1-r)} + \frac{\phi\left(\tilde{L}_r\right)-\theta\left(\tilde{L}_r\right)}{\theta\left(\tilde{L}_r\right)+\phi\left(\tilde{L}_r\right)} + \frac{\phi\left(\tilde{L}_r\right)-\theta\left(\tilde{L}_r\right)}{2\pi-\theta\left(\tilde{L}_r\right)-\phi\left(\tilde{L}_r\right)} \tag{86.122}$$

6. Set $r = r + 1$, $\omega_p = \theta(L_r)$, $\omega_s = \phi(L_r)$, and go to Step 2.
7. Determine $L_R = \tilde{L}_r$ minimizing

$$\frac{1}{\tilde{L}_R} + \frac{\phi\left(\tilde{L}_R\right)-\theta\left(\tilde{L}_R\right)}{\theta\left(\tilde{L}_R\right)+\phi\left(\tilde{L}_R\right)} + \frac{\phi\left(\tilde{L}_R\right)-\theta\left(\tilde{L}_R\right)}{2\pi-\theta\left(\tilde{L}_R\right)-\phi\left(\tilde{L}_R\right)} \tag{86.123}$$

At the first step in this procedure, L_1 is determined to minimize the estimated overall complexity of $G_1^{(1)}(z)$, $G_2^{(1)}(z)$, and the remaining $F_1^{(1)}(z)$, which is given by (86.122) as a fraction of N_{opt}. Compared to (86.111) for the one-stage design, $1/\tilde{L}_r$ is replaced in (86.122) by the first term. This term estimates the complexity of $F_1^{(1)}(z)$ based on the use of (86.121) with $\omega_p = \theta(\tilde{L}_r)$ and $\omega_s = \phi(\tilde{L}_r)$ and the fact that it is an $R - 1$ stage design. Also, L_2 is redetermined based on the same assumptions and the process is continued in the same manner. Finally, L_R is determined to minimize the sum of the estimated orders of $G_1^{(R)}(z)$, $G_2^{(R)}(z)$, and $F^{(R)}(z)$ like in the one-stage design [cf. (86.111)].

Example 2. Consider the specifications of Example 1. For a two-stage design, the above procedure gives $L_1 = L_2 = 6$. For these values, $F^{(0)}(z) \equiv H(z)$ and $F^{(1)}(z)$ are Case A designs ($l = 1$) with $\theta = 0.4\pi$ and $\phi = 0.412\pi$; and $\theta = 0.4\pi$ and $\phi = 0.472\pi$, respectively. The minimum orders of $G_1^{(1)}(z)$, $G_2^{(1)}(z)$, $G_1^{(2)}(z)$, $G_2^{(2)}(z)$, and $F^{(2)}(z)$ are 26, 40, 28, 36, and 74, respectively. Compared with the conventional direct-form FIR filter of order 2541, the number of multipliers and adders required by this design (107 and 204) are only 8 percent at the expense of a 15 percent increase in the overall filter order (to 2920). For a three-stage design, we get $L_1 = L_2 = L_3 = 4$. In this case, $F^{(0)}(z)$, $F^{(1)}(z)$, and $F^{(2)}(z)$ are Case B designs ($l = 1$) with $\theta = 0.392\pi$ and $\phi = 0.4\pi$; $\theta = 0.4\pi$ and $\phi = 0.432\pi$; and $\theta = 0.272\pi$ and $\phi = 0.4\pi$, respectively. The minimum orders of $G_1^{(1)}(z)$, $G_2^{(1)}(z)$, $G_1^{(2)}(z)$, $G_2^{(2)}(z)$, $G_1^{(3)}(z)$, $G_2^{(3)}(z)$, and $F^{(3)}(z)$ are 16, 28, 18, 24, 16, 32, and 40, respectively. The number of multipliers and adders (94 and 174) are only 7 percent of those required by the direct-form equivalent at the expense of a 26 percent increase in the overall filter order (to 3196). The amplitude responses of the resulting two-stage and three-stage designs are depicted in Fig. 86.34.

Design of Narrowband Filters

Another general approach for designing multiplier-efficient FIR filters has been proposed by Jing and Fam [2]. This design technique is based on iteratively using the fact that there exist efficient implementation forms for filters with $\omega_s < \pi/2$ and for filters with $\omega_p > \pi/2$. A filter with $\omega_s < \pi/2$ is called a *narrowband* filter while that with $\omega_p > \pi/2$ is called a *wideband* filter. This subsection considers the design of narrowband filters, whereas the next subsection is devoted to the design of wideband filters. Finally, these techniques are combined, resulting in the Jing-Fam approach.

© 2003 by CRC Press LLC

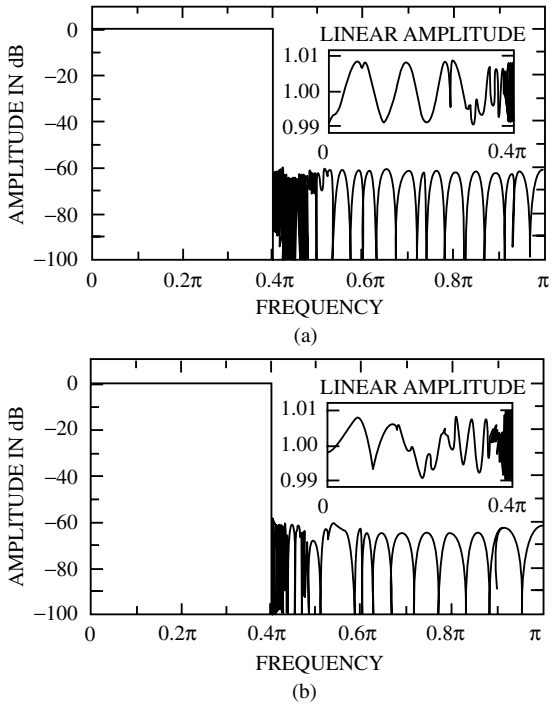

FIGURE 86.34 Amplitude responses for filters synthesized using the multistage frequency-response masking approach. (a) Two-stage filter. (b) Three-stage filter.

When the stopband edge of $H(z)$ is less than $\pi/2$, the first transition band of $F(z^L)$ can be used as that of $H(z)$ (see Fig. 86.35), that is,

$$\omega_p = \theta/L \quad \text{and} \quad \omega_s = \phi/L \tag{86.124}$$

In this case, the overall transfer function can be written in the following, simplified form [6] and [8]:

$$H(z) = F(z^L)G(z) \tag{86.125}$$

where the orders of both $F(z)$ and $G(z)$ can be freely selected to be either even or odd. As shown in Fig. 86.35, the role of $G(z)$ is to provide the desired attenuation on those regions where $F(z^L)$ has extra unwanted passband and transition band regions, that is, on

$$\Omega_s(L,\omega_s) = \bigcup_{k=1}^{\lfloor L/2 \rfloor} \left[k\frac{2\pi}{L} - \omega_s,\ \min\left(k\frac{2\pi}{L} + \omega_s, \pi \right) \right] \tag{86.126}$$

There exist two ways of designing the subfilters $F(z^L)$ and $G(z)$. In the first case, they are determined, by means of the Remez algorithm, to satisfy

$$1 - \delta_p^{(F)} \le F(\omega) \le 1 + \delta_p^{(F)} \quad \text{for } \omega \in [0,\ L\omega_p] \tag{86.127a}$$

© 2003 by CRC Press LLC

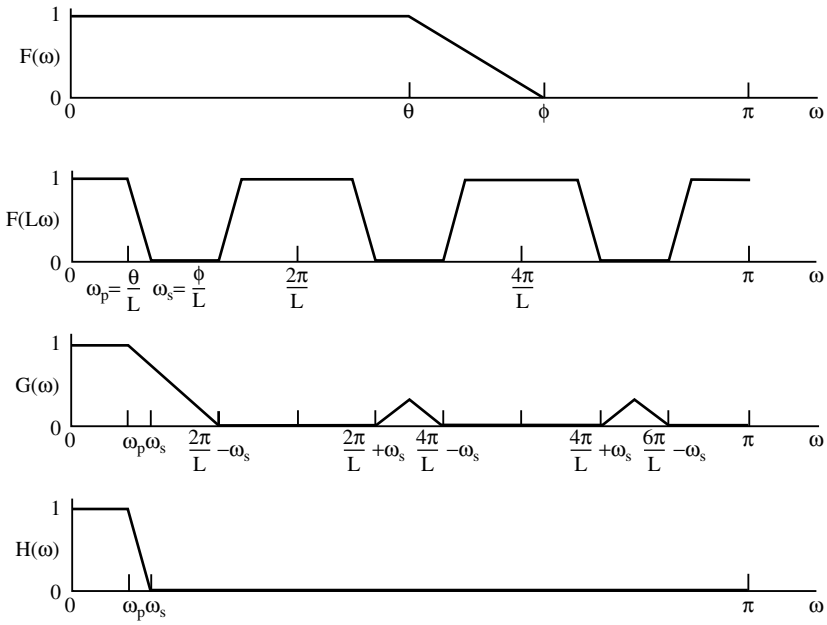

FIGURE 86.35 Synthesis of a narrowband filter as a cascade of a periodic and a nonperiodic filter.

$$-\delta_s \le F(\omega) \le \delta_s \qquad \text{for } \omega \in [L\omega_s, \pi] \tag{86.127b}$$

$$1-\delta_p^{(G)} \le G(\omega) \le 1+\delta_p^{(G)} \qquad \text{for } \omega \in [0, \omega_p] \tag{86.127c}$$

$$-\delta_s \le G(\omega) \le \delta_s \qquad \text{for } \omega \in \Omega_s(L, \omega_s) \tag{86.127d}$$

where

$$\delta_p^{(G)} + \delta_p^{(F)} = \delta_p \tag{86.127e}$$

The ripples $\delta_p^{(F)}$ and $\delta_p^{(G)}$ can be selected, e.g., to be half the overall ripple δ_p. In the above specifications, both $F(z^L)$ and $G(z)$ have $[0, \omega_p]$ as a passband region.

Another approach, leading to a considerable reduction in the order of $G(z)$, is to design simultaneously $F(\omega)$ to satisfy

$$1-\delta_p \le F(\omega)G(\omega/L) \le 1+\delta_p \qquad \text{for } \omega \in [0, L\omega_p] \tag{86.128a}$$

$$-\delta_s \le F(\omega)G(\omega/L) \le \delta_s \qquad \text{for } \omega \in [L\omega_s, \pi] \tag{86.128b}$$

and $G(\omega)$ to satisfy

$$G(0) = 1 \tag{86.129a}$$

$$-\delta_s \le F(L\omega)G(\omega) \le \delta_s \qquad \text{for } \omega \in \Omega_s(L, \omega_s) \tag{86.129b}$$

The desired overall solution can be obtained by iteratively determining, by means of the Remez algorithm, $F(z)$ to meet the criteria of (86.128a) and (86.128a) and $G(z)$ to meet the criteria of (86.129a) and (86.129b). Typically, only three to five designs of both of the subfilters are required to arrive at a solution that does not change if further iterations are used. For more details, see [8] or [10]. FIGURE 86.36 Typical amplitude responses for a filter of the form $H(z) = F(z^L)G(z)$. $L = 8$, $\omega_p = 0.025\pi$, $\omega_s = 0.05\pi$, $\delta_p = 0.01$, and $\delta_s = 0.001$. (a) $F(z^L)$ of order 26 in z^L. (b) $G(z)$ of order 19. (c) Overall filter.

typical responses for $G(z)$ and $F(z^L)$ and for the overall optimized design. As seen in this figure, $G(z)$ has all its zeros on the unit circle concentrating on providing the desired attenuation for the overall response on $\Omega_s(L, \omega_s)$, whereas $F(z^L)$ makes the overall response equiripple in the passband and in the stopband portion $[\omega_s, \pi/L]$.

For the order of $F(z)$, a good estimate is

$$N_F \approx \frac{\Phi(\delta_p, \delta_s)/L}{\omega_s - \omega_p} \tag{86.130}$$

so that it is $1/L$th of that of an optimum conventional nonperiodic filter meeting the given overall criteria. The order of $G(z)$, in turn, can be estimated accurately by [10]

$$N_G = \cosh^{-1}(1/\delta_s)\left[\frac{1}{X\left(\omega_p, \frac{2\pi}{L} - \frac{\omega_p + 2\omega_s}{3}\right)} + \frac{L/2}{X\left(\frac{L\omega_p}{2}, \pi - \frac{L(\omega_p + 2\omega_s)}{6}\right)}\right] \tag{86.131a}$$

© 2003 by CRC Press LLC

where

$$X(\omega_1, \omega_2) = \cosh^{-1}\left[\left(2\cos\omega_1 - \cos\omega_2 + 1\right)/\left(1 + \cos\omega_2\right)\right] \tag{86.131b}$$

The minimization of the number of multipliers, $[(N_F + 2)/2] + [(N_G + 2)/2]$, with respect to L can be performed conveniently by evaluating the sum of the above estimated orders for the admissible values of L, $2 \le L < \pi/\omega_s$. The upper limit is a consequence of the fact that the stopband edge angle of $F(z)$, $\phi = L\omega_s$, must be less than π. The following example illustrates the minimization of the filter complexity.

Example 3. The narrowband specifications are $\omega_p = 0.025\pi$, $\omega_s = 0.05\pi$, $\delta_p = 0.01$, and $\delta_s = 0.001$. Figure 86.37(a) shows the estimated N_F, N_G, and $N_F + N_G$ as functions of L, whereas Fig. 86.37(b) shows the corresponding actual minimum orders. It is seen that the estimated orders are so close to the actual ones that the minimization of the filter complexity can be accomplished based on the use of the above estimation formulas. It is also observed that $N_F + N_G$ is a unimodal function of L. With the estimates, $L = 8$ gives the best result. The estimated orders are $N_F = 25$ and $N_G = 19$, whereas the actual orders are $N_F = 26$ and $N_G = 19$. The amplitude responses for the subfilters and for the overall filter are depicted in Fig. 86.36. This design requires 24 multipliers and 45 adders. The minimum order of a conventional direct-form design is 216, requiring 109 multipliers and 216 adders. The price paid for these 80 percent reductions in the filter complexity is a 5 percent increase in the overall filter order (from 216 to 227).

In the cases where L can be factored into the product

$$L = \prod_{r=1}^{R} L_r \tag{86.132}$$

where the L_r's are integers, further savings in the filter complexity can be achieved by designing $G(z)$ in the following multistage form [8]:

$$G(z) = G_1(z)G_2\left(z^{L_1}\right)G_3\left(z^{L_1L_2}\right)\cdots G_R\left(z^{L_1L_2\cdots L_{R-1}}\right) \tag{86.133}$$

Another alternative to reduce the number of adders and multipliers is to use special structures for implementing $G(z)$ [8]–[10].

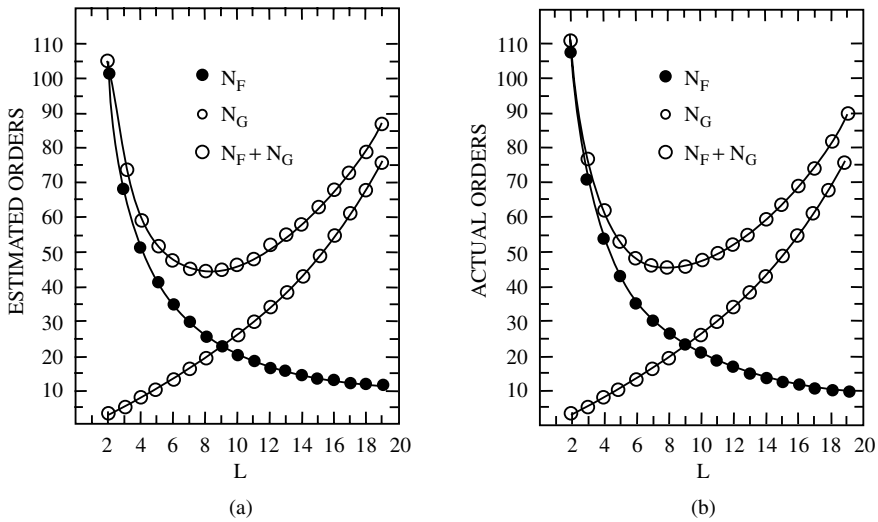

FIGURE 86.37 Estimated and actual subfilter orders as well as the sum of the subfilter orders vs. L in a typical narrowband case.

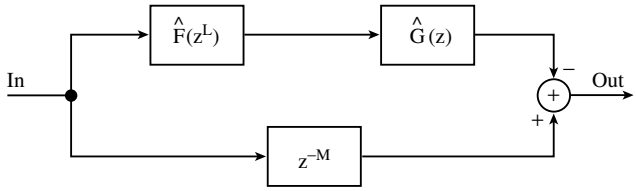

FIGURE 86.38 Implementation for a wideband filter in the form $H(z) = z^{-M} - (-1)^M F[(-z^L)G(-z)$. $\hat{F}(z^L) = (-1)^M F[(-z)^L]$ and $\hat{G}(z) = G(-z)$.

Design of Wideband Filters

The synthesis of a wideband filter $H(z)$ can be converted into the design of a narrowband filter based on the following fact. If $\hat{H}(z)$ of even order $2M$ is a low-pass design with the following edges and ripples:

$$\hat{\omega}_p = \pi - \omega_s, \quad \hat{\omega}_s = \pi - \omega_p, \quad \hat{\delta}_p = \delta_s, \quad \hat{\delta}_s = \delta_p \tag{86.134}$$

then

$$H(z) = z^{-M} - (-1)^M \hat{H}(-z) \tag{86.135}$$

is a low-pass filter having the passband and stopband edge angles at ω_p and ω_s and the passband and stopband ripples of δ_p and δ_s. Hence, if ω_p and ω_s of $H(z)$ are larger than $\pi/2$, then $\hat{\omega}_p$ and $\hat{\omega}_s$ of $\hat{H}(z)$ are smaller than $\pi/2$ [10]. This enables us to design $\hat{H}(z)$ in the form

$$\hat{H}(z) = F(z^L)\, G(z) \tag{86.136}$$

using the techniques of the previous subsection, yielding

$$H(z) = z^{-M} - (-1)^M F\left[(-z)^L\right] G(-z) \tag{86.137a}$$

where

$$M = (LN_F + N_G)/2 \tag{86.137b}$$

is half the order of $F(z^L)G(z)$. For implementation purposes, $H(z)$ is expressed as

$$H(z) = z^{-M} - \hat{F}(z^L)\hat{G}(z), \quad \hat{F}(z^L) = (-1)^M F\left[(-z)^L\right], \quad \hat{G}(z) = G(-z) \tag{86.138}$$

An implementation of this transfer function is shown in Fig. 86.38, where the delay term z^{-M} can be shared with $\hat{F}(z^L)$. To avoid half-sample delays, the order of $\hat{F}(z^L)\hat{G}(z)$ has to be even.

Example 4. The wideband specifications are $\omega_p = 0.95\pi$, $\omega_s = 0.975\pi$, $\delta_p = 0.001$, and $\delta_s = 0.01$. From (86.134), the specifications of $\hat{H}(z)$ become $\hat{\omega}_p = 0.025\pi$, $\hat{\omega}_s = 0.05\pi$, $\hat{\delta}_p = 0.01$, and $\hat{\delta}_s = 0.001$. These are the narowband specifications of Example 3. The desired wideband design is thus obtained by using the subfilters $F(z^L)$ and $G(z)$ of Fig. 86.36 ($L = 8$, $N_F = 26$, and $N_G = 19$). However, the overall order is odd (227). A solution with even order is achieved by increasing the order of $G(z)$ by one ($N_G = 20$). Figure 86.39 shows the amplitude response of the resulting filter, requiring 25 multipliers, 46 adders, and 228 delay elements. The corresponding numbers for a conventional direct-form equivalent of order 216 are 109, 216, and 216, respectively.

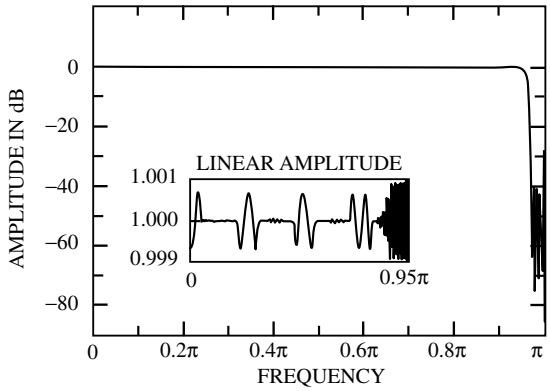

FIGURE 86.39 Amplitude response for a wideband filter implemented as shown in Fig. 86.38.

Generalized Designs

The Jing–Fam approach [2] is based on iteratively using the facts that a narrowband filter can be implemented effectively as $H(z) = F(z^L)G(z)$ and a wideband filter in the form of (86.137a) and (86.137b). In this approach, a narrowband filter is generated [9] as

$$H(z) \equiv \hat{H}_1(z) = G_1(z)F_1\left(z^{L_1}\right) \tag{86.139a}$$

where

$$F_1(z) = z^{-M_1} - (-1)^{M_1}\hat{H}_2(-z) \quad \hat{H}_2(z) = G_2(z)F_2\left(z^{L_2}\right) \tag{86.139b}$$

$$F_2(z) = z^{-M_2} - (-1)^{M_2}\hat{H}_3(-z) \quad \hat{H}_3(z) = G_3(z)F_3\left(z^{L_3}\right) \tag{86.139c}$$

$$\vdots \qquad \vdots \qquad \vdots$$

$$F_{R-2}(z) = z^{-M_{R-2}} - (-1)^{M_{R-2}}\hat{H}_{R-1}(-z) \quad \hat{H}_{R-1}(z) = G_{R-1}(z)F_{R-1}\left(z^{L_{R-1}}\right) \tag{86.139d}$$

$$F_{R-1}(z) = z^{-M_{R-1}} - (-1)^{M_{R-1}}\hat{H}_R(-z) \quad \hat{H}_R(z) = G_R(z) \tag{86.139e}$$

with M_r for $r = 1, 2, \ldots, R-1$ being half the order of $\hat{H}_{r+1}(z)$. Here, the basic idea is to convert iteratively the design of the narrowband overall filter into the designs of narrowband transfer function $\hat{H}_r(z)$ for $r = 2, 3, \ldots, R$ until the transition bandwidth of the remaining $\hat{H}_r(z) = G_R(z)$ becomes large enough and, correspondingly, its complexity (the number of multipliers) is low enough. The desired conversion is performed by properly selecting the L_r's and designing the lower-order filters $G_r(z)$ for $r = 1, 2, \cdots, R-1$.

In order to determine the conditions for the L_r's as well as the design criteria for the $G_r(z)$'s, we consider the rth iteration, where

$$\hat{H}_r(z) = G_r(z)F_r\left(z^{L_r}\right) \tag{86.140a}$$

with

$$F_r(z) = z^{-M_r} - (-1)^{M_r}\hat{H}_{r+1}(-z) \tag{86.140b}$$

Let the ripples of $\hat{H}_r(z)$ be $\hat{\delta}_p^{(r)}$ and $\hat{\delta}_s^{(r)}$ and the edges be located at $\omega_p^{(r)} < \pi/2$ and $\omega_s^{(r)} < \pi/2$. Since $F_r(z)$ is implemented in the form of (86.140b), it cannot alone take care of shaping the passband response

© 2003 by CRC Press LLC

of $\hat{H}_r(z)$. Therefore, the simultaneous criteria for $G_r(z)$ and $F_r(z)$ are stated according to (86.127a)–(86.127e) so that the passband and stopband regions of $G_r(z)$ are, respectively, $[0, \omega_p^{(r)}]$ and $\Omega_s(L_r, \omega_s^{(r)})$ with $\Omega_s(L, \omega_s)$ given by (86.126). L_r has to be determined such that the edges of $F_r(z)$, $L_r\omega_p^{(r)}$ and $L_r\omega_s^{(r)}$, become larger than $\pi/2$ and, correspondingly, the edges of $\hat{H}_{r+1}(z)$, $\omega_p^{(r+1)} = \pi - L_r\omega_s^{(r)}$ and $\omega_s^{(r+1)} = \pi - L_r\omega_p^{(r)}$, become less than $\pi/2$.

In the case of the specifications of (86.127a)–(86.127e), the stopband ripple of $G_r(z)$, denoted for later use by $\delta_s^{(r)}$, and that of $F_r(z)$ are equal to $\hat{\delta}_s^{(r)}$, whereas the sum of the passband ripples is equal to $\hat{\delta}_p^{(r)}$. Denoting by $\delta_p^{(r)}$ the passband ripple selected for $G_r(z)$, the corresponding ripple of $F_r(z)$ is $\hat{\delta}_p^{(r)} - \delta_p^{(r)}$. Since $F_r(z)$ and $\hat{H}_{r+1}(z)$ interchange the ripples, the ripple requirements for $\hat{H}_{r+1}(z)$ are $\hat{\delta}_p^{(r+1)} = \hat{\delta}_s^{(r)}$ and $\hat{\delta}_s^{(r+1)} = \hat{\delta}_p^{(r)} - \delta_p^{(r)}$.

The criteria for the $G_r(z)$'s for $r = 1, 2, \cdots, R$ can thus be stated as

$$1 - \delta_p^{(r)} \le G_r(\omega) \le 1 + \delta_p^{(r)} \quad \text{for } \omega \in \left[0,\ \omega_p^{(r)}\right] \tag{86.141a}$$

$$-\delta_s^{(r)} \le G_r(\omega) \le \delta_s^{(r)} \quad \text{for } \omega \in \Omega_s^{(r)} \tag{86.141b}$$

where

$$\Omega_s^{(r)} = \begin{cases} \displaystyle\bigcup_{k=1}^{\lfloor L_r/2 \rfloor} \left[k\frac{2\pi}{L_r} - \omega_s^{(r)},\ \min\left(k\frac{2\pi}{L_r} + \omega_s^{(r)},\ \pi \right) \right] & \text{for } r < R \\ \left[\omega_s^{(R)},\ \pi \right] & \text{for } r = R \end{cases} \tag{86.141c}$$

Here, the $\omega_p^{(r)}$'s and $\omega_s^{(r)}$'s for $R = 2, 3, \cdots, R$ are determined iteratively as

$$\omega_p^{(r)} = \pi - L_{r-1}\omega_s^{(r-1)} \quad \omega_s^{(r)} = \pi - L_{r-1}\omega_p^{(r-1)} \tag{86.141d}$$

where $\omega_p^{(1)} = \omega_p$ and $\omega_s^{(1)} = \omega_s$ are the edges of the overall design, and the $\delta_s^{(r)}$'s as

$$\delta_s^{(r)} = \begin{cases} \delta_p - \displaystyle\sum_{\substack{k=1 \\ k \text{ odd}}}^{r-1} \delta_p^{(k)} & \text{for } r \text{ even} \\ \delta_s - \displaystyle\sum_{\substack{k=2 \\ k \text{ even}}}^{r-1} \delta_p^{(k)} & \text{for } r \text{ odd} \end{cases} \tag{86.141e}$$

where δ_p and δ_s are the ripple values of the overall filter and $\delta_p^{(r)}$ is the passband ripple selected for $G_r(z)$. In order for the overall filter to meet the given ripple requirements, $\delta_s^{(R)}$ and the $\delta_p^{(r)}$'s have to satisfy for R even

$$\sum_{\substack{k=2 \\ k \text{ even}}}^{R} \delta_p^{(k)} = \delta_s, \quad \delta_s^{(R)} + \sum_{\substack{k=1 \\ k \text{ odd}}}^{R-1} \delta_p^{(k)} = \delta_p \tag{86.142a}$$

or for R odd

$$\sum_{\substack{k=1 \\ k \text{ odd}}}^{R} \delta_p^{(k)} = \delta_p, \quad \delta_s^{(R)} + \sum_{\substack{k=2 \\ k \text{ even}}}^{R-1} \delta_p^{(k)} = \delta_s \tag{86.142b}$$

In the above, the L_r's have to be determined such that the $\omega_s^{(r)}$'s for $r < R$ become smaller than $\pi/2$. It is also desired that for the last filter stage $G_R(z)$, $\omega_s^{(R)}$ is smaller than $\pi/2$.

TABLE 86.15 Explicit Form for the Transfer Function in the Jing-Fam Approach

$$H(z)=H_1\left(z^{\hat{L}_1}\right)\left\{I_2 z^{-\hat{M}_2}+H_2\left(z^{\hat{L}_2}\right)\left[I_3 z^{-\hat{M}_3}+H_3\left(z^{\hat{L}_3}\right)\left(\cdots\right.\right.\right.$$

$$\left.\left.\left.\left\{I_{R-1} z^{-\hat{M}_{R-1}}+H_{R-1}\left(z^{\hat{L}_{R-1}}\right)\left[I_R z^{-\hat{M}_R}+H_R\left(z^{\hat{L}_R}\right)\right]\right\}\cdots\right)\right]\right\},$$

where

$$H_r\left(z^{\hat{L}_r}\right)=H_r^{(1)}\left(z^{K_r\hat{L}_r}\right)H_r^{(2)}\left(z^{\hat{L}_r}\right)$$

$$H_r^{(1)}(z)=G_r^{(1)}\left(J_r^{(1)}z\right),\quad H_r^{(2)}(z)=S_r G_r^{(2)}\left(J_r^{(2)}z\right)$$

$$S_1=1,\quad S_r=-(-1)^{\hat{M}_r/\hat{L}_r},\quad r=2,3,\cdots,R$$

$$J_1^{(2)}=1,\quad J_2^{(2)}=-1,\quad J_r^{(2)}=-\left[J_{r-1}^{(2)}\right]^{L_{r-1}},\quad r=3,4,\cdots,R$$

$$J_r^{(1)}=\left[J_r^{(2)}\right]^{K_r}$$

$$\hat{L}_1=1,\quad \hat{L}_r=\prod_{k=1}^{r-1}L_k,\quad r=2,3,\cdots,R$$

$$\hat{M}_R=\frac{1}{2}\hat{L}_R N_R,\quad \hat{M}_{R-r}=\hat{M}_{R-r+1}+\frac{1}{2}\hat{L}_{R-r}N_{R-r},\quad r=1,2,\cdots,R-2$$

$$I_2=1,\quad I_r=\left[J_{r-1}^{(2)}\right]^{\hat{M}_r/\hat{L}_{r-1}},\quad r=3,4,\cdots,R$$

$$N_r=K_r N_r^{(1)}+N_r^{(2)}$$

$N_r^{(1)}$ and $N_r^{(2)}$ are the orders of $G_r^{(1)}(z)$ and $G_r^{(2)}(z)$, respectively.

If $2\pi/L_r-\omega_s^{(r)}<\pi/2$ for $r<R$ or $\omega_s^{(R)}<\pi/2$, then the arithmetic complexity of $G_r(z)$ can be reduced by designing it, using the techniques of previous subsections, in the form

$$G_r(z)=G_r^{(1)}\left(z^{K_r}\right)G_r^{(2)}(z) \tag{86.143}$$

It is preferred to design the subfilters of $G_r(z)$ in such a way that the passband shaping is done entirely by $G_r^{(1)}(z^{K_r})$. The number of multipliers in the $G_r(z)$'s for $r=1, 2, \cdots, R-1$ can be reduced by the experimentally observed fact that the overall filter still meets the given criteria when the stopband regions of these filters are decreased by using in (86.141c) the substitution

$$\left(2\omega_s^{(r)}+\omega_p^{(r)}\right)\Big/3\mapsto\omega_s^{(r)} \tag{86.144}$$

After some manipulations, $H(z)$ as given by (86.139a)–(86.139e) and (86.143) can be rewritten in the explicit form shown in Table 86.15. If $G_r(z)$ is a single-stage design, then $G_r^{(1)}(z^{K_r})\equiv 1$. In order to obtain the desired overall solution, the overall order of $G_r(z)$ for $r\geq 2$, denoted by N_r in Table 86.15, has to be even. Realizations for the overall transfer function are given in Fig. 86.40, where

$$m_r=\hat{M}_r-\hat{M}_{r+1}=\frac{1}{2}\hat{L}_r N_r,\quad r=2,3,\cdots,R-1,\quad m_R=\hat{M}_R \tag{86.145}$$

The structure of Fig. 86.40(b) is preferred since the delay terms z^{-m_r} can be shared with $H_R^{(1)}(z^{K_R\hat{L}_R})$ or, if this filter stage is not present, with $H_R^{(2)}(z^{\hat{L}_R})$. This is because the overall order of this filter stage is usually larger than the sum of the m_r's.

© 2003 by CRC Press LLC

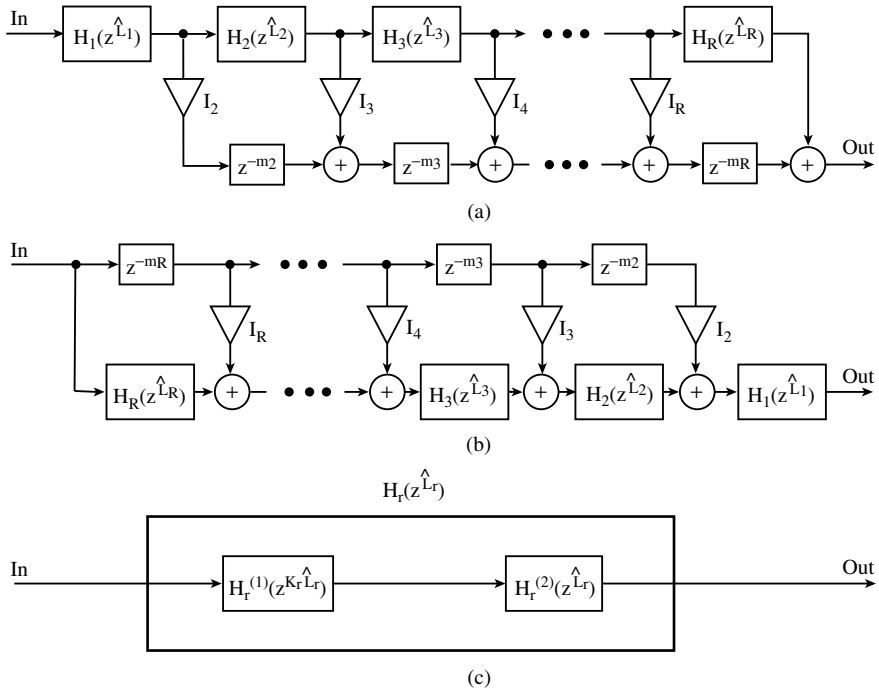

FIGURE 86.40 Implementations for a filter synthesized using the Jing-Fam approach. (a) Basic structure. (b) Transposed structure. (c) Structure for the subfilter $H_r(z^{\hat{L}_r})$.

If the edges ω_p and ω_s of the overall filter are larger than $\pi/2$, then we set $H(z) \equiv F_1(z)$ in (86.139a). In this case, $\delta_p^{(1)} \equiv 0$, $L_1 \equiv 1$, and $G_1(z)$, $\omega_p^{(1)}$, and $\omega_s^{(1)}$ are absent. Furthermore, $\omega_p^{(2)} = \pi - \omega_s$, and $\omega_s^{(2)} = \pi - \omega_p$, and $H_1(z)$ is absent in Fig. 86.40 and in Table 86.15.

The remaining problem is to select R, the L_r's, the K_r's, and the ripple values such that the filter complexity is minimized. The following example illustrates this.

Example 5. Consider the specifications of Example 1, that is, $\omega_p = 0.4\pi$, $\omega_s = 0.402\pi$, $\delta_p = 0.01$, and $\delta_s = 0.001$. In this case, the only alternative is to select $L_1 = 2$. The resulting passband and stopband regions for $G_1(z)$ are (the substitution of (86.144) is used)

$$\Omega_p^{(1)} = [0,\ 0.4\pi] \quad \text{and} \quad \Omega_s^{(1)} = [0.5987\pi,\ \pi]$$

For $\hat{H}_2(z)$, the edges become $\omega_p^{(2)} = \pi - L_1\omega_s = 0.196\,\pi$ and $\omega_s^{(2)} = \pi - L_1\omega_p = 0.2\,\pi$. For L_2, there are two alternatives to make the edges of $\hat{H}_3(z)$, $\omega_p^{(3)} = \pi - L_2\omega_s^{(2)}$ and $\omega_s^{(3)} = \pi - L_2\omega_p^{(2)}$, less than $\pi/2$. These are $L_2 = 3$ and $L_2 = 4$. For $R = 5$ stages, there are the following four alternatives to make all the $\omega_s^{(r)}$'s smaller than $\pi/2$:

$$L_1 = 2 \quad L_2 = 4 \quad L_3 = 3 \quad L_4 = 2$$

$$L_1 = 2 \quad L_2 = 4 \quad L_3 = 4 \quad L_4 = 4$$

$$L_1 = 2 \quad L_2 = 3 \quad L_3 = 2 \quad L_4 = 4$$

$$L_1 = 2 \quad L_2 = 3 \quad L_3 = 2 \quad L_4 = 3$$

Among these alternatives, the first one results in an overall filter with the minimum complexity. In this case, the edges of $\hat{H}_3(z)$, $\hat{H}_4(z)$, and $\hat{H}_5(z) \equiv G_5(z)$ become as shown in Table 86.16. The corresponding passband and stopband regions for $G_2(z)$, $G_3(z)$, $G_4(z)$, and $G_5(z)$ are

$$\Omega_p^{(2)} = [0, 0.196\pi], \quad \Omega_s^{(2)} = [0.3013\pi, 0.6987\pi] \cup [0.8013\pi, \pi]$$

$$\Omega_p^{(3)} = [0, 0.2\pi], \quad \Omega_s^{(3)} = [0.4560\pi, 0.8773\pi]$$

$$\Omega_p^{(4)} = [0, 0.352\pi], \quad \Omega_s^{(4)} = [0.616\pi, \pi]$$

$$\Omega_p^{(5)} = [0, 0.2\pi], \quad \Omega_s^{(5)} = [0.296\pi, \pi]$$

What remains is to determine the ripple requirements. From (86.142b), it follows for $R = 5$, $\delta_p^{(1)} + \delta_p^{(3)} + \delta_p^{(5)} = \delta_p$ and $\delta_p^{(2)} + \delta_p^{(4)} + \delta_p^{(6)} = \delta_s$. By simply selecting the ripple values in these summations to be equal, the required ripples for the $G_r(z)$'s become as shown in Table 86.16.

The first and fourth subfilter are single-stage filters since their stopband edges are larger than $\pi/2$, whereas the remaining three filters are two-stage designs. The parameters describing the overall filter are shown in Table 86.16, whereas Fig. 86.41(a) depicts the response of this filter. The number of multipliers and the order of this design are 78 and 4875, whereas the corresponding numbers for the direct-form equivalent are 1271 and 2541. The number of multipliers required by the proposed design is thus only 6 percent of that of the direct-form filter. Since the complexity of $H_5(z^{\dot{L}_5})$ is similar to those of the earlier filter stages, $R = 5$ is a good selection in this example.

The overall filter order as well as the number of multipliers can be decreased by selecting smaller ripple values for the first stages, thereby allowing larger ripples for the last stages. Proper selections for the ripple requirements and filter orders are shown in Table 86.17. The first four filters have been optimized such that their passband variations are minimized. The first criteria are met by a half-band filter of order 34, having the passband and stopband edges at 0.4013π and 0.5987π. Since every second impulse response coefficient of this filter is zero-valued except for the central coefficient with an easily implementable value of 1/2, this filter requires only nine multipliers. For the last stage, K_5 is reduced to 2 to decrease the overall filter order. The order of the resulting overall filter [see Fig. 86.41(b)] is 3914, which is 54 percent higher than that of the direct-form equivalent. The number of multipliers is reduced to 70.

The Jing-Fam approach cannot be applied directly for synthesizing filters whose edges are very close to $\pi/2$. This problem can, however, be overcome by slightly changing the sampling rate or, if this is not possible, by shifting the edges by a factor 3/2 by using decimation by this factor at the filter input and

interpolation by the same factor at the filter output [2]. One attractive feature of the Jing-Fam approach is that it can be combined with multirate filtering to reduce the filter complexity even further [7].

When comparing the above designs with the filters synthesized using the multistage frequency-response masking technique (Example 2), it is observed that the above designs require slightly fewer multipliers at the expense of an increased overall filter order. Both of these general approaches are applicable to those specifications that are not very narrowband or very wideband. For most very narrowband and wideband cases, filters synthesized in the simplified forms $H(z) = F(z^L)G(z)$ and $H(z) = z^{-M} - (-1)^M F[(-z)^L]G(-z)$, respectively, give the best results (see Examples 3 and 4).

87.1 Properties of IIR Filters

Sawasd Tantaratana

System Function and Impulse Response

A digital filter with impulse response having infinite length (i.e., its values outside any finite interval cannot all be zero) is termed infinite impulse response (IIR) filter. The most important class of IIR filters can be described by the difference equation

$$\begin{aligned} y(n) = {} & b_0 x(n) + b_1 x(n-1) + \cdots + b_M x(n-M) \\ & - a_1 y(n-1) - a_2 y(n-2) - \cdots - a_N y(n-N) \end{aligned} \tag{87.1}$$

where $x(n)$ is the input, $y(n)$ is the output of the filter, $\{a_1, a_2, \ldots, a_N\}$, and $\{b_0, b_1, \ldots, b_M\}$ are the filter coefficients. We assume that $a_N \neq 0$. The impulse response is the output of the system when it is driven by a unit impulse at $n = 0$, with the system being initially at rest, i.e., the output being zero prior to applying the input. We denote the impulse response by $h(n)$. With $x(0) = 1$, $x(n) = 0$, for $n \neq 0$, and $y(n) = 0$ for $n < 0$, we can compute $h(n)$, $n \leq 0$, from (87.1) in a recursive manner.

Taking the z-transform of (87.1), we obtain the system function

$$H(z) = \frac{Y(z)}{X(z)} = \frac{b_0 + b_1 z^{-1} + \cdots + b_M z^{-M}}{1 + a_1 z^{-1} + a_2 z^{-2} + \cdots a_N z^{-N}} \tag{87.2}$$

© 2003 by CRC Press LLC

N is the order of the filter. The system function and the impulse response are related through the z-transform and its inverse, i.e.,

$$H(z)=\sum_{n=-\infty}^{\infty}h(n)z^{-n}\quad h(n)=\frac{1}{2\pi j}\oint_C H(z)z^{n-1}dz \tag{87.3}$$

where C is a closed counterclockwise contour in the region of convergence. See Chapter 3 for z-transform.

We assume that $M \le N$. Otherwise, the system function can be written as

$$\begin{aligned}H(z)=&\left[c_0+c_1z^{-1}+\cdots+c_{M-N}z^{-(M-N)}\right]\\&+\left[\frac{b_0'+b_1'z^{-1}+\cdots+b'_N z^{-N}}{1+a_1z^{-1}+a_2z^{-2}+\cdots+a_Nz^{-N}}\right]\end{aligned} \tag{87.4}$$

which is an FIR filter in parallel with an IIR filter, or as

$$H(z)=\left[c_0'+c_1'z^{-1}+\cdots+c'_{M-N}z^{-(M-N)}\right]\left[\frac{b_0''+b_1''z^{-1}+\cdots+b_N''z^{-N}}{1+a_1z^{-1}+a_2z^{-2}+\cdots+a_Nz^{-N}}\right] \tag{87.5}$$

which is an FIR filter in cascade with an IIR filter. FIR filters are covered in Chapter 86. This chapter covers IIR filters.

For ease of implementation, it is desirable that the coefficients $\{a_1, a_2, \ldots, a_N\}$ and $\{b_0, b_1, \ldots, b_M\}$ be real numbers (as opposed to complex numbers), which is another assumption that we make, unless it is specified otherwise.

Causality (Physical Realizability)

A causal (physically realizable) filter is one whose output value does not depend on future input values. A noncausal filter cannot be realized in real time since some future input values are needed in computing the current output value. The difference equation in (87.1) can represent a causal system or a noncausal system. If the output $y(n)$ is calculated, for an increasing value of n, from $x(n)$, $x(n-1)$, …, $x(n-M)$, $y(n-1)$, …, $y(n-N)$, according to the right-hand side of (87.1), then the difference equation represents a causal system. On the other hand, we can rewrite (87.1) as

$$\begin{aligned}y(n-N)=\frac{1}{a_N}&\left[b_0x(n)+b_1x(n-1)+\cdots+b_Mx(n-M)\right.\\&\left.-y(n)-a_1y(n-1)-\cdots-a_{N-1}y(n-N+1)\right]\end{aligned} \tag{87.6}$$

If the system calculates $y(n-N)$, for a decreasing value of n, using the right-hand side of (87.6), then the system is noncausal since $y(n-N)$ depends on $x(n)$, …, $x(n-M)$, which are future input values. We shall assume that the IIR filter represented by (87.1) is causal. It follows from this assumption the $h(n) = 0$ for $n < 0$ and that the convergence region of $H(z)$ is of the form: $|z| > R_0$, where R_0 is a nonnegative constant.

Noncausal filters are useful in practical applications where the output need not be calculated in real time or where the variable n does not represent time, such as in image processing where n is a spatial variable. Generally, a noncausal filter can be modified to be causal by adding sufficient delay at the output.

© 2003 by CRC Press LLC

Poles and Zeros

Rewriting (87.2) we have

$$H(z) = z^{N-M} \frac{b_0 z^M + b_1 z^{M-1} + \cdots + b_{M-1} z + b_M}{z^N + a_1 z^{N-1} + \cdots + a_{N-1} z + a_N} \tag{87.7}$$

Assuming b_0, $b_M \neq 0$, then there are N poles given by the roots of the denominator polynomial and M zeros given by the roots of the numerator polynomial. In addition, there are $N - M$ zeros at the origin on the complex plane. The locations of the poles and zeros can be plotted on the complex z plane. Denoting the poles by $p_1, p_2, \ldots p_N$ and the nonzero zeros by $q_1, q_2, \ldots q_M$, we can write

$$H(z) = b_0 z^{N-M} \frac{(z-q_1)(z-q_2)\cdots(z-q_M)}{(z-p_1)(z-p_2)\cdots(z-p_N)} \tag{87.8}$$

Since we assume that the coefficients $\{a_1, a_2, \ldots, a_N\}$ and $\{b_0, b_1, \ldots, b_M\}$ are real-valued, for each complex-valued pole (i.e., pole off the real axis on the z plane) there must be another pole that is the complex conjugate of the first. Similarly, complex-valued zeros must exist in complex-conjugate pairs. The combination of a complex-conjugate pole pair (or zero pair) yields a second-order polynomial with real coefficients. Real-valued pole (or zero) can appear single in (87.8).

It is clear from (87.8) that knowing all the pole and zero locations, we can write the system function to within a constant factor. Since the constant factor is only a gain, which can be adjusted as desired, specifying the locations of the poles and zeros essentially specifies the system function of the IIR filter.

Stability

A causal IIR filter is stable (in the sense that a bounded input gives rise to a bounded output) if all the poles lie inside the unit circle. If there are one or more simple poles on the unit circle (and all the others lie inside the unit circle), then the filter is marginally stable, giving a sustained oscillation. If there are multiple poles (more than one pole at the same location) on the unit circle or if there is at least one pole outside the unit circle, a slight input will give rise to an output with increasing magnitude. For most practical filters, all the poles are designed to lie inside the unit circle. In some special IIR systems (such as oscillators), poles are placed on the unit circle to obtain the desired result.

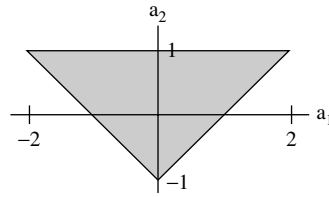

FIGURE 87.1 Region for the coefficients a_1 and a_2 that yield a stable second-order IIR filter.

Given the system function in the form of (87.2) or (87.7), the stability can be verified by finding all the poles of the filters and checking to see if all of them are inside the unit circle. Equivalently, stability can be verified directly from the coefficients $\{a_i\}$, using the Schür–Cohn algorithm [4]. For a second-order system ($N = 2$), if the coefficients a_1 and a_2 lie inside the triangle in Fig. 87.1, then the system is stable.

Frequency Response

The frequency response of the IIR filter is the value of the system function evaluated on the unit circle on the complex plane, i.e., with $z = e^{j2\pi f}$, where f varies from 0 to 1, or from –1/2 to 1/2. The variable f represents the digital frequency. For simplicity, we write $H(f)$ for $H(z)|_{z = \exp(j2\pi f)}$. Therefore.

$$H(f) = b_0 e^{j2\pi(N-M)f} \frac{(e^{j2\pi f} - q_1)(e^{j2\pi f} - q_2)\cdots(e^{j2\pi f} - q_M)}{(e^{j2\pi f} - p_1)(e^{j2\pi f} - p_2)\cdots(e^{j2\pi f} - p_N)} \tag{87.9}$$

© 2003 by CRC Press LLC

$H(f)$ is generally a complex function of f, consisting of the real part $H_R(f)$ and the imaginary part $H_I(f)$. It can also be expressed in terms of the magnitude $|H(f)|$ and the phase $\theta(f)$

$$H(f) = H_R(f) + jH_I(f) = |H(f)|e^{j\theta(f)} \tag{87.10}$$

From (87.9) we see that the magnitude response $|H(f)|$ equals the product of the magnitudes of the individual factors in the numerator, divided by the product of the magnitudes of the individual factors in the denominator. The magnitude square can be written as

$$|H(f)|^2 = H(f)H^*(f) = [H_R(f)]^2 + [H_I(f)]^2 \tag{87.11}$$

Since $H^\star(f) = H^\star(1/z^\star)|_{z = \exp(j2\pi f)}$ and $H^\star(1/z^\star) = H(z^{-1})$ when all the coefficients of $H(z)$ are real, we have

$$|H(f)|^2 = H(z)H(z^{-1})\Big|_{z=\exp(j2\pi f)} \tag{87.12}$$

Using (87.12), the magnitude square can be put in the form

$$|H(f)|^2 = \frac{\sum_{k=0}^{M} \tilde{b}_k \cos(2\pi k f)}{\sum_{k=0}^{N} \tilde{a}_k \cos(2\pi k f)} \tag{87.13}$$

where the coefficients are given by

$$\begin{aligned} \tilde{b}_0 &= \sum_{j=0}^{M} b_j^2 \quad \tilde{b}_k = 2\sum_{j=k}^{M} b_j b_{j-k} \quad k = 1, \cdots, M \\ \tilde{a}_0 &= \sum_{j=0}^{N} a_j^2 \quad \tilde{a}_k = 2\sum_{j=k}^{N} a_j a_{j-k} \quad k = 1, \cdots, N \end{aligned} \tag{87.14}$$

with the understanding that $a_0 = 1$.Given $\{\tilde{b}_0, \tilde{b}_1, \ldots, \tilde{b}_M\}$ we can find $\{b_0, b_1, \ldots, b_M\}$ and vice versa. Similarly, $\{\tilde{a}_0, \tilde{a}_1, \ldots, \tilde{a}_M\}$ and $\{a_0, a_1, \ldots, a_M\}$ can be computed from each other. The form in (87.13) is useful in computer-aided design of IIR filters using linear programming [1].

We see from (87.9) that the phase response $\theta(f)$ equals the sum of the phases of the individual factors in the numerator, minus the sum of the phases of the individual factors in the denominator. The phase can be written in terms of the real and imaginary parts of $H(f)$ as

$$\theta(f) = \arctan\left[\frac{H_I(f)}{H_R(f)}\right] \tag{87.15}$$

A filter having linear phase in a frequency band (e.g., in the passband) means that there is no phase distortion in that band.

The group delay is defined as

$$\tau(f) = -\frac{1}{2\pi}\frac{d}{df}\theta(f) \tag{87.16}$$

The group delay corresponds to the delay, from the input to the output, of the envelope of a narrowband signal [3]. A linear phase gives rise to a constant group delay. Nonlinearity in the phase appears as deviation of the group delay from a constant value.

© 2003 by CRC Press LLC

The magnitude response of an IIR filter does not change, except for a constant factor, if a zero is replaced by the reciprocal of its complex conjugate, i.e., if $(z - q)$ is replaced with $(z - 1/q^*)$. This can be seen as follows. Letting $\tilde{H}(z)$ be the system function without the factor $(z - q)$, we have

$$H(z) = \tilde{H}(z)(z-q) = \tilde{H}(z)\left(z-1/q^*\right)\frac{(z-q)}{\left(z-1/q^*\right)} = \hat{H}(z)\frac{(z-q)}{\left(z-1/q^*\right)} \tag{87.17}$$

where $\hat{H}(z)$ is $H(z)$ with the zero at q being replaced with a zero at $1/q^*$. It follows from (87.17) that

$$\begin{aligned}
\left|H(f)\right|^2 &= H(z)H^*\left(1/z^*\right)\Big|_{z=\exp(j2\pi f)} \\
&= \hat{H}(z)\hat{H}^*\left(1/z^*\right)\frac{(z-q)\left(z^{-1}-q^*\right)}{\left(z-1/q^*\right)\left(z^{-1}-1/q\right)}\Bigg|_{z=\exp(j2\pi f)} \\
&= |q|^2\left|\hat{H}(f)\right|^2
\end{aligned}$$

Similarly, replacing the pole at p with a pole at $1/p^*$ will not alter the magnitude of the response except for a constant factor. This property is useful in changing an unstable IIR filter to a stable one without altering the magnitude response.

Compared to an FIR filter, an IIR filter requires a much lower order than a FIR filter to achieve the same requirement of the magnitude response. However, the phase of a stable casual IIR filter cannot be made linear. This is the major reason not to use an IIR filter in applications where linear phase is essential. Nevertheless, using phase compensation such as allpass filters (see the subsection on allpass filters), the phase of an IIR filter can be adjusted close to linear. This process increases the order of the overall system, however. Note that if causality is not required, then a linear-phase IIR filter can be obtained using a time-reversal filter [1].

Realizations

A realization of an IIR filter according to (87.1) is shown in Fig. 87.2(a), which is called Direct Form I. By rearranging the structure, we can obtain Direct Form II, as shown in Fig. 87.2(b). Through transposition, we can obtain Transposed Direct Form I and Transposed Direct Form II as shown in Fig. 87.2(c) and (d).

The system function can be put in the form

$$H(z) = \prod_{i=1}^{K}\frac{b_{i0} + b_{i1}z^{-1} + b_{i2}z^{-2}}{1 + a_{i1}z^{-1} + a_{i2}z^{-2}} \tag{87.18}$$

by factoring the numerators and denominators into second-order factors, or in the form

$$H(z) = \frac{b_N}{a_N} + \sum_{i=1}^{K}\frac{b_{i0} + b_{i1}z^{-1}}{1 + a_{i1}z^{-1} + a_{i2}z^{-2}} \tag{87.19}$$

by partial fraction expansion. The value of K is $N/2$ when N is even and it is $(N + 1)/2$ when N is odd. When N is odd, one of a_{i2} must be zero, as well as one of b_{i2} in (87.18) and one of b_{i1} in (87.19). All the coefficients in (87.18) and (87.19) are real numbers. According to (87.18), the IIR filter can be realized by K second-order IIR filters in cascade, as shown in Fig. 87.3(a). According to (87.19), the IIR filter realized by K second-order IIR filters and one scaler (i.e., b_N/a_N) in parallel, as depicted in Fig. 87.3(b). Each second-order subsystem can use any of the structures in Fig. 87.2.

© 2003 by CRC Press LLC

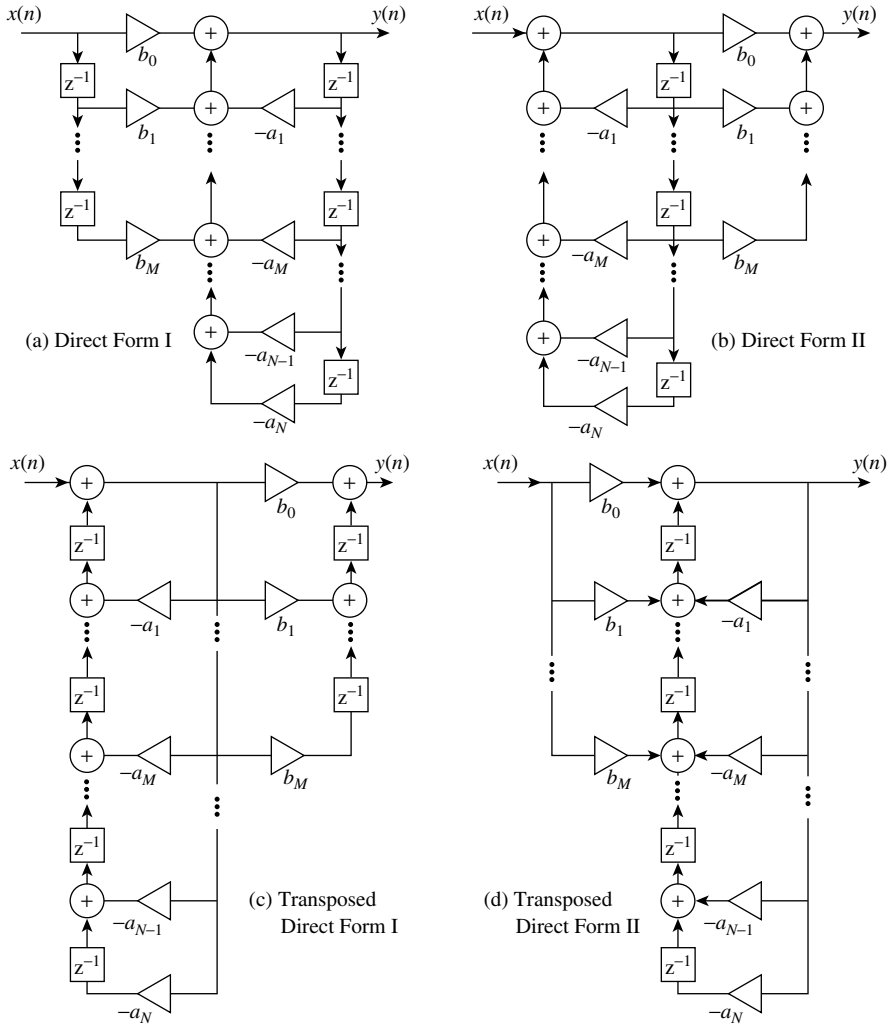

FIGURE 87.2 Direct form realizations of IIR filters.

There are many other realizations for IIR filters, such as state-space structures [2], wave structure (Section 87.3), and lattice structures (Section 87.4).

Actual implementation of IIR filters requires that the signals and the coefficients be represented in a finite number of bits (or digits). Quantization of the coefficients to a finite number of bits essentially changes the filter coefficients, hence the frequency response changes. Coefficient quantization of a stable IIR filter may yield an unstable filter. For example, consider a second-order IIR filter with $a_1 = 1.26$ and $a_2 = 0.3$, which correspond to pole locations of –0.9413 and – 0.3187, respectively. Suppose that we quantize these coefficients to two bits after the decimal point, yielding a quantized a_1 of 1.01 in binary or 1.25 and a quantized a_2 of 0.01 in binary or 0.25. This pair correspond to pole locations at –1.0 and –0.25, respectively. Since one pole is on the unit circle, the IIR filter with quantized coefficients produces an oscillation. In this example, the quantization is equivalent to moving a point inside the triangle in Fig. 87.1 to a point on the edge of the triangle. Different realizations are affected differently by coefficient quantization. Chapter 88 investigates coefficient quantization and roundoff noise in detail.

© 2003 by CRC Press LLC

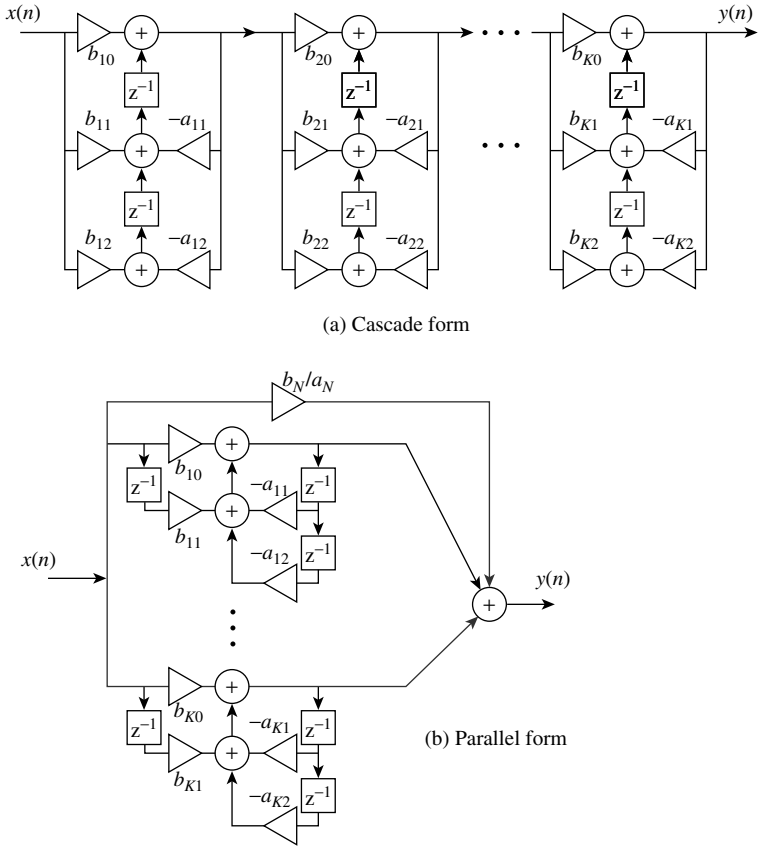

FIGURE 87.3 Cascade and parallel realizations of IIR filters.

Minimum Phase

An IIR filter is a minimum-phase filter if all the zeros and poles are inside the unit circle. A minimum-phase filter introduces the smallest group delay among all filters that have the same magnitude response. A minimum-phase IIR filter can be constructed from a nonminimum-phase filter by replacing each zero (or pole) outside the unit circle with a zero (or pole) that is the reciprocal of its complex conjugate, as illustrated in Fig. 87.4. This process moves all zeros and poles outside the unit circle to the inside. The magnitude response does not change, except for a constant factor, which is easily adjusted.

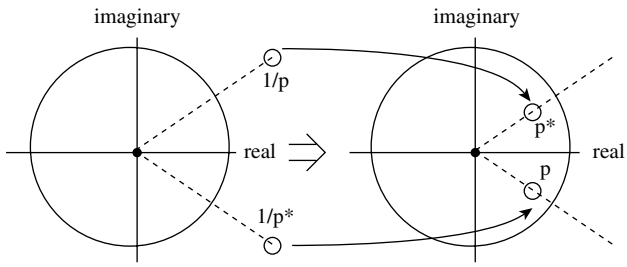

FIGURE 87.4 Changing a zero location to obtain a minimum-phase filter.

© 2003 by CRC Press LLC

Given an IIR filter $H(z)$ with input $x(n)$ and output $y(n)$, the inverse filter $1/H(z)$ can reconstruct $x(n)$ from $y(n)$ by feeding $y(n)$ to the input of $1/H(z)$. Assuming that both the filter and the inverse filter are causal, both of them can be stable only if $H(z)$ is a minimum-phase filter.

Allpass Filters

An allpass filter has a magnitude response of unity (or constant). An Nth order IIR allpass filter with real coefficients has a system function given by

$$H(z) = z^{-N}\frac{D(z)}{D(z^{-1})} = z^{-N}\frac{a_N z^N + \cdots + a_2 z^2 + a_1 z + 1}{1 + a_1 z^{-1} + a_2 z^{-2} + \cdots + a_N z^{-N}} \tag{87.20}$$

$$= z^{-N}\frac{(1 - p_1 z)(1 - p_2 z)\cdots(1 - p_N z)}{(1 - p_1 z^{-1})(1 - p_2 z^{-2})\cdots(1 - p_N z^{-1})} \tag{87.21}$$

Since $H(z)H(z^{-1}) = 1$, it follows that $|H(f)|^2 = 1$. The factor z^{-N} is included so that the filter is causal. Equation (87.21) implies that zeros and poles come in reciprocal pairs: if there is a pole at $z = p$, then there is zero at $z = 1/p$, as illustrated in Fig. 87.5.

Since the coefficients are real, poles and zeros off the real axis must exist in quadruplets: poles at p and p^* and zeros at $1/p$ and $1/p^*$, where $|p| < 1$ for stability. For poles and zeros on the real axis, they exist in reciprocal pairs: pole at p and zero at $1/p$, where p is real and $|p| < 1$ for stability. Since the numerator and the denominator in (87.20) share the same set of coefficients, we need only N multiplications in realizing an Nth order allpass filter.

The system function in (87.20) can be written as the product (or sum) of first- and second-order allpass filters. The system function and the phase response of a first-order allpass filter is given by

$$H(z) = \frac{a_1 z + 1}{z + a_1} \tag{87.22}$$

$$\theta(f) = \arctan\left[\frac{(a_1^2 - 1)\sin(\omega)}{2a_1 + (a_1^2 + 1)\cos(\omega)}\right] \tag{87.23}$$

where $\omega = 2\pi f$. For a second-order allpass filter, they are

$$H(z) = \frac{a_2 z^2 + a_1 z + 1}{z^2 + a_1 z + a_2} \tag{87.24}$$

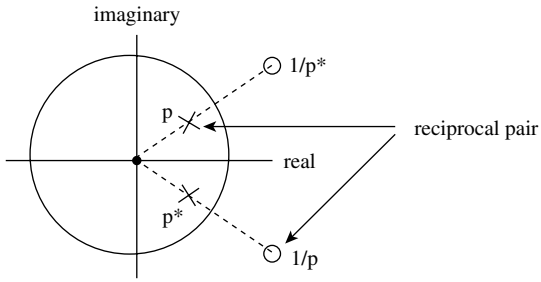

FIGURE 87.5 Pole-zero reciprocal pair in an allpass IIR filter.

© 2003 by CRC Press LLC

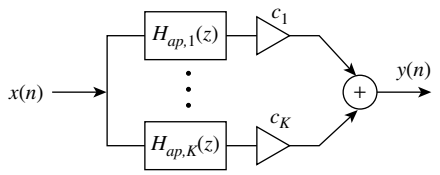

FIGURE 87.6 Block diagram of an IIR filter, using allpass filters.

$$\theta(f) = \arctan\left[\frac{2a_1(a_2-1)\sin(\omega)+(a_2^2-1)\sin(2\omega)}{2a_2+a_1^2+2a_1(a_2+1)\cos(\omega)+(a_2^2+1)\cos(2\omega)}\right] \tag{87.25}$$

The group delay $\tau(f)$ of an allpass filter is always ≤ 0.The output signal energy of (87.20) is the same as the input signal energy, i.e., $\sum_{n=-\infty}^{\infty}|y(n)|^2 = \sum_{n=-\infty}^{\infty}|x(n)|^2$ which means that the allpass filter is a lossless system. Note that if we attempt to find a minimum-phase filter from a stable allpass filter, by moving all the zeros inside the unit circle, all poles and zeros would cancel out, yielding the trivial filter with a system function of unity.

A more general form of (87.20), allowing the coefficients to be complex, is Nth order allpass filter with system function

$$H(z) = z^{-N}\frac{D^*(z^*)}{D(z^{-1})} = z^{-N}\frac{a_N^* z^N+\cdots+a_2^* z^2+a_1^* z+1}{1+a_1 z^{-1}+a_2 z^{-2}+\cdots+a_N z^{-N}} \tag{87.26}$$

$$= z^{-N}\frac{(1-p_1^* z)(1-p_2^* z)\cdots(1-p_N^* z)}{(1-p_1 z^{-1})(1-p_2 z^{-1})\cdots(1-p_N z^{-1})} \tag{87.27}$$

Therefore, for a pole at $z = p$ there is a zero at $z = 1/p^*$, i.e., poles and zeros exist in reciprocal–conjugate pairs.

Allpass filters have been used as building blocks for various applications [5]. Particularly, an allpass filter can be designed to approximate a desired phase response. Therefore, an allpass filter in cascade with an IIR filter can be used to compensate the nonlinear phase of the IIR filter. Such a cascade filter has a system function of the form $H(z) = H_{\text{IIR}}(z)H_{\text{ap}}(z)$, where $H_{\text{IIR}}(z)$ is an IIR filter satisfying some magnitude response and $H_{\text{ap}}(z)$ is an allpass filter that compensates for the nonlinearity of the phase response of $H_{\text{IIR}}(z)$. Allpass filters in parallel connection can be used to approximate a desired magnitude response. For this, the system function is in the form $H(z) = \sum_{k=1}^{K} c_i H_{\text{ap},i}(z)$, where $H_{\text{ap},i}(z)$ is an allpass filter and c_i is a coefficient. A block diagram is shown in Fig. 87.6.

87.2 Design of IIR Filters

Sawasd Tantaratana

Introduction

A filter is generally designed to satisfy a frequency response specification. IIR filter design normally focuses on satisfying a magnitude response specification. If the phase response is essential, it is usually satisfied by a phase compensation filter, such as an allpass filter (see Section 87.1). We will adopt a magnitude specification that is normalized so that the maximum magnitude is 1. The magnitude square in the passband must be at least $1/(1 + \varepsilon^2)$ and at most 1, while it must be no larger than δ^2 in the stopband, where ε and δ are normally small. The passband edge is denoted by f_p and the stopband edge by f_s. Figure 87.7(a) shows such a specification for a low-pass filter. The region between the passband and the stopband is the transition band. There is no constraint on the response in the transition band. Another specification that is often used is shown in Fig. 87.7(b), using δ_1 and δ_2 to specify the acceptable magnitude. Given δ_1 and δ_2, they can be converted to ε and δ using $\varepsilon = 2\delta_1^{0.5}/(1 - \delta_1)$ and $\delta = \delta_2/(1 + \delta_1)$. The magnitude is often specified in dB, which is $20 \log_{10}|H(f)|$. Specifications for other types of filters (high-pass, bandpass, and bandstop) are similar.

We can classify various IIR filter design methods into three categories: the design using analog prototype filter, the design using digital frequency transformation, and computer-aided design. In the first category, an analog filter is designed to the (analog) specification and the analog filter transfer function is transformed to digital system function using some kind of transformation. The second category assumes that a digital low-pass filter can be designed. The desired digital filter is obtained from the digital low-pass filter by a digital frequency transformation. The last category uses some algorithm to choose the coefficients so that the response is as close (in some sense) as possible to the desired filter. Design methods in the first two categories are simple to do, requiring only a handheld calculator. Computer-aided design requires some computer programming, but it can be used to design nonstandard filters.

Analog Filters

Here, we describe four basic types of analog low-pass filters that can be used as prototype for designing IIR filters. For each type, we give the transfer function, its magnitude response, and the order N needed to satisfy the (analog) specification. We will use $H_a(s)$ for the transfer function of an analog filter, where s is the variable in the Laplace transform. Each of these filters has all its poles on the left-half s plane, so that it is stable. We will use the variable λ to represent the analog frequency in radians per second. The frequency response $H_a(\lambda)$ is the transfer function evaluated at $s = j\lambda$. The analog low-pass filter specification is given by

© 2003 by CRC Press LLC

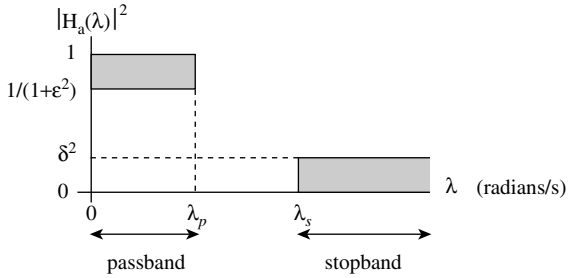

FIGURE 87.8 Specification for an analog low-pass filter.

$$\begin{aligned} \left(1+\varepsilon^2\right)^{-1} \le \left|H_a(\lambda)\right|^2 \le 1 \qquad & \text{for } 0 \le \left(\lambda/2\pi\right) \le \left(\lambda_p/2\pi\right) \text{Hz} \\ 0 \le \left|H_a(\lambda)\right|^2 \le \delta^2 \qquad & \text{for } \left(\lambda_s/2\pi\right) \le \left(\lambda/2\pi\right) < \infty \text{ Hz} \end{aligned} \tag{87.28}$$

where λ_p and λ_s are the passband edge and stopband edge, respectively. The specification is sketched in Figure 87.8.

Butterworth Filters. The transfer function of an Nth order Butterworth filter is given by

$$H_a(s) = \begin{cases} \displaystyle\prod_{i=1}^{N/2} \frac{1}{\left(s/\lambda_c\right)^2 - 2\text{Re}\left(s_i\right)\left(s/\lambda_c\right) + 1} & N = \text{even} \\ \displaystyle\frac{1}{\left(s/\lambda_c\right)+1} \prod_{i=1}^{(N-1)/2} \frac{1}{\left(s/\lambda_c\right)^2 - 2\text{Re}\left(s_i\right)\left(s/\lambda_c\right) + 1} & N = \text{odd} \end{cases} \tag{87.29}$$

where $\lambda_p \le \lambda_c \le \lambda_s$ and $s_i = \exp\{j(1 + (2i - 1)/N)\pi/2\}$. The magnitude response square is

$$\left|H_a(\lambda)\right|^2 = \frac{1}{1+\left(\lambda/\lambda_c\right)^{2N}} \tag{87.30}$$

Figure 87.9 shows the magnitude response $|H_a(\lambda)|$, with $\lambda_c = 1$. Note that a Butterworth filter is an all-pole (no zero) filter, with the poles being at $s = \lambda_c s_i$ and $s = \lambda_c s_i^*$, $i = 1, \ldots, N/2$ if N is even or $i = 1, \ldots, (N - 1)/2$ if N is odd, where x^* denotes the complex conjugate of x. When N is odd, there is another pole at $s = -\lambda_c$. All N poles are on the left-half s plane, located on the circle with radius λ_c. Therefore, the filter in (87.29) is stable.

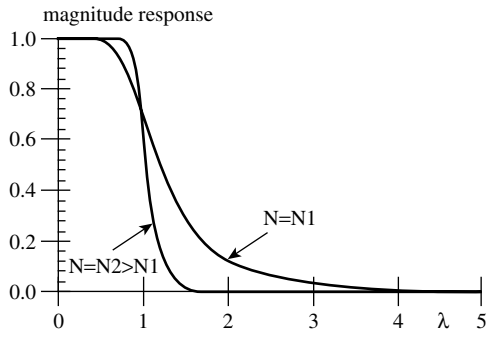

FIGURE 87.9 Magnitude responses of Butterworth filters.

© 2003 by CRC Press LLC

To satisfy the specification in (87.28), the filter order can be calculated from

$$N = \text{integer} \geq \frac{\log\left[\varepsilon / \left(\delta^{-2} - 1\right)^{1/2}\right]}{\log\left[\lambda_p / \lambda_s\right]} \tag{87.31}$$

The value of λ_c can be chosen as any value in the following range:

$$\lambda_p \varepsilon^{-1/N} \leq \lambda_c \leq \lambda_s \left(\delta^{-2} - 1\right)^{-1/(2N)} \tag{87.32}$$

If we choose $\lambda_c = \lambda_p \varepsilon^{-1/N}$, then the magnitude response square passes through $1/(1 + \varepsilon^2)$ at $\lambda = \lambda_p$. If we choose $\lambda_c = \lambda_s (\delta^{-2} - 1)^{-1/(2N)}$, then the magnitude response square passes through δ^2 at $\lambda = \lambda_s$. If λ_c is between these two values, then the magnitude square will be $\geq 1/(1 + \varepsilon^2)$ at $\lambda = \lambda_p$, and $\leq \delta^2$ at $\lambda = \lambda_s$.

***Chebyshev Filters* (*Type-I Chebyshev Filters*).** A Chebyshev filter is also an all-pole filter. The *N*th order Chebyshev filter has a transfer function given by

$$H_a(s) = C \prod_{i=1}^{N} \frac{1}{(s - p_i)} \tag{87.33}$$

where

$$C = \begin{cases} -\displaystyle\prod_{i=1}^{N} p_i & N \text{ is odd} \\ \left(1 + \varepsilon^2\right)^{-1/2} \displaystyle\prod_{i=1}^{N} p_i & N \text{ is even} \end{cases} \tag{87.34a}$$

$$p_i = -\lambda_p \sinh(\phi) \sin\left(\frac{2i-1}{2N}\pi\right) + j\lambda_p \cosh(\phi) \cos\left(\frac{2i-1}{2N}\pi\right) \tag{87.34b}$$

$$\phi = \frac{1}{N} \ln\left[\frac{1 + \left(1 + \varepsilon^2\right)^{1/2}}{\varepsilon}\right] \tag{87.34c}$$

The value of C normalizes the magnitude so that the maximum magnitude is 1. Note that C is always a positive constant. The poles are on the left-half s plane, lying on an ellipse centered at the origin with a minor radius of $\lambda_p \sinh(\phi)$ and major radius of $\lambda_p \cosh(\phi)$. Except for one pole when N is odd, all the poles have a complex conjugate pair. Specifically, $p_i = p^*_{N-i+1}$, $i = 1, 2, \ldots, N/2$ or $(N - 1)/2$. Combining each complex conjugate pair in (87.33) yields a second-order factor with real coefficients. The magnitude response can be computed from (87.33) through (87.34c) with $s = j\lambda$. Its square can also be written as

$$\left|H_a(\lambda)\right|^2 = \frac{1}{1 + \varepsilon^2 T_N^2\left(\lambda / \lambda_p\right)} \tag{87.35}$$

where $T_N(x)$ is the Nth degree Chebyshev polynomial of the first kind, which is given recursively by

$$\begin{gathered} T_0(x) = 1 \quad T_1(x) = x \\ T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x) \quad n \geq 1 \end{gathered} \tag{87.36}$$

© 2003 by CRC Press LLC

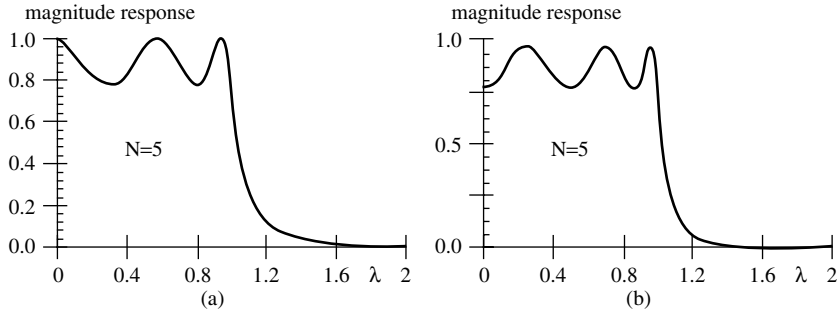

FIGURE 87.10 Magnitude responses of Chebyshev filters.

Notice that $T_N^2(\pm 1) = 1$. Therefore, we have from (87.35) that the magnitude square passes through $1/(1 + \varepsilon^2)$ at $\lambda = \lambda_p$, i.e., $|H_a(\lambda_p)|^2 = 1/(1 + \varepsilon^2)$. Note also that $T_N(0) = (-1)^{N/2}$ for even N and it is 0 for odd N. Therefore, $|H_a(0)|^2$ equals $1/(1 + \varepsilon^2)$ for even N and it equals 1 for odd N. Figure 87.10 shows some examples of magnitude response square.

The filter order required to satisfy the specifications in (87.28) is

$$N \geq \frac{\cosh^{-1}\left[\left(\delta^{-2}-1\right)^{1/2}/\varepsilon\right]}{\cosh^{-1}\left(\lambda_s/\lambda_p\right)}$$

$$= \frac{\log\left\{\left[\left(\delta^{-2}-1\right)^{1/2}/\varepsilon\right]+\left[\left(\delta^{-2}-1\right)/\varepsilon^2-1\right]^{1/2}\right\}}{\log\left\{\left(\lambda_s/\lambda_p\right)+\left(\left(\lambda_s/\lambda_p\right)^2-1\right)^{1/2}\right\}} \tag{87.37}$$

which can be computed knowing ε, δ, λ_p, and λ_s.

Inverse Chebyshev Filters (Type-II Chebyshev Filters). Notice from Fig. 87.10 that the Chebyshev filter has magnitude response containing equiripples in the passband. The equiripples can be arranged to go inside the stopband, for which case we obtain inverse Chebyshev filters. The magnitude response square of the inverse Chebyshev filter is

$$\left|H_a(\lambda)\right|^2 = \frac{1}{1+\dfrac{\left(\delta^{-2}-1\right)}{T_N^2\left(\lambda_2/\lambda\right)}} \tag{87.38}$$

Since $T_N^2(\pm 1) = 1$, (87.38) gives $|H_a(\lambda_s)|^2 = \delta^2$. Figure 87.11 depicts some examples of (87.38). Note that $|H_a(\infty)|$ equals 0 if N is odd and it equals δ if N is even.

The transfer function giving rise to (87.38) is given by

$$H_a(s) = \begin{cases} C\displaystyle\prod_{i=1}^{N}\frac{(s-q_i)}{(s-p_i)} & N \text{ is even} \\ \dfrac{C}{\left(s-p_{(N+1)/2}\right)}\displaystyle\prod_{\substack{i=1 \\ i\neq(N+1)/2}}^{N}\frac{(s-q_i)}{(s-p_i)} & N \text{ is odd} \end{cases} \tag{87.39}$$

© 2003 by CRC Press LLC

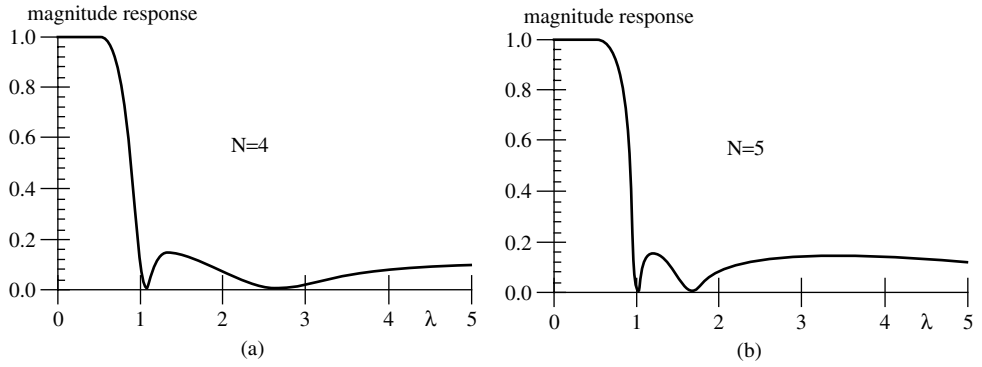

FIGURE 87.11 Magnitude responses of inverse Chebyshev filters.

where

$$C = \begin{cases} \displaystyle\prod_{i=1}^{N} \frac{p_i}{q_i} & N \text{ is even} \\ \displaystyle -p_{(N+1)/2} \prod_{\substack{i=1 \\ i \neq (N+1)/2}}^{N} \frac{p_i}{q_i} & N \text{ is odd} \end{cases} \tag{87.40a}$$

$$p_i = \frac{\lambda_s}{\alpha_i^2 + \beta_i^2}(\alpha_i - j\beta_i) \qquad q_i = j\frac{\lambda_s}{\cos\left(\dfrac{2i-1}{2N}\pi\right)} \tag{87.40b}$$

$$\alpha_i = -\sinh(\phi)\sin\left(\frac{2i-1}{2N}\pi\right) \quad \beta_i = \cosh(\phi)\cos\left(\frac{2i-1}{2N}\pi\right) \tag{87.40c}$$

$$\phi = \frac{1}{N}\cosh^{-1}\left(\delta^{-1}\right) = \frac{1}{N}\ln\left[\delta^{-1} + \left(\delta^{-2} - 1\right)^{1/2}\right] \tag{87.40d}$$

Note that the zeros are on the imaginary axis on the *s* plane. The filter order *N* required to satisfy the specification in (87.28) is the same as the order for the Chebyshev filter, given by (87.37).

Another form for the inverse Chebyshev filter has a magnitude response square given by

$$\left|H_a(\lambda)\right|^2 = \frac{1}{1 + \varepsilon^2 \dfrac{T_N^2\left(\lambda_s/\lambda_p\right)}{T_N^2\left(\lambda_s/\lambda\right)}} \tag{87.41}$$

which passes through $1/(1 + \varepsilon^2)$ at $\lambda = \lambda_p$. For further details of this form see [2].

Elliptic Filters (Cauer Filters). Elliptic filters have equiripples in both the passband and the stopband. We summarize the magnitude response and the transfer function of an elliptic filter as follows. Detail of derivation can be found in [1] and [6].

The magnitude response square is given by

$$\left|H_a(\lambda)\right|^2 = \frac{1}{1 + \varepsilon^2 R_N^2(\lambda)} \tag{87.42}$$

© 2003 by CRC Press LLC

where $R_N(\lambda)$ is the Chebyshev rational function given by

$$R_N(\lambda)=\begin{cases}\dfrac{\left(\delta^{-2}-1\right)^{1/4}}{\varepsilon^{1/2}}\lambda\displaystyle\prod_{i=1}^{(N-1)/2}\dfrac{\lambda^2-\lambda_r\mathrm{sn}^2\left[\dfrac{2iK(\lambda_r)}{N},\lambda_r\right]}{\lambda^2\lambda_r\mathrm{sn}^2\left[\dfrac{2iK(\lambda_r)}{N},\lambda_r\right]-1} & N=\text{odd}\\ \dfrac{\left(\delta^{-2}-1\right)^{1/4}}{\varepsilon^{1/2}}\displaystyle\prod_{i=1}^{N/2}\dfrac{\lambda^2-\lambda_r\mathrm{sn}^2\left[\dfrac{(2i-1)K(\lambda_r)}{N},\lambda_r\right]}{\lambda^2\lambda_r\mathrm{sn}^2\left[\dfrac{(2i-1)K(\lambda_r)}{N},\lambda_r\right]-1} & N=\text{even}\end{cases} \tag{87.43}$$

Here, $\lambda_r=\lambda_p/\lambda_s$, $K(t)$ is the complete elliptic integral of the first kind given by

$$K(t)=\int_0^{\pi/2}\frac{d\theta}{\left[1-t^2\sin^2\theta\right]^{1/2}}=\int_0^1\frac{dx}{\left[\left(1-x^2\right)\left(1-t^2x^2\right)\right]^{1/2}} \tag{87.44}$$

The Jacobian elliptic sine function $\mathrm{sn}[u,t]$ is defined as

$$\mathrm{sn}\left[u,t\right]=\sin\phi\quad\text{if } u=\int_0^{\phi}\frac{d\theta}{\left[1-t^2\sin^2\theta\right]^{1/2}} \tag{87.45}$$

The integral

$$F(\phi,t)=\int_0^{\phi}\frac{d\theta}{\left(1-t^2\sin^2\theta\right)^{1/2}}=\int_0^{\sin\phi}\frac{dx}{\left[\left(1-x^2\right)\left(1-t^2x^2\right)\right]^{1/2}} \tag{87.46}$$

is called the elliptic integral of the first kind. Note that $K(t)=F(\pi/2,t)$.

The transfer function corresponding to the magnitude response in (87.42) is

$$H_a(s)=\begin{cases}\dfrac{C}{(s+p_0)}\displaystyle\prod_{i=1}^{(N-1)/2}\frac{\left(s^2+B_i\right)}{\left(s^2+A_{i1}s+A_{i2}\right)} & N\text{ odd}\\ C\displaystyle\prod_{i=1}^{N/2}\frac{\left(s^2+B_i\right)}{\left(s^2+A_{i1}s+A_{i2}\right)} & N\text{ even}\end{cases} \tag{87.47}$$

where

$$C=\begin{cases}p_0\displaystyle\prod_{i=1}^{(N-1)/2}\frac{A_{i2}}{B_i} & N\text{ is odd}\\ \dfrac{1}{\left(1+\varepsilon^2\right)^{1/2}}\displaystyle\prod_{i=1}^{N/2}\frac{A_{i2}}{B_i} & N\text{ is even}\end{cases} \tag{87.48}$$

© 2003 by CRC Press LLC

The pole p_0, and the coefficients B_i, A_{i1}, A_{i2} are calculated as follows:

$$\lambda_r = \frac{\lambda_p}{\lambda_s} \quad \lambda_c = \sqrt{\lambda_p \lambda_s} \quad \alpha = 0.5 \frac{1-\left(1-\lambda_r^2\right)^{1/4}}{1+\left(1-\lambda_r^2\right)^{1/4}} \tag{87.49a}$$

$$\beta = e^{-\pi K\left[\left(1-\lambda_r^2\right)^{1/2}\right]/K(\lambda_r)} \approx \alpha + 2\alpha^5 + 15\alpha^9 + 150\alpha^{13} \tag{87.49b}$$

$$\gamma = \frac{1}{2N} \ln\left[\frac{\left(1+\varepsilon^2\right)^{1/2}+1}{\left(1+\varepsilon^2\right)^{1/2}-1}\right] \tag{87.49c}$$

$$\sigma = \left| \frac{2\beta^{1/4} \sum_{k=0}^{\infty} (-1)^k \beta^{k(k+1)} \sinh\left[(2k+1)\gamma\right]}{1+2\sum_{k=1}^{\infty} (-1)^k \beta^{k^2} \cosh\left[2k\gamma\right]} \right| \tag{87.49d}$$

$$\zeta = \left(1+\lambda_r \sigma^2\right)\left(1+\frac{\sigma^2}{\lambda_r}\right) \quad \eta = \begin{cases} i & N \text{ odd} \\ i-0.5 & N \text{ even} \end{cases} \tag{87.49e}$$

$$\psi_i = \frac{2\beta^{1/4} \sum_{k=0}^{\infty} (-1)^k \beta^{k(k+1)} \sin\left[(2k+1)\pi\eta/N\right]}{1+2\sum_{k=1}^{\infty} (-1)^k \beta^{k^2} \cos\left[2k\pi\eta/N\right]} \tag{87.49f}$$

$$\mu_i = \left[\left(1-\lambda_r \psi_i^2\right)\left(1-\frac{\psi_i^2}{\lambda_r}\right)\right]^{1/2} \tag{87.49g}$$

$$p_0 = \lambda_c \sigma \quad B_i = \frac{\lambda_c^2}{\psi_i^2} \quad A_{i1} = \frac{2\lambda_c \sigma \mu_i}{1+\sigma^2 \psi_i^2} \quad A_{i2} = \lambda_c^2 \frac{\sigma^2 \mu_i^2 + \zeta \psi_i^2}{\left[1+\sigma^2 \psi_i^2\right]^2} \tag{87.49h}$$

The infinite summations above converge very quickly, so that only a few terms are needed in actual calculation. A simple program can be written to compute the values in (87.49a) through (87.49h).

The filter order required to satisfy (87.28) is calculated from

$$N \geq \frac{1}{\log(\beta)} \log\left[\frac{\varepsilon^2}{16\left(\delta^{-2}-1\right)}\right] \tag{87.50}$$

where β is given by (87.49b). An example of the magnitude response is plotted in Fig. 87.12. We see that there are ripples in both the passband and the stopband.

Comparison. In comparing the filters given above, the Butterworth filter requires the highest order and the elliptic filter requires the smallest order to satisfy the same passband and stopband specifications.

© 2003 by CRC Press LLC

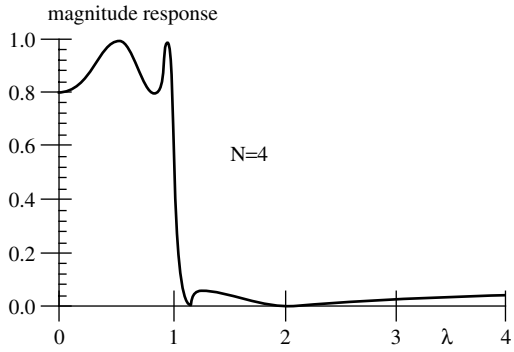

FIGURE 87.12 Magnitude response of elliptic filter.

The Butterworth filter and the inverse Chebyshev filter have nicer (closer to linear) phase characteristics in the passband than Chebyshev and elliptic filters. The magnitude responses of the Butterworth and Chebyshev filters decrease monotonically in the stopband to zero, which reduces the aliasing caused by some analog-to-digital transformations.

Design Using Analog Prototype Filters

In this subsection, we consider designing IIR filters using analog prototype filters. This method is suitable for designing the standard types of filters: low-pass filter (LPF), high-pass filter (HPF), bandpass filter (BPF), and bandstop filter (BSF). The basic idea is to transform the digital specification to analog specification, design an analog filter, and then transform the analog filter transfer function to digital filter system function. Several types of transformation have been studied.

The design steps are outlined by Fig. 87.13. Given the desired magnitude response $|H^x(f)|$ of digital LPF, HPF, BPF, or BSF, it is transformed to analog magnitude specification (of the corresponding type: LPF, HPF, BPF, or BSF) $|H_a^x(\lambda)|$. The analog magnitude specification is then transformed to analog LPF magnitude specification $|H_a(\lambda)|$. We then design an analog prototype filter as discussed in the subsection on analog filters, obtaining analog LPF transfer function $H_a(s)$. Next, the analog LPF transfer function is transformed to analog transfer function $H_a^x(s)$ of the desired type (LPF, HPF, BPF, or BSF), followed by a transformation to digital filter system function $H^x(z)$. By combining the appropriate steps, we can obtain transformations to go directly from $|H^x(f)|$ to $|H_a(\lambda)|$ and directly from $H_a(s)$ to $H(z)$, as indicated by the dotted lines in Fig. 87.13. Note that for designing digital LPF, the middle steps involving $|H_a^x(\lambda)|$ and $H_a^x(s)$ are not applicable.

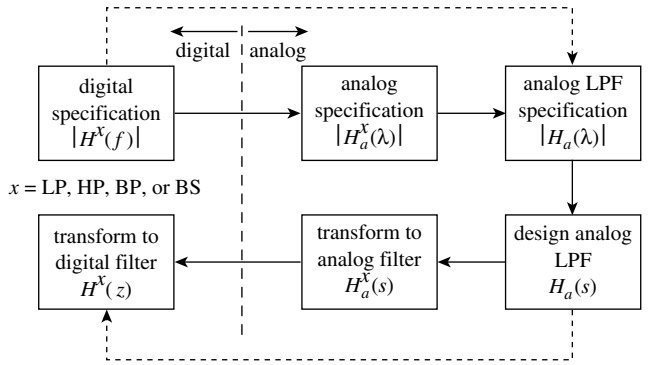

FIGURE 87.13 Diagram outlining the steps involved in designing IIR filter using analog prototype filter.

© 2003 by CRC Press LLC

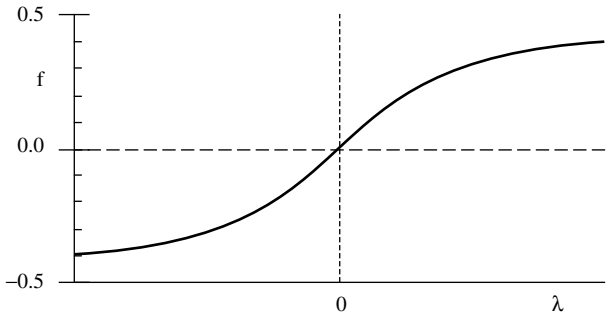

FIGURE 87.14 Relation between λ and f for bilinear transformation.

Transformations

There are several types of transformations. They arise from approximating continuous-time signals and systems by discrete-time signals and systems. Table 87.1 shows several transformations, with their advantages and disadvantages. The constant T is the sampling interval. The resulting mapping is used for transforming $H_a(s)$ to $H(z)$. For example, in the backward difference approximation we obtain $H(z)$ by replacing the variable s with $(1 - z^{-1})/T$ in $H_a(s)$, i.e., $H(z) = H_a(s)|_{s=(1-z^{-1})/T}$. The bilinear transformation is the best all-around method, followed by the impulse invariant method. Therefore, we describe these two transformations in more detail.

Bilinear Transformation. Using this transformation, the analog filter is converted to digital filter by replacing s in the analog filter transfer function with $(2/T)\ (1 - z^{-1})/(1 + z^{-1})$, i.e.,

$$H(z) = H_a(s)\Big|_{s=(2/T)\left(1-z^{-1}\right)/\left(1+z^{-1}\right)} \tag{87.51}$$

From the mapping, we can show as follows that the imaginary axis on the s plane is mapped to the unit circle on the z plane. Letting $s = j\lambda$, we have

$$\begin{aligned} z &= \frac{(2/T)+s}{(2/T)-s} = \frac{(2/T)+j\lambda}{(2/T)-j\lambda} \\ &= \frac{\sqrt{(2/T)^2+(\lambda)^2}\,e^{j\arctan\left(\lambda/(2/T)\right)}}{\sqrt{(2/T)^2+(\lambda)^2}\,e^{j\arctan\left(-\lambda/(2/T)\right)}} = e^{j2\arctan(\lambda T/2)} \end{aligned} \tag{87.52}$$

which is the unit circle on the z plane as λ goes from $-\infty$ to ∞. Writing $z = e^{j2\pi f}$ in (87.52), we obtain the relation between the analog frequency λ and the digital frequency f:

$$f = \frac{1}{\pi}\arctan\left(\frac{\lambda T}{2}\right) \qquad \lambda = \frac{2}{T}\tan(\pi f) \tag{87.53}$$

which is plotted in Fig. 87.14. Equation (87.53) is used for converting digital specification to analog specification, i.e., $\lambda_s = (2/T)\tan(\pi f_s)$ and $\lambda_p = (2/T)\tan(\pi f_p)$. In a complete design process, starting from the digital specification and ending at the digital filter system function, as outlined in Fig. 87.13, the sampling interval T is canceled out in the process. Hence, it has no effect and any convenient value (such as 1 or 2) can be used.

TABLE 87.1 Various Types of Analog-to-Digital Transformation

Type of Transformation	Principle	Resulting mapping	Advantages	Disadvantages
Backward difference approximation	$\frac{dy}{dt} \approx \frac{y(n)-y(n-1)}{T}$	$s = \frac{1-z^{-1}}{T}$, $z = \frac{1}{1-sT}$ s plane z plane  unit circle	1. Stable analog filter yields stable digital filter.	1. Left-half s plane is not mapped onto unit circle on z plane. Pole locations will be in the circle centered at 0.5 with radius 0.5 on the z plane.
Forward difference approximation	$\frac{dy}{dt} \approx \frac{y(n+1)-y(n)}{T}$	$s = \frac{z-1}{T}$, $z = 1+sT$ s plane z plane 	1. Stable analog filter may not yield stable digital filter. 2. Left-half s plane is not mapped onto unit circle on z plane.	
Impulse invariant method	Sample the analog impulse response: $h(n) = h_a(nT)$	Transform $H_a(s) = \sum_{i=1}^{N} \frac{b_i}{(s-p_i)}$ to $H(z) = \sum_{i=1}^{N} \frac{b_i}{[1-z^{-1}\exp(p_iT)]}$ s plane z plane  mapping of pole locations	1. Preserve shape of impulse response. 2. Stable analog filter yields stable digital filter. 3. The analog frequency and digital frequency are linearly related, $\lambda T = 2\pi f$, $-0.5 \le f \le 0.5$.	1. Aliasing in the frequency domain (due to many-to-one mapping from s plane to z plane). $T \cdot H(f) = \sum_{k=-\infty}^{\infty} H_a\left(2\pi \frac{f+k}{T}\right)$
Bilinear transformation	Approximate $y(t) = \int_{t-T}^{t} y'(\tau)d\tau + y(t-T)$ by $y(n) = \frac{T}{2}[y'(n) + y'(n-1)] + y(n-1)$	$s = \frac{2}{T}\frac{1-z^{-1}}{1+z^{-1}}$, $z = \frac{(2/T)+s}{(2/T)-s}$ s plane z plane 	1. Stable analog filter yields stable digital filter. 2. Left-half s plane is mapped onto unit circle on z plane, a one-to-one mapping.	1. Frequency warping—nonlinear relation between analog frequency and digital frequency.
Matched z transformation	Map each pole and zero on s plane directly to pole and zero on the z plane.	Transform $H_a(s) = \prod_{i=1}^{N} \frac{(s-q_i)}{(s-p_i)}$ to $H(z) = \prod_{i=1}^{N} \frac{[1-z^{-1}\exp(q_iT)]}{[1-z^{-1}\exp(p_iT)]}$ s plane z plane  mapping of pole and zero locations	1. Stable analog filter yields stable digital filter.	1. Aliasing in the frequency domain (due to many-to-one mapping from s plane to z plane).

Impulse Invariant Method. This method approximates the analog filter impulse response $h_a(t)$ by its samples separated by T seconds. The result is the impulse response $h(n)$ of the digital filter, i.e., $h(n) = h_a(nT)$. From this relation, it can be shown that

© 2003 by CRC Press LLC

$$H(f)=\frac{1}{T}\sum_{k=-\infty}^{\infty}H_a(\lambda)\Big|_{\lambda=2\pi(f+k)/T}=\frac{1}{T}\sum_{k=-\infty}^{\infty}H_a\left(2\pi\frac{f+k}{T}\right) \tag{87.54}$$

The analog and digital frequencies are related by

$$f=\frac{\lambda T}{2\pi}\ \text{ for }\ |f|\le 0.5 \tag{87.55}$$

From (87.54), the digital filter frequency response is the sum of shifted versions of the analog filter frequency response. There is aliasing if $H_a(\lambda)$ is not zero for $|\lambda/2\pi| > 1/(2T)$. Therefore, the analog filter used in this method should have a frequency response that goes to zero quickly as λ goes to ∞. Because of the aliasing, this method cannot be used for designing a high-pass filter. Writing the analog filter transfer function in the form

$$H_a(s)=\sum_{i=1}^{N}\frac{b_i}{(s-p_i)} \tag{87.56}$$

it follows that the analog impulse response is given by $h_a(t) = \sum_{i=1}^{N} b_i e^{p_i t}$ and the digital filter system function can be obtained as

$$\begin{aligned}H(z)&=\sum_{n=0}^{\infty}h(n)z^{-n}=\sum_{n=0}^{\infty}h_a(nT)z^{-n}\\&=\sum_{i=1}^{N}b_i\sum_{n=0}^{\infty}\left(e^{p_iT}z^{-1}\right)^n=\sum_{i=1}^{\infty}\frac{b_i}{\left(1-e^{p_iT}z^{-1}\right)}\end{aligned} \tag{87.57}$$

Therefore, an analog filter transfer function $H_a(s) = \sum_{i=1}^{N} b_i/(s - p_i)$ gets transformed to a digital filter system function $H(z) = \sum_{i=1}^{N} b_i/(1 - e^{p_i T} z^{-1})$ as shown in Table 87.1. Similar to the bilinear transformation, in a complete design process the choice of T has no effect (except for the final magnitude scaling factor).

Low-Pass Filters (LPF's)

We give one example in designing an LPF using the impulse invariant method and one example using the bilinear transformation.

In this example, suppose that we wish to design a digital filter using an analog Butterworth prototype filter. The digital filter specification is

$$20\log|H(f)|\ge -2\text{dB}\quad \text{for } 0\le f\le 0.11$$

$$20\log|H(f)|\le -10\text{dB}\quad \text{for } 0.2\le f\le 0.5$$

where the log is of base 10. Therefore, we have $\varepsilon = 0.7648$, $\delta = 0.3162$, $f_p = 0.11$, and $f_s = 0.2$. Let us use the impulse invariant method. Therefore, the analog passband edge and stopband edge are $\lambda_p = 0.22\pi/T$ and $\lambda_s = 0.4\pi/T$, respectively. We use the same ripple requirements: $\varepsilon = 0.7648$ and $\delta = 0.3162$. Using these values, a Butterworth filter order is calculated from (87.31), yielding $N \ge 2.3$. So, we choose $N = 3$. With $\lambda_c = \lambda_p \varepsilon^{-1/N} = 0.2406\pi/T$, we find the analog filter transfer function to be

© 2003 by CRC Press LLC

$$H_a(s) = \frac{\lambda_c^3}{(s+\lambda_c)(s^2+\lambda_c s+\lambda_c^2)}$$

$$= \lambda_c\left[\frac{1}{s+\lambda_c} + \frac{-0.5-j0.5/\sqrt{3}}{s+0.5(1-j\sqrt{3})\lambda_c} + \frac{-0.5+j0.5/\sqrt{3}}{s+0.5(1+j\sqrt{3})\lambda_c}\right]$$

$$= \frac{0.7559}{T}\left[\frac{1}{s+0.7559/T} + \frac{-0.5-j0.5/\sqrt{3}}{s+0.3779(1-j\sqrt{3})/T}\right.$$

$$\left. + \frac{-0.5+j0.5/\sqrt{3}}{s+0.3779(1+j\sqrt{3})/T}\right]$$

Using (87.56) and (87.57) we obtain the digital filter system function:

$$H(z) = \frac{0.7559}{T}\left[\frac{1}{1-e^{-0.7559}z^{-1}} + \frac{-0.5-j0.5/\sqrt{3}}{1-e^{-0.3779(1-j\sqrt{3})}z^{-1}} + \frac{-0.5+j0.5/\sqrt{3}}{1-e^{-0.3779(1+j\sqrt{3})}z^{-1}}\right]$$

$$= \frac{0.7559}{T}\left[\frac{1}{1-0.469z^{-1}} - \frac{1-0.7846z^{-1}}{1-1.0873z^{-1}+0.4696z^{-2}}\right]$$

Due to aliasing, the maximum value of the resulting magnitude response (which is at $f = 0$ or $z = 1$) is no longer equal to 1, although the analog filter has maximum magnitude (at $\lambda = 0$ or $s = 0$) of 1. Note that the choice of T affects only the scaling factor, which is only a constant gain factor. If we adjust the system function so that the maximum magnitude is 1, i.e., $|H(f)| = 1$, we have

$$H(z) = 0.7565\left[\frac{1}{1-0.4696z^{-1}} - \frac{1-0.7846z^{-1}}{1-1.0873z^{-1}+0.4696z^{-2}}\right]$$

The magnitude response in dB and the phase response are plotted in Fig. 87.15. From the result, $|H(f)| = -1.97$ dB at $f = 0.11$ and $|H(f)| = -113.42$ dB at $f = 0.2$; both satisfy the desired specification. The aliasing in this example is small enough that the resulting response still meets the specification. It is possible that

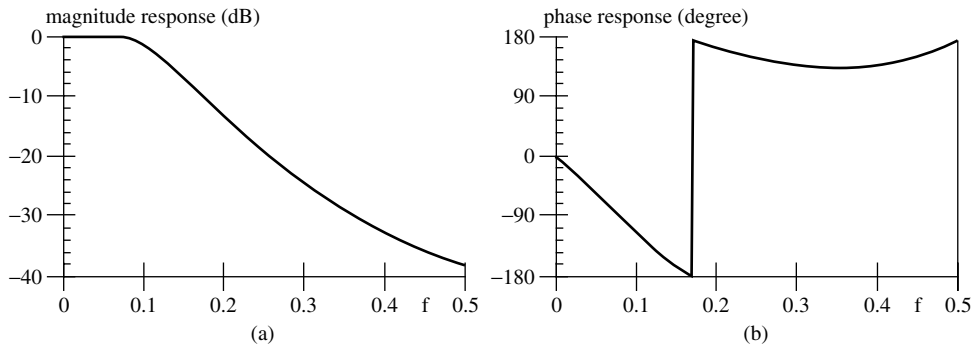

FIGURE 87.15 Frequency response of the LP filter designed using impulse invariant method.

© 2003 by CRC Press LLC

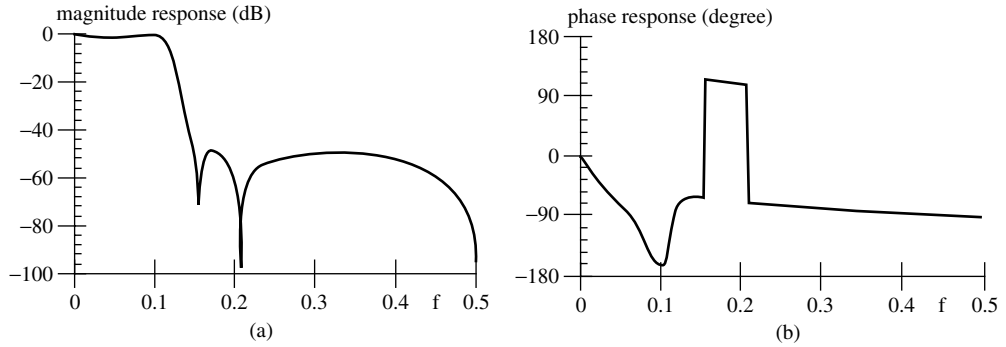

FIGURE 87.16 Frequency response of the LPF designed using bilinear transformation.

the aliasing is large enough that the designed filter does not meet the specification. To compensate for the unknown aliasing, we may want to use smaller ε and δ in designing the analog prototype filter.

In this next example, we demonstrate the design method using bilinear transformation, with an analog elliptic prototype filter. Let the desired filter specification be

$$\left|H(f)\right|^2 \geq 0.8 \quad (\text{or} \quad -0.97\,\text{dB}) \quad \text{for } 0 \leq f \leq 0.1125$$

$$\left|H(f)\right|^2 \leq 2.5\times10^{-5} \quad (\text{or} \quad -46.02\,\text{dB}) \quad \text{for } 0.15 \leq f \leq 0.5$$

which means $\varepsilon = 0.5$, $\delta = 0.005$, $f_p = 0.1125$, and $f_s = 0.15$. For bilinear transformation, we calculate the analog passband and stopband edges as $\lambda_p = (2/T)\tan(\pi f_p) = 0.7378/T$ and $\lambda_s = (2/T)\tan(\pi f_s) = 1.0190/T$, respectively. Therefore, $\lambda_p/\lambda_s = 0.7240$. From (87.50) we obtain the order $N \geq 4.8$. So, we use $N = 5$. The analog elliptic filter transfer function is calculated from (87.47)–(87.49) to be

$$H_a(s) = \frac{7.8726\times10^{-3}\left[\left(\frac{sT}{2}\right)^2 + 0.6006\right]\left[\left(\frac{sT}{2}\right)^2 + 0.2782\right]}{\left[\left(\frac{sT}{2}\right)^2 + 0.1311\right]\left[\left(\frac{sT}{2}\right)^2 + 0.1689\left(\frac{sT}{2}\right) + 0.0739\right]\left[\left(\frac{sT}{2}\right)^2 - 0.0457\left(\frac{sT}{2}\right) + 0.1358\right]}$$

To convert to digital filter system function, we replace s with $(2/T)(1 - z^{-1})/(1 + z^{-1})$. Equivalently, we replace $sT/2$ with $(1 - z^{-1})/(1 + z^{-1})$, yielding

$$H(z) = \frac{1.0511\times10^{-2}\left(1+z^{-1}\right)\left(1-0.4991z^{-1}+z^{-2}\right)\left(1-1.1294z^{-1}+z^{-2}\right)}{\left(1-0.7682z^{-1}\right)\left(1-1.4903z^{-1}+0.7282z^{-2}\right)\left(1-1.5855z^{-1}+1.0838z^{-2}\right)}$$

Note that the choice of T has no effect on the resulting system function. The magnitude response in dB and the phase response are plotted in Fig. 87.16, which satisfies the desired magnitude specification. Note the equiripples in both the passband and the stopband.

High-Pass Filters (HPF's)

As mentioned above, the impulse invariant method is not suitable for high-pass filters, due to aliasing. Therefore, we will only discuss the bilinear transformation. In addition to the procedure used with designing an LPF, we need to transform the analog high-pass specification to analog low-pass specification and transform the resulting analog LPF to analog HPF. There is a simple transformation for this job: replacing s in the analog LPF transfer function with $1/s$. In terms of the frequency, $j\lambda$ becomes $1/j\lambda = j(-1/\lambda)$, i.e., a

© 2003 by CRC Press LLC

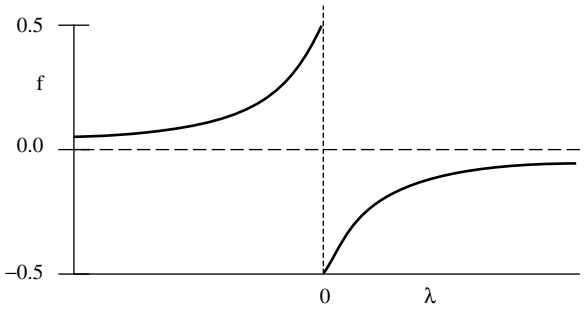

FIGURE 87.17 The relation for designing an HPF.

low frequency is changed to a (negative) high frequency. Therefore, an analog LPF becomes an analog HPF. When combined with the bilinear transformation, this process gives the transformation

$$s = \frac{T}{2}\frac{\left(1+z^{-1}\right)}{\left(1-z^{-1}\right)} \quad \text{or} \quad z = \frac{s+\left(T/2\right)}{s-\left(T/2\right)} \tag{87.58}$$

Writing $s = j\lambda$, we can show that $z = \exp\{j[2\arctan(2\lambda/T) - \pi]\}$. With $z = \exp(j2\pi f)$, we have

$$\lambda = \frac{T}{2}\tan\left[\pi\left(f+0.5\right)\right] \tag{87.59}$$

To write f in terms of λ, we can show that, after adjusting the range of f to $[-1/2, 1/2]$,

$$f = \begin{cases} -\dfrac{1}{2}+\dfrac{1}{\pi}\arctan\left(2\lambda/T\right) & \lambda > 0 \\ \dfrac{1}{2}+\dfrac{1}{\pi}\arctan\left(2\lambda/T\right) & \lambda < 0 \end{cases} \tag{87.60}$$

Equations (87.59) and (87.60) give the relation between the digital frequency and the analog frequency, corresponding to the transformation in (87.58). This relation is plotted in Fig. 87.17, from which we see that a low digital frequency corresponds to a high analog frequency and vice versa.

We can summarize the design steps as follows. Given a digital HPF specification as in Fig. 87.18, it is converted to an analog LPF specification using (87.59) to obtain the passband and stopband edges λ_p and λ_s from f_p and f_s, respectively. With λ_p, λ_s, ε, and δ, we design the low-pass analog prototype filter. Let the transfer function be $H_a(s)$. This transfer function is then converted to digital HPF system function by replacing s with $(T/2)(1 + z^{-1})/(1 - z^{-1})$. Note that this corresponds to the procedure in Fig. 87.13, with the bypass of the "analog specification" block and the "transform to analog filter" block, as indicated by the dotted lines in Fig. 87.13.

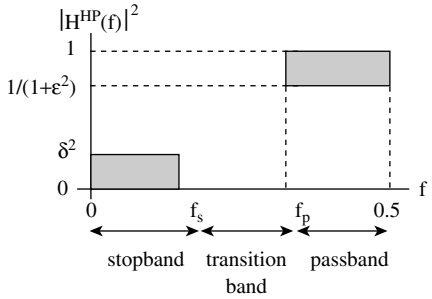

FIGURE 87.18 Digital HPF specification.

© 2003 by CRC Press LLC

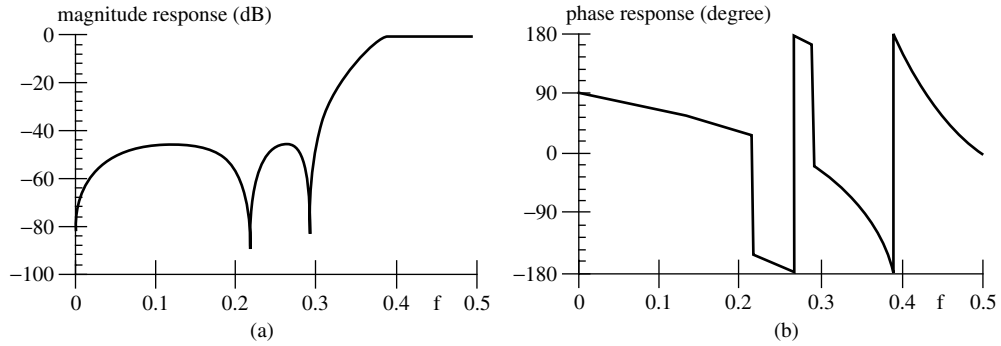

FIGURE 87.19 Frequency response of the HPF designed using bilinear transformation.

As an example, consider designing a digital HPF with the following specification:

$$\left|H^{HP}(f)\right|^2 \geq 0.8 \quad (\text{or} -0.97 \text{ dB}) \quad \text{for } 0.4 \leq f \leq 0.5$$

$$\left|H^{HP}(f)\right|^2 \leq 2.5\times10^{-5} \quad (\text{or} -46.02 \text{ dB}) \quad \text{for } 0 \leq f \leq 0.3$$

which means $\varepsilon = 0.5$, $\delta = 0.005$, $f_p = 0.4$, and $f_s = 0.3$. Since T does not affect the result, we let $T = 2$ for convenience. We calculate the analog LPF passband and stopband edges as $\lambda_p = \tan[\pi(0.5 + f_p)] = -0.3249$ rad/s and $\lambda_s = \tan[\pi(0.5 + f_s)] = -0.7265$ rad/s. Since the magnitude response is symmetry with respect to $\lambda = 0$, we use $\lambda_p = 0.3249$ rad/s and $\lambda_s = 0.7265$ rad/s. Therefore, $\lambda_s/\lambda_p = 2.2361$. Suppose that we choose the inverse Chebyshev filter as the analog prototype filter. From (87.37), we obtain the order $N \geq 4.6$. So, we use $N = 5$. From (87.39), the low-pass analog inverse Chebyshev filter transfer function is

$$H_a(s) = \frac{1.8160\times10^{-2}\left(s^2+0.5835\right)\left(s^2+1.5276\right)}{\left(s+0.4822\right)\left(s^2+0.6772s+0.2018\right)\left(s^2-0.2131s+0.1663\right)}$$

To convert to digital filter system function, we replace s with $(1 + z^{-1})/(1 - z^{-1})$, yielding

$$H^{HP}(z) = \frac{1.8920\times10^{-2}\left(1-z^{-1}\right)\left(1+0.5261z^{-1}+z^{-2}\right)\left(1-0.4175z^{-1}+z^{-2}\right)}{\left(1+0.3493z^{-1}\right)\left(1+0.8496z^{-1}+0.2792z^{-2}\right)\left(1+1.2088z^{-1}+0.6910z^{-2}\right)}$$

The magnitude response and the phase response are plotted in Fig. 87.19.

Bandpass Filters (BPF's)

A magnitude response specification for a digital BPF is depicted in Fig. 87.20(a). Note that there are two passband edges (f_{p1} and f_{p2}) and two stopband edges (f_{s1} and f_{s2}). For the bilinear transformation $s = (2/T)(1 + z^{-1})/(1 + z^{-1})$ we can transform the digital BPF specification to an analog BPF specification by letting

$$\begin{aligned} \lambda_{p1} &= \frac{2}{T}\tan\left(\pi f_{p1}\right) \quad \lambda_{p2} = \frac{2}{T}\tan\left(\pi f_{p2}\right) \\ \lambda_{s1} &= \frac{2}{T}\tan\left(\pi f_{s1}\right) \quad \lambda_{s2} = \frac{2}{T}\tan\left(\pi f_{s2}\right) \end{aligned} \tag{87.61}$$

and keeping the same ε and δ.

© 2003 by CRC Press LLC

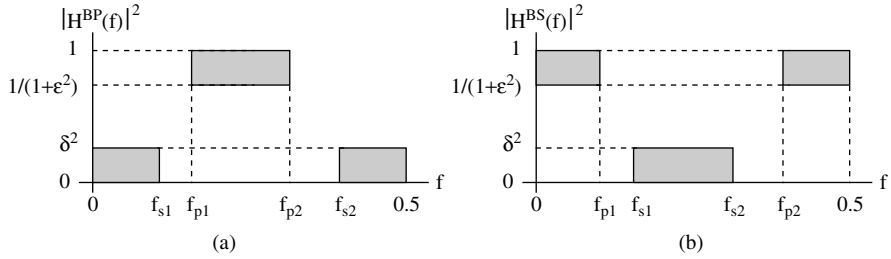

FIGURE 87.20 Magnitude specifications for digital BPF and BSF. (a) Digital BPF specification. (b) Digital BSF specification.

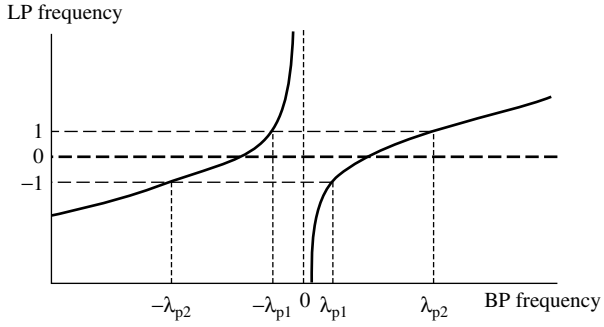

FIGURE 87.21 Relation between λ and λ' for bandpass-to-low-pass conversion.

Now, we need a transformation between an analog BPF and an analog LPF. To distinguish between the variable s and λ for the two filters, let us use s' and λ' for the analog LPF and s and λ for the analog BPF, respectively. A transformation for converting an analog LPF to an analog BPF is given by

$$s' = \frac{s^2 + \lambda_0^2}{Ws} \quad \text{or} \quad \lambda' = \frac{\lambda^2 - \lambda_0^2}{W\lambda} \tag{87.62}$$

where

$$W = \lambda_{p2} - \lambda_{p1} \quad \text{and} \quad \lambda_0^2 = \lambda_{p1}\lambda_{p2} \tag{87.63}$$

Figure 87.21 depicts an example of the relation between λ and λ'. Note that λ_{p1} and λ_{p2} get mapped to $\lambda' = -1$ and $+1$, respectively. Therefore, the analog LPF has a passband edge of 1. The values of λ_{s1} and λ_{s2} get mapped to $\lambda'_{s1} = -|(\lambda_{s1}^2 - \lambda_0^2)/(W\lambda_{s1})|$ and $\lambda'_{s2} = |(\lambda_{s2}^2 - \lambda_0^2)/(W\lambda_{s2})|$. However, these two values may not be negative of each other. Since the analog LPF must have a symmetric magnitude response, we must use the more stringent of the two stopband edges, i.e., the smaller of $|\lambda'_{s1}|$ and $|\lambda'_{s2}|$. Letting

$$\lambda'_s = \min\left\{\left|\lambda'_{s1}\right|, \left|\lambda'_{s2}\right|\right\} = \min\left\{\left|\frac{\lambda_{s1}^2 - \lambda_0^2}{W\lambda_{s1}}\right|, \left|\frac{\lambda_{s2}^2 - \lambda_0^2}{W\lambda_{s2}}\right|\right\} \tag{87.64}$$

we now have the analog LPF specification. Therefore, a prototype analog LPF can be designed.

The design process can be summarized as follows. First, the desired digital BPF magnitude specification is converted to an analog BPF magnitude specification using (87.61). Then the analog BPF specification is converted to an analog LPF specification using λ'_s calculated from (87.64) and $\lambda'_p = 1$. Next, a prototype analog LPF is designed with the values of ε, δ, $\lambda'_p = 1$, and $\lambda'_s = 1$, yielding an analog LPF transfer function

© 2003 by CRC Press LLC

$H_a(s')$. The LPF transfer function is converted to an analog BPF transfer function $H_a^{\mathrm{HP}}(s)$, using the transformation (from s' to s) given in (87.62). Finally, the analog BPF transfer function is converted to a digital BPF transfer function $H^{\mathrm{BP}}(z)$ using the bilinear transformation $s = (2/T)(1 - z^{-1})/(1 + z^{-1})$. As before, the value of T does not affect the result.

For example, let the desired digital BPF have the following specification:

$$\left|H^{\mathrm{BP}}(f)\right|^2 \begin{cases} \geq 0.8 \quad (-0.97\mathrm{dB}) & \text{for } 0.25 \leq f \leq 0.3 \\ \leq 2.5\times10^{-5} \quad (-46.02\mathrm{dB}) & \text{for } 0 \leq f \leq 0.2 \quad \text{and } 0.35 \leq f \leq 0.5 \end{cases}$$

which means $\varepsilon = 0.5$, $\delta = 0.005$, $f_{p1} = 0.25$, $f_{p2} = 0.3$, $f_{s1} = 0.2$, and $f_{s2} = 0.35$. Let $T = 2$ for convenience. Using $\lambda = \tan(\pi f)$, we obtain the analog BPF passband and stopband edges as $\lambda_{p1} = \tan(\pi f_{p1}) = 1.0$ rad/s, $\lambda_{p2} = \tan(\pi f_{p2}) = 1.3764$ rad/s, $\lambda_{s1} = \tan(\pi f_{s1}) = 0.7265$ rad/s, and $\lambda_{s2} = \tan(\pi f_{s2}) = 1.9626$ rad/s. Therefore, $\lambda^2_0 = 1.3764$ and $W = 0.3764$. So, we have $\lambda'_s = \min\{3.1030, 3.3509\} = 3.1030$ rad/s. Suppose that we use the elliptic LPF as an analog prototype filter. With $\varepsilon = 0.5$, $\delta = 0.005$, $\lambda'_p = 1$, and $\lambda'_s = 3.1030$ rad/s, we need an elliptic filter of order $N = 3$. The low-pass analog elliptic filter transfer function is

$$H_a(s') = \frac{4.1129\times10^{-2}\left(s'^2 + 12.6640\right)}{\left(s' + 0.5174\right)\left(s'^2 + 0.4763s' + 1.0067\right)}$$

Replacing s' with $(s^2 + 1.3764)/(0.3764s)$ yields the analog BPF transfer function

$$H_a^{BP}(s) = \frac{1.5480\times10^{-2}s\left(s^4 + 4.5467s^2 + 1.8944\right)}{\left(s^2 + 0.1947s + 1.3764\right)\left(s^4 + 0.1793s^3 + 2.8953s^2 + 0.2467s + 1.8944\right)}$$

Note than an Nth-order LPF become a $2N$th-order BPF. To convert to digital filter system function, we replace s with $(1 - z^{-1})/(1 + z^{-1})$, yielding

$$H^{\mathrm{BP}}(z) = \frac{7.2077\times10^{-3}\left(1 - z^{-2}\right)\left(1 + 0.4807z^{-1} + 1.1117z^{-2} + 0.4807z^{-3} + z^{-4}\right)}{\left(1 + 0.2928z^{-1} + 0.8485z^{-2}\right)\left(1 + 0.5973z^{-1} + 1.8623z^{-2} + 0.5539z^{-3} + 0.8629z^{-4}\right)}$$

The magnitude and phase responses are plotted in Fig. 87.22.

Note that for the transformation in (87.62), we can also let $W = \lambda_{s2} - \lambda_{s1}$ and $\lambda_0^2 = \lambda_{s1}\lambda_{s2}$, instead of (87.63). Such a choice will give $\lambda'_s = 1$. The passband edge for the prototype LPF is now calculated from $\lambda'_p = \min\{|(\lambda_{p1}^2 - \lambda_0^2)/(W\lambda_{p1})|, |(\lambda_{p2}^2 - \lambda_0^2)/(W\lambda_{p2})|\}$.

Bandstop Filters (BSF's)

A digital BSF specification is depicted in Fig. 87.20(b). As in the case of BPF there are two passband edges (f_{p1} and f_{p2}) and two stopband edges (f_{s1} and f_{s2}). A transformation from analog BSF to analog LPF is given by

$$s' = \frac{Ws}{s^2 + \lambda_0^2} \text{ or } \lambda' = \frac{W\lambda}{\lambda_0^2 - \lambda^2} \tag{87.65}$$

where W and λ^2_0 are given by (87.63). Note that the expression for s in (87.65) is the reciprocal of that in (87.62). The relation between the LPF frequency λ' and the BSF frequency λ is depicted in Fig. 87.23.

© 2003 by CRC Press LLC

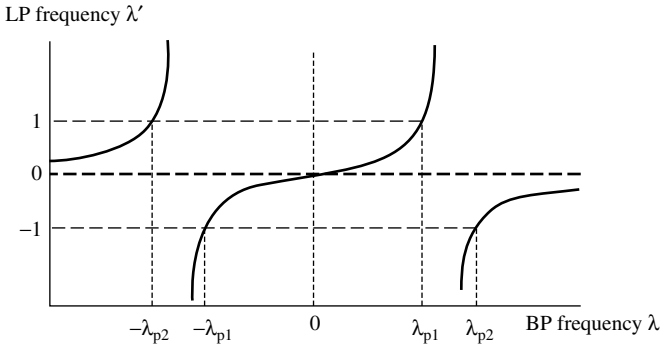

FIGURE 87.23 Relation between λ and λ′ for bandstop-to-low-pass conversion.

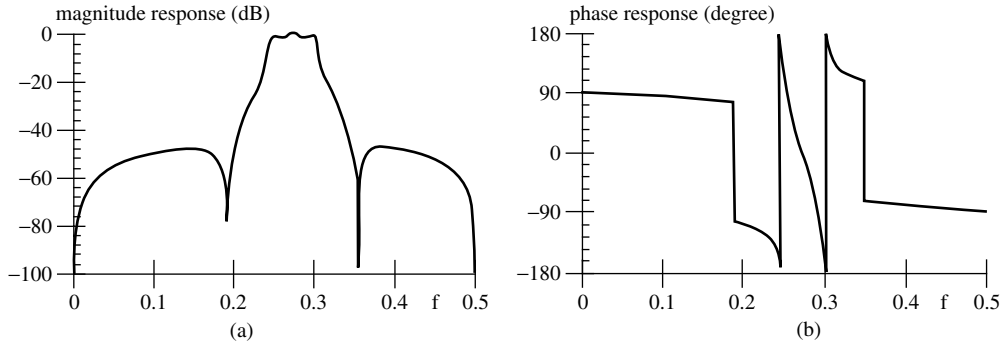

FIGURE 87.22 Frequency response of the designed digital BPF.

The passband edges λ_{p1}, and λ_{p2} get mapped to $\lambda' = 1$ and –1, respectively. The values of λ_{s1} and λ_{s2} get mapped to $\lambda'_{s1} = |W\lambda_{s1}/(\lambda^2_0 - \lambda^2_{s1})|$ and $\lambda'_{s2} = -|W\lambda_{s2}/(\lambda^2_0 - \lambda^2_{s2})|$. Therefore, the passband edge and stopband edge of the prototype analog LPF are 1 and λ'_s, respectively, where

$$\lambda'_s = \min\left\{|\lambda'_{s1}|,\ |\lambda'_{s2}|\right\} = \min\left\{\left|\frac{W\lambda_{s1}}{\lambda_0^2 - \lambda_{s1}^2}\right|,\ \left|\frac{W\lambda_{s2}}{\lambda_0^2 - \lambda_{s2}^2}\right|\right\} \tag{87.66}$$

The design process for the BSF can follow the same process as the design for the BPF, except that we use (87.65) and (87.66) instead of (87.62) and (87.64).

Similar to case of the BPF, we can also let $W = \lambda_{s2} - \lambda_{s1}$ and $\lambda_0^2 = \lambda_{s1}\lambda_{s2}$, instead of (87.63), for the transformation in (87.65). The stopband edge and the passband edge for the prototype LPF are now $\lambda'_s = 1$ and $\lambda'_p = \min\{|W\lambda_{p1}/(\lambda^2_{p1} - \lambda^2_0|, |W\lambda_{p2}/(\lambda^2_{p2} - \lambda^2_0)|\}$.

Design Using Digital Frequency Transformations

This method assumes that we can design a digital LPF. The desired filter is then obtained from the digital LPF by transforming the digital LPF in the z domain. Let us denote the z variable for the digital LPF by z' and that for the desired digital filter by z. Similarly, we use f' for the digital frequency of the digital LPF and f for the frequency of the desired digital filter. Suppose that the digital LPF has system function $H(z')$ and the desired digital filter has system function $H^x(z)$, where x stands for LP, HP, BP, or BS. The system function $H^x(z)$ is obtained from $H(z')$ by replacing z' with an appropriate function of z. The LPF $H(z')$ can be designed using the method discussed in the subsection on design using analog prototype filters, or by some other means. The specification for the digital LPF is obtained from the specification

© 2003 by CRC Press LLC

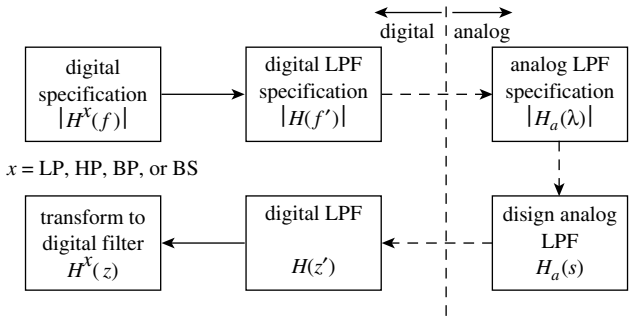

FIGURE 87.24 Design process using digital frequency transformation.

of the desired digital filter through the relation between f' and f. The relation depends on the specific transformation. Note that the difference between the method in this subsection and the method described previously is that the transformation between the desired type of filter and the LPF is in the digital domain (the z domain) for the current method, whereas it is in the analog domain (the s domain) in the previous method. Figure 87.24 shows the design process using digital frequency transformation. The advantage of the current method is that in designing a desired digital HPF, BPF, or BSF, we design a digital LPF, which can make use of the impulse invariant method, in addition to the bilinear transformation. This is not the case for the method discussed previously, due to excessive aliasing.

Low-Pass Filters

We can transform a digital LPF to a digital LPF using the transformation

$$z' = \frac{z+\alpha}{1+\alpha z} \qquad |\alpha| < 1 \tag{87.67}$$

With $z = \exp(j2\pi f)$ and $z' = \exp(j2\pi f')$, we can show that the two digital frequencies are related by

$$f' = \frac{1}{2\pi}\arctan\left[\frac{(1-\alpha^2)\sin 2\pi f}{2\alpha + (1+\alpha^2)\cos 2\pi f}\right] \tag{87.68}$$

The relation (87.68) is plotted in Fig. 87.25(a). If $\alpha = 0$, then $z' = z$ and $f' = f$, which is the trivial case. When $\alpha \neq 0$, there is frequency warping introduced by the transformation. After choosing α, we can transform the desired digital LPF specification to another digital LPF specification, i.e., calculate f_p' and f_s' from f_p and f_s. With f_p, f_s, ε, and δ, a digital LPF can then be designed to satisfy the specification. The resulting system function is then transformed to the desired LPF using (87.67). This method may yield a filter of lower or higher order (due to the frequency warping) compared to the case in which there is no digital frequency transformation ($\alpha = 0$).

As an alternative to specifying α, we can specify f_p', which, together with f_p, specifies the value of α, according to (87.68). With the value of α, we can calculate f_s' from f_s. We can also exchange the role of the passband edge with the stopband edge, i.e., we specify f_s' and compute α from the values of f_s' and f_s. With α, f_p' can be determined from f_p.

High-Pass Filters

To transform a digital LPF to a digital HPF, we can use the transformation

$$z' = -\frac{z+\alpha}{1+\alpha z} \quad |\alpha| < 1 \tag{87.69}$$

© 2003 by CRC Press LLC

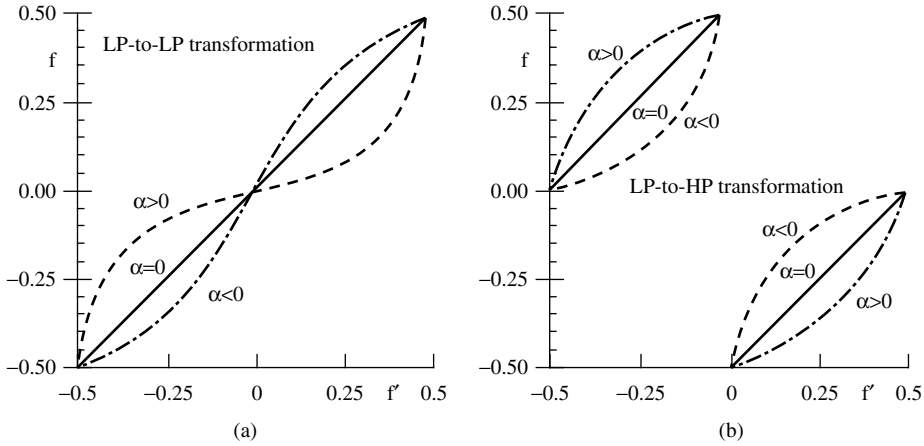

FIGURE 87.25 Frequency relation for digital frequency transformations: (a) low-pass to low-pass; (b) low-pass to high-pass.

Substituting $z = \exp(j2\pi f)$ and $z' = \exp(j2\pi f')$, we obtain the relation between the two digital frequencies:

$$f' = \frac{1}{2\pi}\arctan\left[\frac{-\left(1-\alpha^2\right)\sin 2\pi f}{-2\alpha-\left(1+\alpha^2\right)\cos 2\pi f}\right] \tag{87.70}$$

This relation is plotted in Fig. 87.25(b). If $\alpha = 0$, then $z' = -z$ and $f' = f + \pi$. The design process proceeds as follows. After choosing the value of α, the desired digital HPF specification is transformed to the digital LPF specification, using the relation in (87.70). Using the resulting values of f_s', f_p', together with the ripple specifications (ε and δ), a digital LPF is designed to satisfy the specification. The resulting LPF system function $H(z')$ is then transformed to the desired HPF by substituting z' with $-(z + \alpha)/(1 + \alpha z)$, given by (87.69). Similar to the case of the LPF, we can specify f_p' (instead of α) and calculate the required value of α from f_p' and f_p.

Bandpass Filters

To transform a digital LPF to a digital HPF, we can use the transformation

$$z' = -\frac{1+\dfrac{2\alpha k}{k+1}z+\dfrac{k-1}{k+1}z^2}{\dfrac{k-1}{k+1}+\dfrac{2\alpha k}{k+1}z+z^2} \quad |\alpha|<1, \quad k>0 \tag{87.71}$$

This implies the following relation between the two digital frequencies:

$$f' = \frac{1}{2\pi}\arctan\left[\frac{(1-b)\left\{2a\sin 2\pi f+(1+b)\sin 4\pi f\right\}}{-a^2-2b-2a(1+b)\cos 2\pi f-\left(b^2+1\right)\cos 4\pi f}\right] \tag{87.72}$$

where $a = 2\alpha k/(k + 1)$ and $b = (k - 1)/(k + 1)$. An example of (87.72) is plotted in Fig. 87.26. If $\alpha = 0$, the curve would be odd symmetric with respect to $f = 0.25$. The design process is similar to the case of the HPF, except that there are now two passband edges, f_{p1}' and $|f_{p2}'|$, and two stopband edges, f_{s1}' and $|f_{s2}'|$, for the digital LPF to satisfy (see Fig. 87.26). To satisfy both sets, we let $f_p' = \max\{f_{p1}', |f_{p2}'|\}$ and $f_s' = \min\{f_{s1}', |f_{s2}'|\}$ be the passband and stopband edges for the digital LPF filter.

© 2003 by CRC Press LLC

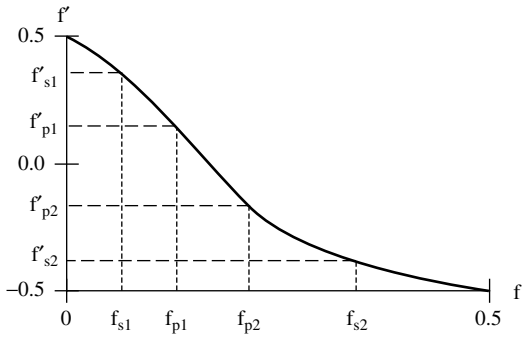

FIGURE 87.26 Frequency relation for PB to LP digital frequency transformation.

If we specify f_p', then together with f_{p1} and f_{p2} they determine the values of α and k:

$$\alpha = \frac{\cos\left[\pi\left(f_{p2} + f_{p1}\right)\right]}{\cos\left[\pi\left(f_{p2} - f_{p1}\right)\right]} \qquad k = \cot\left[\pi\left(f_{p2} - f_{p1}\right)\right]\tan\left(\pi f_p'\right) \tag{87.73}$$

With the value of α and k, we calculate the values of f_{s1}' and f_{s2}' from (87.72) and let $f_s' = \min\{f_{s1}', |f_{s2}'|\}$. Thus we have f_p', f_s', ε, and δ as the digital LPF specification. After a digital LPF is designed to satisfy this specification, it is converted to digital BPF by the transformation in (87.71).

Bandstop Filters

To transform a digital LPF to a digital BSF, we can use

$$z' = \frac{1 + \dfrac{2\alpha k}{k+1}z + \dfrac{k-1}{k+1}z^2}{\dfrac{k-1}{k+1} + \dfrac{2\alpha k}{k+1}z + z^2} \quad |\alpha| < 1, \quad k > 0 \tag{87.74}$$

The corresponding relation between the two digital frequencies is

$$f' = \frac{1}{2\pi}\arctan\left[\frac{-(1-b)\left\{2a\sin 2\pi f + (1+b)\sin 4\pi f\right\}}{a^2 + 2b + 2a(1+b)\cos 2\pi f + \left(b^2+1\right)\cos 4\pi f}\right] \tag{87.75}$$

where $a = 2\alpha k/(k+1)$ and $b = (k-1)/(k+1)$. An example is plotted in Fig. 87.27. The design process is the same as described in the subsection on bandpass filters.

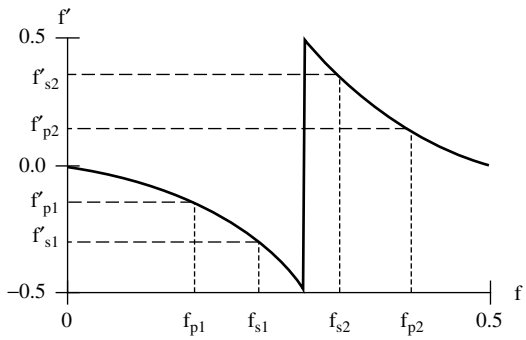

FIGURE 87.27 Frequency relation for BS to LP digital frequency transformation.

© 2003 by CRC Press LLC

When f_p' is specified, together with f_{p1} and f_{p2}, the values of α and k can be calculated from

$$\alpha = \frac{\cos\left[\pi\left(f_{p2} + f_{p1}\right)\right]}{\cos\left[\pi\left(f_{p2} - f_{p1}\right)\right]} \quad k = \tan\left[\pi\left(f_{p2} - f_{p1}\right)\right]\tan\left(\pi f_p'\right) \tag{87.76}$$

With these values, we can calculate the values of f_{s1}' and f_{s2}' from (87.75). Letting $f_s' = \min\{f_{s1}', |f_{s2}'|\}$, we now have f_p', f_s', ε, and δ, which constitute the digital LPF specification. A digital LPF is then designed and converted to digital BSF by the transformation in (87.74).

Computer-Aided Designs

The general idea is to use an algorithm to search for a set of coefficients such that the resulting response (magnitude and/or phase) is "close" to the desired response. The "closeness" is in some well-defined sense. The advantage of such a method is that it can be used to design nonstandard filters, such as multiband filters, phase equalizers, differentiators, etc. However, it requires a computer program to execute the algorithm. In addition, it usually cannot directly determine the order N such that the passband and stopband ripples are within the desired ranges. The order is usually determined through several trials.

Let us put the IIR system function in the form

$$H(z) = b_0 \prod_{i=1}^{K} \frac{1 + b_{i1}z^{-1} + b_{i2}z^{-2}}{1 + a_{i1}z^{-1} + a_{i2}z^{-2}} = \frac{N(z)}{D(z)} \tag{87.77}$$

The constant b_0 is included in the numerator $N(z)$. The design problem involves choosing $4K + 1$ coefficients: (b_0, b_{11}, b_{12}, a_{11}, a_{12}, …, b_{K1}, b_{K2}, a_{K1}, a_{K2}), which will be denoted by the vector $\boldsymbol{\gamma}$.

The frequency response is written in terms of the magnitude response and phase response as

$$H(f) = \frac{N(f)}{D(f)} = A(f)e^{j\theta(f)} \tag{87.78}$$

where $A(f) = |H(f)|$ is the magnitude response and $\theta(f) = \arctan\{\text{Imag}[H(f)]/\text{Real}[H(f)]\}$ is the phase response. The group delay is

$$\tau(f) = -\frac{1}{2\pi}\frac{d}{df}\theta(f) \tag{87.79}$$

Suppose that the desired frequency response is given by

$$H_d(f) = \frac{N_d(f)}{D_d(f)} = A_d(f)e^{j\theta_d(f)} \tag{87.80}$$

with $\tau_d(f)$ being the group delay. As mentioned above, $H_d(f)$ does not have to be one of the standard filters.

Our objective is to choose the coefficients $\boldsymbol{\gamma}$ so that the resulting filter response is close to the desired response. The closeness may be defined over the whole frequency band $0 \le f \le 0.5$, or only over certain frequency bands. For example, if some frequency bands are designated as transition bands, then they are not included in the computation of the closeness. To use computer algorithms, we sample the response at discrete frequencies, say at L frequencies: $0 \le f_1, \cdots, f_L \le 0.5$. These frequencies must be sufficiently dense over the frequency bands that the closeness is computed. To accommodate different levels of ripples in various frequency bands, we also include a weighting function $W(f_i)$, $1 \le i \le L$, in the computation of the closeness.

© 2003 by CRC Press LLC

A suitable measure for the closeness is through the pth error, defined as

$$E(\mathbf{f},\boldsymbol{\gamma}) = \left[\sum_{i=1}^{L} W(f_i)\left|H_d(f_i) - H(f_i)\right|^p\right]^{1/p} \tag{87.81}$$

where $\mathbf{f}$ is the vector representing $(f_1, \ldots, f_L)$. If only the magnitude is of interest, then the error is

$$E_A(\mathbf{f},\boldsymbol{\gamma}) = \left[\sum_{i=1}^{L} W(f_i)\left|A_d(f_i) - A(f_i)\right|^p\right]^{1/p} \tag{87.82}$$

and if only the group delay is of interest the error is

$$E_\tau(\mathbf{f},\boldsymbol{\gamma}) = \left[\sum_{i=1}^{L} W(f_i)\left|\tau_d(f_i) - \tau(f_i)\right|^p\right]^{1/p} \tag{87.83}$$

The magnitude error and the group delay error can also be linearly combined as

$$E_c(\mathbf{f},\boldsymbol{\gamma}) = \beta E_A(\mathbf{f},\boldsymbol{\gamma}) + (1-\beta)E_\tau(\mathbf{f},\boldsymbol{\gamma}) \quad 0 \le \beta \le 1 \tag{87.84}$$

Given the weighting function, we seek the set of coefficients $\boldsymbol{\gamma}$ that minimizes one of the errors in (87.81)–(87.84). When $p = 1$, the error is the weighted absolute error and the minimization yields the minimum absolute error solution. When $p = 2$, the error is the weighted root-mean-square error and the solution is the minimum weighted root-mean-square error. When $p \to \infty$, the largest error dominates. Consequently, the pth error is the maximum over $1 \le i \le L$ of the weighted error. For example, (87.81) becomes

$$E(\mathbf{f},\boldsymbol{\gamma}) = \max_{1\le i\le L} W(f_i)\left|H_d(f_i) - H(f_i)\right| \tag{87.85}$$

Minimizing E($\mathbf{f}$, $\boldsymbol{\gamma}$) yields the minimax solution. A minimax solution gives equiripples in each of the bands having equal weighting function inside the band.

There are algorithms for obtaining the solutions that minimize the above errors; we do not present them here. For detail see the references. Several programs have been published previously in [3].

87.3 Wave Digital Filters

Stuart S. Lawson

Introduction

The wave digital filter (WDF) belongs to the sub-class of digital filters that are derived from suitable analog networks by the application of the bilinear transformation. However, they differ from most other methods that use the bilinear transformation because the design technique aims to preserve desirable attributes in the original analog reference network. This is achieved by using a scattering parameter formulation that can be viewed as a linear transformation on the voltages and currents to yield wave variables, which will be used in the final wave digital filter. In this section, we will see how the wave digital equivalents of well known analog components such as resistors, inductors, capacitors, and unit elements are derived. More importantly, the design process will be explained in detail with many examples to illustrate its use.

The desirable attributes we mentioned above relate to the low sensitivity to element variations in the case of double-terminated lossless analog filters. Sensitivity in digital filters is not quite the same as it is in analog filters, but normally we can say that low sensitivity implies low coefficient quantization error and in certain circumstances low roundoff noise. These analog filters can be designed so that, at frequencies of minimum loss, the source will deliver maximum power into the load. At these points of maximum available power transfer (MAP), the derivative of the loss with respect to any reactive component is zero. Although the number of MAP points in the filter's passband is finite, we can be fairly certain that at other passband frequencies, the attenuation sensitivity will be small. This can be achieved for the classical filter approximations, e.g., Chebyshev, Butterworth, elliptic, etc. This property has led to the replacement of bulky inductors by gyrators and to the concept of the frequency-dependent negative resistance. Effectively, the inductor is being simulated by active circuit elements such as operational amplifiers. The technique has been extended to the design of switched capacitor filters as well.

Similarly, we can design digital filters that are modeled on the behavior of lossless analog networks. The approach we take consists of representing the behavior of the analog components in the filter by wave variables. The analog filters, henceforth known as **reference** filters, that will be of use to us are as follows:

1. Double-terminated lossless ladder network
2. Double-terminated lossless lattice network
3. Double-terminated lossless transmission-line network

To derive a WDF there are two main design approaches which both lead to the same type of structure. We will call the first approach the **one-port approach** as it treats resistors, inductors, and capacitors as one-ports and derives their digital equivalents. Interconnection is provided by **adaptors,** which are digital representations of series and parallel junctions. In the **two-port approach**, all components are treated as two-ports and interconnection can be performed directly without the use of adaptors. However, there are special arrangements for the terminations.

© 2003 by CRC Press LLC

Wave Digital Filter Principles

The first stage in transforming an analog network into wave digital form is to represent the circuit equations in terms of wave variables. For an n-port circuit element, the transformation from voltage and current, V_k and I_k, to wave variables, A_k, B_k, $k = 1, \ldots, n$ is as follows:

$$\begin{bmatrix} A_k \\ B_k \end{bmatrix} = \begin{bmatrix} 1 & R_k \\ 1 & -R_k \end{bmatrix} \begin{bmatrix} V_k \\ I_k \end{bmatrix} \tag{87.86}$$

where R_k is the **port resistance** at port k and is a free parameter whose value will be set to avoid delay-free loops. A_k, B_k are known, respectively, as the incident and reflected wave at port k from the analogy with scattering parameter theory. This transformation is known as the voltage wave formulation because A_k, B_k have the dimensions of volts. It is clear that the transformation from voltage and current to voltage waves is linear.

For a given one-port circuit element ($n = 1$), the voltage-current relationship is known and is of the form $V = IZ$ for an impedance Z. Thus, if we eliminate V and I using (87.86) we find that

$$\frac{B}{A} = \frac{Z - R}{Z + R} \tag{87.87}$$

Equation (87.87) defines the reflection coefficient S for the impedance Z. Thus, $B = SA$ and we can think of A as input, B as output, and S as the transfer function.

The behavior of a passive two-port (Fig. 87.28) can be described by ABCD parameters in the form

$$\begin{bmatrix} V_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} V_2 \\ I_2 \end{bmatrix} \tag{87.88}$$

where both currents I_1 and I_2 flow into the network and B and D will subsequently have different signs than usual. Our convention makes the algebra a little easier when cascading two-ports. The 2×2 matrix of (87.88) will be referred to as a *modified* ABCD matrix.

The voltages and currents in (87.86) and (87.88) can be eliminated to obtain the following:

$$\begin{bmatrix} A_1 \\ B_1 \end{bmatrix} = \begin{bmatrix} \alpha & \beta \\ \gamma & \delta \end{bmatrix} \begin{bmatrix} A_2 \\ B_2 \end{bmatrix} \tag{87.89}$$

where

$$\alpha = \tfrac{1}{2}\left(A + CR_1 + BG_2 + DR_1G_2\right)$$

$$\beta = \tfrac{1}{2}\left(A + CR_1 - BG_2 - DR_1G_2\right)$$

$$\gamma = \tfrac{1}{2}\left(A - CR_1 + BG_2 - DR_1G_2\right)$$

$$\delta = \tfrac{1}{2}\left(A - CR_1 - BG_2 + DR_1G_2\right)$$

and $G_2 = 1/R_2$.

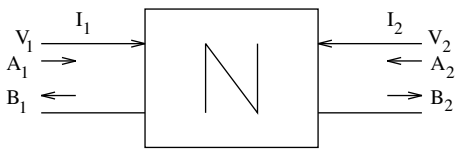

FIGURE 87.28 Passive two-port network.

© 2003 by CRC Press LLC

In a similar way to the one-port case we are interested in obtaining the relationship

$$\underline{B} = \mathbf{S}\underline{A} \tag{87.90}$$

but now **S** is a 2×2 scattering matrix and $\underline{A}$, $\underline{B}$ are the 2-element input and output vectors, respectively. The elements of **S** can be derived from (87.89) and are as follows:

$$\left.\begin{aligned} S_{11} &= \delta/\beta \\ S_{12} &= -\Delta/\beta \\ S_{21} &= 1/\beta \\ S_{22} &= -\alpha/\beta \end{aligned}\right\} \tag{87.91}$$

where

$$\Delta = \begin{vmatrix} \alpha & \beta \\ \gamma & \delta \end{vmatrix} = -R_1 G_2$$

The *signal-flow graph* (SFG) of a general WDF two-port is shown in Fig. 87.29 using the scattering parameter representation of (87.90). Cascading two-ports together, it is clear that loops will be formed due to the terms S_{11} and S_{22}. These loops cause problems only if they are delay free and so it is necessary to ensure that either the transfer function for S_{11} or S_{22} has a factor of z^{-1}. This leads to two possibilities when deriving SFGs for two-ports.

An important and useful side effect of using wave variables is that the resulting WDF network has two inputs and two outputs. With reference to Fig. 87.29, normally A_2 is set to zero, the two outputs are then related by $|B_1|^2 + |B_2|^2 = 1$ so that if B_1 is the lowpass filtered version of A_1, then B_2 is the highpass filtered version, etc.

Building Blocks

One-Ports

For an Inductor, $V = (sL)I$ and on using (87.87) with $R = L$, we find that

$$\frac{B}{A} = \frac{s-1}{s+1} \tag{87.92}$$

and, on applying the bilinear transformation, we get simply that

$$B = -z^{-1}A \tag{87.93}$$

The SFG or *wave-flow diagram* (WFD) of (87.93) is shown in Fig. 87.30. Thus for an inductor, the WFD is nothing more than a delay and sign inversion. However, the consequences of setting $R = L$ will be felt later when we wish to interconnect components.

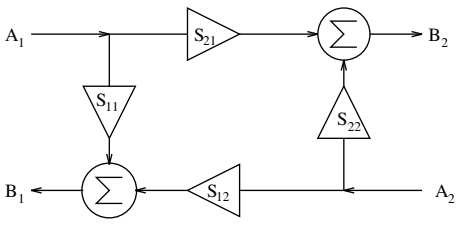

FIGURE 87.29 Signal-flow graph of general WDF two-port.

© 2003 by CRC Press LLC

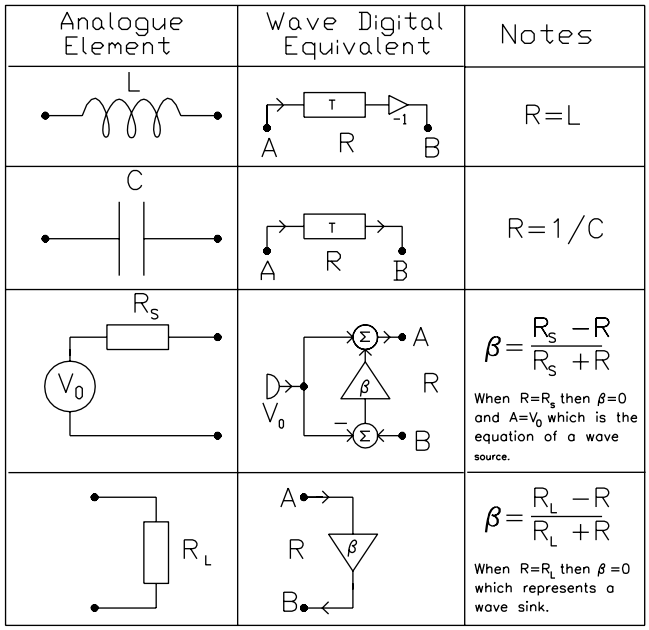

FIGURE 87.30 Wave-flow diagrams (WFD) of basic one-port circuit elements.

Using a similar technique, the WFD's for other two-terminal devices can be easily derived. The most useful ones are summarized in Fig. 87.30.

Two-Ports

Introduction. In this subsection we look at the WFD's of series inductors and shunt capacitances treated as two-ports. With these two, we are able to derive straightforwardly the WFD's of other two ports required in modeling double-terminated lossless ladder networks. It turns out that for each case, series L or shunt C, there are two WFD's corresponding to whether S_{11} or S_{22} has a delay-free path.

Series Inductor. The modified ABCD matrix of a series inductor is given by

$$\begin{bmatrix} 1 & -sL \\ 0 & -1 \end{bmatrix} \tag{87.94}$$

The elements of the scattering matrix, **S** are

$$\left.\begin{aligned} S_{11} &= \frac{R_2 - R_1 + sL}{R_2 + R_1 + sL} \\ S_{12} &= \frac{2R_1}{R_2 + R_1 + sL} \\ S_{21} &= \frac{2R_2}{R_2 + R_1 + sL} \\ S_{22} &= \frac{R_1 - R_2 + sL}{R_2 + R_1 + sL} \end{aligned}\right\} \tag{87.95}$$

subject to the following constraints:

© 2003 by CRC Press LLC

$$\left.\begin{aligned} S_{11} + S_{12} &= 1 \\ S_{21} + S_{22} &= 1 \end{aligned}\right\} \tag{87.96}$$

Combining (87.90) and (87.95) gives

$$\left.\begin{aligned} B_1 &= S_{11}\left(A_1 - A_2\right) + A_2 \\ B_2 &= S_{22}(A_2 - A_1) + A_1 \end{aligned}\right\} \tag{87.97}$$

Thus, we need only realize S_{11} and S_{22} to define the series inductance. Finally, if we now apply the bilinear transformation to the equations for S_{11} and S_{22} we find that, after simplification,

$$S_{11} = \frac{\alpha_1 + \alpha_3 z^{-1}}{1 + \alpha_2 z^{-1}} \tag{87.98}$$

and

$$S_{22} = -\frac{\alpha_3 + \alpha_1 z^{-1}}{1 + \alpha_2 z^{-1}} \tag{87.99}$$

where

$$\alpha_1 = \frac{R_2 - R_1 + L}{R_2 + R_1 + L}$$

$$\alpha_2 = \frac{R_2 + R_1 - L}{R_2 + R_1 + L}$$

$$\alpha_3 = \frac{R_2 - R_1 - L}{R_2 + R_1 + L}$$

In addition, a linear constraint exists between these multiplier constants,

$$\alpha_1 + \alpha_2 = 1 + \alpha_3$$

which will enable us to reduce their number to two. To avoid delay-free loops on interconnection, using the arguments of the previous section, either α_1 or α_3 must be zero. This gives rise to two possible WFD's.

For the first case, let $\alpha_1 = 0$ then $R_1 = R_2 + L$ and

$$S_{11} = \frac{\alpha_3 z^{-1}}{1 + \alpha_2 z^{-1}} \tag{87.100}$$

and

$$S_{22} = -\frac{\alpha_3}{1 + \alpha_2 z^{-1}} \tag{87.101}$$

and

$$\alpha_2 = 1 + \alpha_3 = R_2 / R_1 \tag{87.102}$$

It is important to note that (i) there is now only one independent multiplier constant, (ii) port 1 resistance is dependent on the value of the inductor and port 2 resistance, and (iii) $S_{11} = -S_{22} z^{-1}$.

© 2003 by CRC Press LLC

Finally, the WFD of the series inductor can be found by combining (87.97), (87.100), (87.101), and (87.102). It is canonic in delay and multipliers.

For the second case, let $\alpha_3 = 0$ then $R_2 = R_1 + L$ and

$$S_{11} = \frac{\alpha_1}{1+\alpha_2 z^{-1}} \tag{87.103}$$

and

$$S_{22} = -\frac{\alpha_1 z^{-1}}{1+\alpha_2 z^{-1}} \tag{87.104}$$

and

$$\alpha_2 = 1-\alpha_1 = R_1/R_2 \tag{87.105}$$

Again, it is important to note that (i) there is now only one independent multiplier constant, (ii) port 2 resistance is dependent on the value of the inductor and port 1 resistance, and (iii) $S_{22} = -S_{11}z^{-1}$.

Finally, the WFD of the series inductor can be found by combining (87.97), (87.103), (87.104), and (87.105). It is also canonic in delay and multipliers.

Shunt Capacitor. For a shunt capacitor of value C farads, the WFD equations are as follows

$$\left.\begin{aligned} B_1 &= \left(S_{11}A_1 + S_{22}A_2\right) + A_2 \\ B_2 &= \left(S_{11}A_1 + S_{22}A_2\right) + A_1 \end{aligned}\right\} \tag{87.106}$$

As in the series inductor case, there are two situations to consider, either $\alpha_1 = 0$ or $\alpha_3 = 0$. If $\alpha_1 = 0$, then

$$G_1 = G_2 + C \tag{87.107}$$

$$S_{22} = \frac{-\alpha_3}{1+\alpha_2 z^{-1}} \tag{87.108}$$

$$S_{11} = -S_{22}z^{-1} \tag{87.109}$$

$$\alpha_2 = 1-\alpha_3 = G_2/G_1 \tag{87.110}$$

and if $\alpha_3 = 0$ then,

$$G_2 = G_1 + C \tag{87.111}$$

$$S_{11} = \frac{\alpha_1}{1+\alpha_2 z^{-1}} \tag{87.112}$$

$$S_{22} = -S_{11}z^{-1} \tag{87.113}$$

$$\alpha_2 = 1+\alpha_1 = G_1/G_2 \tag{87.114}$$

The signal flow graphs of the series inductor and shunt capacitance for each of the two cases are to be found in Figs. 87.31 and 87.32, respectively.

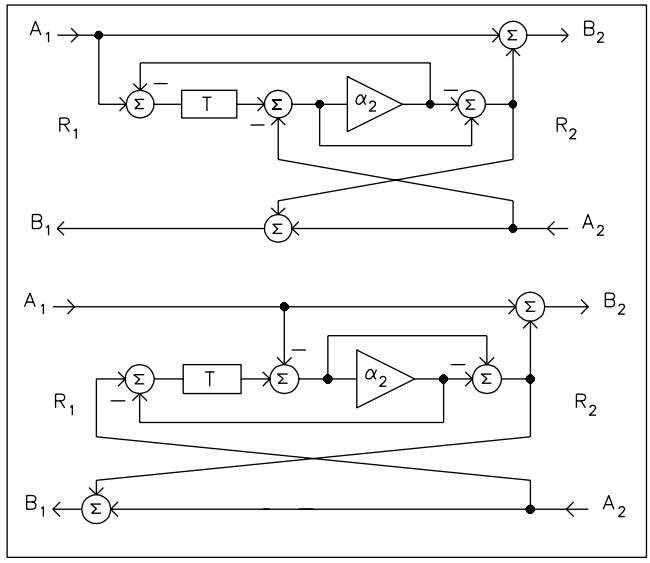

FIGURE 87.32 WFD's for shunt capacitor (a) $\alpha_1 = 0$, (b) $\alpha_3 = 0$.

The Unit Element. The modified ABCD matrix of a lossless transmission line (unit element) is

$$\begin{bmatrix} \cos\theta & -jZ_0 \sin\theta \\ jY_0 \sin\theta & -\cos\theta \end{bmatrix} \tag{87.115}$$

where Z_0 is the characteristic impedance of the line and $Y_0 = 1/Z_0$. Also $\theta = k\Omega$ where k is the line constant and Ω is the angular frequency.

© 2003 by CRC Press LLC

On substituting for A, B, C, and D from (87.115) into (87.89) and (87.91), setting $R_1 = R_2 = Z_0$ and applying the bilinear transform, we find that

$$\left.\begin{aligned} S_{11} &= 0 \\ S_{12} &= z^{-1/2} \\ S_{21} &= z^{-1/2} \\ S_{22} &= 0 \end{aligned}\right\} \tag{87.116}$$

Thus the WFD of a unit element is a half unit delay path from port 1 to port 2 and the same from port 2 to port 1. The delays may be combined into either path to form a unit delay. The effect on the overall transfer function is a linear phase shift.

Building Blocks for Other Series and Shunt Elements. The WFD's of other network elements, e.g., a series-tuned circuit in the shunt-arm or a series capacitance can be obtained by simple transformations on the WFD's of a series inductor or shunt capacitor.

As an example consider the series-tuned circuit in the shunt arm, the impedance Z of which is given by

$$Z = sL + 1/sC \tag{87.117}$$

Applying the bilinear transformation we find that

$$Z = (D + L)\left(\frac{1+\mathcal{T}}{1-\mathcal{T}}\right) \tag{87.118}$$

where

$$\mathcal{T} = \frac{z^{-1}(\beta + z^{-1})}{(1+\beta z^{-1})},\ D = 1/C \text{ and } \beta = (D-L)/(D+L)$$

By comparing this result with that for a shunt capacitance, i.e.,

$$Z = \frac{1}{sC} = \frac{(1+z^{-1})}{(1-z^{-1})C} \tag{87.119}$$

then to obtain the two-port WFD of a series-tuned circuit in the shunt arm from a shunt capacitance, z^{-1} must be replaced by $\mathcal{T}$ and C by $1/(D + L)$. The transformation just discussed together with those for other useful circuit elements are found in Table 87.2. Note that $\mathcal{T}$ is an allpass function, its WFD is shown in Fig. 87.33.

Interconnections

Interconnecting One-Ports and Two-Ports. In the one-port approach, the port resistance of each inductor and capacitor in an LC ladder had been set equal to the corresponding component value. This led to very simple WFD's for these components. To interconnect components with different port resistances, a building block known as an **adaptor** is required. An adaptor is an n-port device in general and its equations are derived by applying Kirchhoff's current and voltage laws at an electrical junction, yielding serial or parallel versions. For most filters of interest, only two- and three-port adaptors are required.

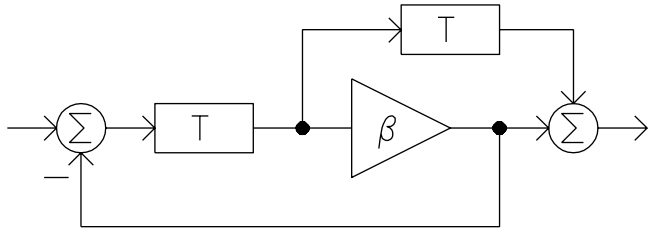

FIGURE 87.33 WFD of series-tuned circuit in shunt arm.

The equations of a three-port parallel adaptor, which has three inputs and three outputs, are as follows:

$$B_k = A_0 - A_k \tag{87.120}$$

where

$$A_0 = \sum_{k=1}^{3} \beta_k A_k,$$

$$\beta_k = \frac{2G_k}{(G_1 + G_2 + G_3)} \quad \text{and}$$

$$G_k = 1/R_k$$

Also $\sum_{k=1}^{3} \beta_k = 2$ so that one multiplier may be eliminated. For interconnection purposes, it is necessary to ensure that at least one port is *reflection-free*, i.e., there is no path from input to output of that port so as to avoid possible delay-free loops. For example, if we wished port 2 to be reflection-free then we would set $\beta_2 = 1$. In this case, the number of independent multipliers drops to one. Furthermore, we have $G_2 = G_1 + G_3$. The WFD of the three-port parallel adaptor with port 2 reflection-free and its symbol are shown in Fig. 87.34.

The corresponding equations for a three-port series adaptor are:

$$B_k = A_k - \beta_k A_0 \tag{87.121}$$

where

$$A_0 = \sum_{k=1}^{3} A_k \quad \text{and}$$

$$\beta_k = \frac{2R_k}{(R_1 + R_2 + R_3)}$$

© 2003 by CRC Press LLC

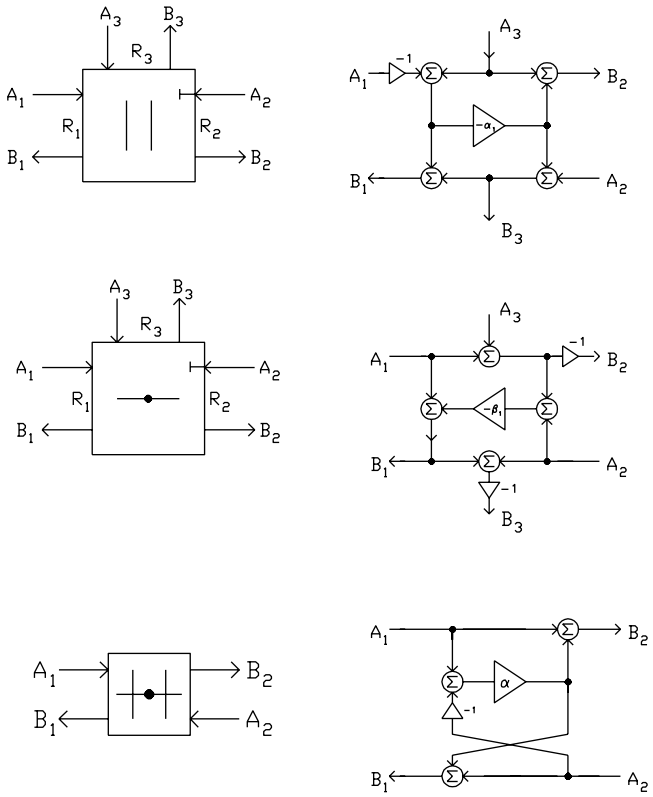

FIGURE 87.34 WFD's of two- and three-port adaptors.

Again we have $\sum_{k=1}^{3}\beta_k = 2$ so that one multiplier can be eliminated. A further multiplier can be eliminated by forcing one port to be reflection-free, port 2 here as in the parallel case. The resulting WFD and its symbol are shown in Fig. 87.34

The WFD's of two-port serial and parallel adaptors are essentially the same and we will refer to them just as two-port adaptors. There are several alternative realizations, each with their particular uses. The input/output equations of one such realization are as follows:

$$\left.\begin{aligned} B_1 &= A_2 + \alpha(A_2 - A_1) \\ B_2 &= A_1 + \alpha(A_2 - A_1) \end{aligned}\right\} \tag{87.122}$$

where $\alpha = (R_1 - R_2)/(R_1 + R_2)$.

The WFD is shown in Fig. 87.34 and, as can be seen, is a particularly simple structure. It turns out that the WFD's of series-tuned and parallel-tuned circuits, discussed earlier, can alternatively be expressed in terms of two-port adaptors (Fig. 87.35). In the series-tuned case, $R_1 = L + D$ and $R_2 = R_1D/L$ while in the parallel-tuned case, $R_1 = LD/(L + D)$ and $R_2 = R_1L/D$. For both cases, $\alpha = -\beta = (L - D)/(L + D)$ and $D = 1/C$. Because R_1 is determined, another two-port adaptor will be required to interconnect these WFD's to the rest of a WDF network.

Lattice Adaptor

The final circuit element to be introduced is, in fact, a complete network and this is the **lattice adaptor**. A symmetrical ladder network can be transformed into a lattice structure (Fig. 87.36) consisting of two pairs of impedances Z_1 and Z_2. The WDF equivalent of the lattice can be represented by the following matrix equation:

© 2003 by CRC Press LLC

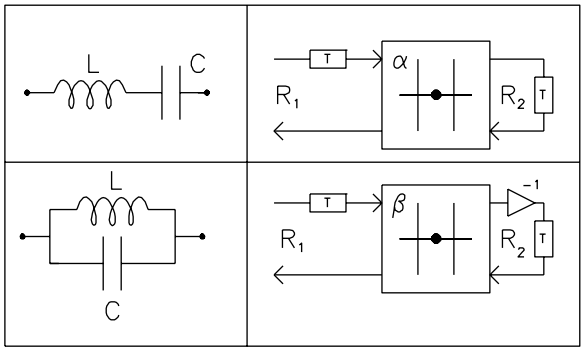

FIGURE 87.35 WFD's of series and parallel tuned circuits using adaptors.

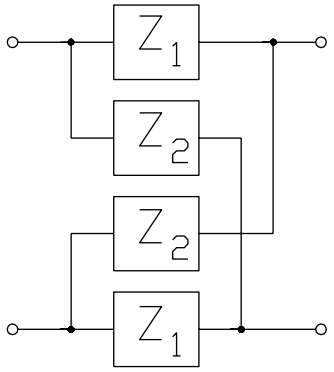

FIGURE 87.36 Double-terminated analog lattice network.

$$\begin{bmatrix} B_1 \\ B_2 \\ B_3 \\ B_4 \end{bmatrix} = \begin{bmatrix} 0 & 0 & \frac{1}{2} & \frac{1}{2} \\ 0 & 0 & -\frac{1}{2} & \frac{1}{2} \\ 1 & -1 & 0 & 0 \\ 1 & 1 & 0 & 0 \end{bmatrix} \begin{bmatrix} A_1 \\ A_2 \\ A_3 \\ A_4 \end{bmatrix} \tag{87.123}$$

where, in addition, $A_3 = S_1B_3$, $A_4 = S_2B_4$, and $S_k = (Z_k - R)/(Z_k + R)$ is the reflectance of the impedance Z_k, $k = 1, 2$ and $R = R_1 = R_2$.

Equation (87.123) defines a four-port lattice adaptor. In practice, A_2 is set to zero and the adaptor simplifies to the WFD shown in Fig. 87.37. The main advantage of using the lattice equivalent of a

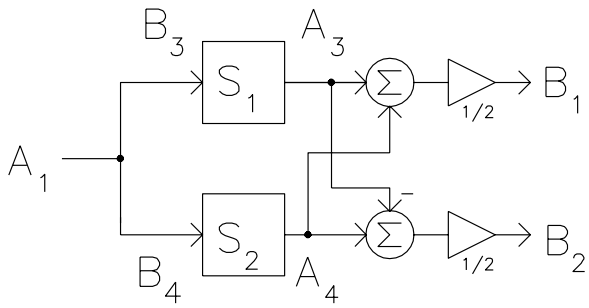

FIGURE 87.37 WFD of lattice WDF structure.

© 2003 by CRC Press LLC

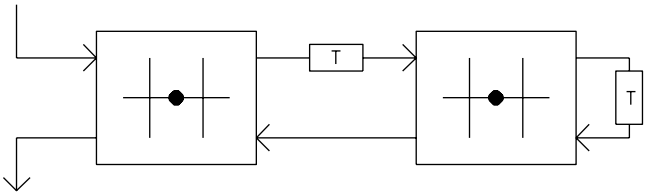

FIGURE 87.38 WFD of second-order all-pass section.

symmetrical ladder network is in the reduction of the number of multipliers and adders in the digital structure. In addition, the lattice WDF does not suffer from the high stopband sensitivity of its analog counterpart. The main reasons are (i) the use of wave variables and (ii) identical impedances can be realized with arbitrary accuracy using a digital representation.

The reflectances can be realized as cascades of first- and second-order allpass sections and design techniques exist that allow the coefficients to be determined easily for the classical filter approximations such as Butterworth, Chebyshev, and elliptic. The WFD of a second-order allpass section using two-port adaptors is shown in Fig. 87.38.

WDF Networks

A few simple rules must be adhered to when constructing complete networks from the WDF building blocks described here. First, blocks can be cascaded so long as the port resistances at the interconnections are equal. Second, on interconnecting building blocks together no delay-free loops must be created. This is assured if the building blocks chosen have one reflection-free port. Although there are two approaches to WDF synthesis, i.e., the one- or two-port approaches, essentially they yield the same filter structures. For example, the WFD of a two-port series inductor is equivalent to a three-port series adaptor in which one of the ports is reflection-free and another is connected to the WFD of a one-port inductor (Fig. 87.30).

Filter Design Methods

Design Choices

The reference filters that are going to be used here are double-terminated LC ladders and lattices together with filters constructed from a cascade of unit elements of differing characteristic impedances. Each of these reference filters is lossless and potentially low roundoff noise WDF's can be derived.

Various design choices are open to us. First, analog filter tables or synthesis can be used to provide component values which can then be transformed using simple relationships into multiplier coefficient values. In two examples, we will look at the design of a lowpass ladder and unit element–based WDF. In a further example we will use a method due to Gazsi which gives explicit formulae for the multiplier coefficients of lattice-based WDF for Butterworth, Chebyshev, inverse Chebyshev, and Cauer approximations. For nonstandard specifications, e.g., for simultaneous magnitude and phase or delay requirements, some form of mathematical optimization is necessary. This will be explored in the last example. First, the methods will be introduced.

Design Using Filter Tables

To design a WDF from the seventh-order LC ladder reference filter shown in Fig. 87.39, we can start from the source or load end. If we begin the WDF synthesis from the source, then the resistive voltage source is replaced by its WDF equivalent from Fig. 87.30 with the port resistance $R = R_s$. The next block is the WFD of a shunt capacitor taken from Fig. 87.32 where $G_1 = G_s + C_1$ and $\alpha_1 = G_s/G_1$. As we add further blocks, each output port resistance/admittance is defined in terms of that input port resistance/admittance and the component value(s). The remaining design equations are as follows:

© 2003 by CRC Press LLC

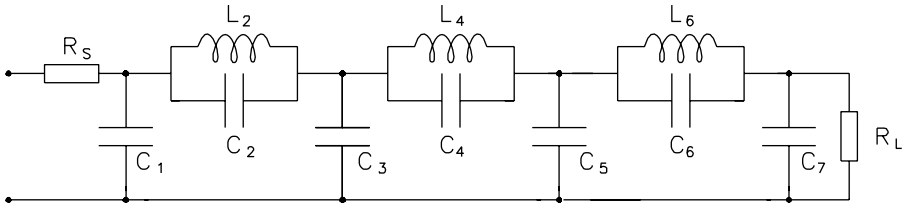

FIGURE 87.39 Seventh-order LC ladder reference filter.

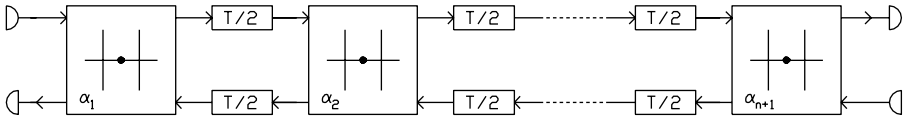

FIGURE 87.40 UE wave digital filter structure.

$$
\left.
\begin{aligned}
&R_2 = R_1 + \frac{L_2}{1+L_2C_2}, \quad G_3 = G_2 + C_3, \quad R_4 = R_3 + \frac{L_4}{1+L_4C_4} \\
&G_5 = G_4 + C_5, \quad R_6 = R_5 + \frac{L_6}{1+L_6C_6}, \quad G_7 = G_6 + C_7 \\
&\alpha_2 = R_1/R_2, \quad \alpha_3 = \frac{\left(1-L_2C_2\right)}{\left(1+L_2C_2\right)}, \quad \alpha_4 = G_2/G_3 \\
&\alpha_5 = R_3/R_4, \quad \alpha_6 = \frac{\left(1-L_4C_4\right)}{\left(1+L_4C_4\right)}, \quad \alpha_7 = G_4/G_5 \\
&\alpha_8 = R_5/R_6, \quad \alpha_9 = \frac{\left(1-L_6C_6\right)}{\left(1+L_6C_6\right)}, \quad \alpha_{10} = G_6/G_7 \\
&\alpha_{11} = \frac{\left(G_7-G_L\right)}{\left(G_7+G_L\right)}
\end{aligned}
\right\} \tag{87.124}
$$

Note that $G_k = 1/R_k$ and the number of multiplier coefficients is equal to 1 less than the number of passive components. The analog component values can be found from tables or by synthesis. The overall transfer function of the WDF, $G(z)$ is given by

$$G(z) = \left(1 + R_7/R_L\right)H(z) \tag{87.125}$$

where $H(z)$ is the transfer function obtained by directly bilinearly transforming the analog transfer function $H(s)$. If we had designed the WDF from the load-end, then the overall transfer function would have been equal to $2H(z)$.

To design a WDF based on a cascade of commensurate transmission line sections or unit elements (UE), we replace each UE by its WDF equivalent, derived in an earlier section. Because their characteristic impedances will, in general, be different, UE's must be interconnected using two-port adaptors. The structure that is obtained is illustrated in Fig. 87.40, where the multiplier (adaptor) values $\{\alpha_k\}$ are given by the following:

$$\alpha_k = \frac{\left(Z_{k-1} - Z_k\right)}{\left(Z_{k-1} + Z_k\right)} \tag{87.126}$$

© 2003 by CRC Press LLC

for $k = 1, 2, \ldots, (n+1)$. Z_k is the characteristic impedance of the kth unit element with $Z_0 = R_s$ and $Z_{n+1} = R_L$.

Direct Synthesis Method

Introduction. The lattice WDF of Fig. 87.37 is arguably the most useful WDF structure because (i) it is economical in its use of multipliers and adders for a given order, (ii) it can realize both minimum and nonminimum phase transfer functions, and (iii) specifications can be met with very low coefficient wordlengths. This is in addition to the general advantages of WDF's. In 1985, Gazsi described an ingenious technique based on work by one of the early pioneers of filter design, Sidney Darlington, to directly synthesize filters using this structure for Butterworth, Chebyshev, and elliptic approximations. The explicit formulae that he derived were simple and easy to program, even for pocket calculators. Because of the importance of Gazsi's work to practical filter design, his method is shown here for the elliptic lowpass filter case.

Determination of Filter Order. To determine the minimum filter order, n, required for a given specification we use the following expression:

$$n = \frac{8\ln\left(4\varepsilon_s/\varepsilon_p\right)}{\ln\left(2k_4\right)} \tag{87.127}$$

where the passband and stopband ripple factors, ε_p and ε_s, are related, respectively, to the passband ripple, a_p, and the minimum stopband attenuation, a_s, by the following expressions:

$$\left.\begin{aligned} a_p &= 10\log\left(1+\varepsilon_p^2\right) \\ a_s &= 10\log\left(1+\varepsilon_s^2\right) \end{aligned}\right\} \tag{87.128}$$

a_p and a_s are measured in dB's. To determine k_4 we use the recurrence relationship,

$$k_{i+1} = k_i^2 + \sqrt{\left(k_i^4 - 1\right)},\ i = 0, 1, 2, 3 \tag{87.129}$$

The initial value, k_1 is calculated from the following set of equations:

$$\left.\begin{aligned} \omega_p &= 2\pi f_p \\ \omega_s &= 2\pi f_s \\ \Omega_p &= \tan\left(\omega_p T/2\right) \\ \Omega_s &= \tan\left(\omega_s T/2\right) \\ k_0 &= \sqrt{\Omega_s/\Omega_p} \end{aligned}\right\} \tag{87.130}$$

where T is the sampling interval. For lowpass designs the order will be odd so that after using (87.127), we need to round up to the nearest odd number, N, say. Because of this a *design margin* will be created which can be exploited when determining the actual values of the passband and stopband parameters.

Calculation of Filter Parameters. We can calculate the bounds of the closed interval, $[f_{s1}, f_s]$ for the stopband edge frequency using the following set of equations:

© 2003 by CRC Press LLC

$$\left.\begin{aligned} r_0 &= \sqrt{\varepsilon_s / \varepsilon_p} \\ r_{i+1} &= r_i^2 + \sqrt{r_i^4 - 1},\ i = 0, 1 \\ s_4 &= \tfrac{1}{2}\left(\sqrt[N]{2r_2}\right)^4 \\ s_{i-1} &= \sqrt{\tfrac{1}{2}\left(s_i + 1/s_i\right)},\ i = 4, 3, 2, 1 \\ f_{s1} &= \tan^{-1}\left(\Omega_p s_0^2\right)/\left(\pi T\right) \end{aligned}\right\} \tag{87.131}$$

After choosing a final stopband edge frequency, $\hat{f}_s$, such that $f_{s1} \le \hat{f}_s \le f_s$, the bounds of the closed interval, $[\varepsilon_{p1}, \varepsilon_p]$ can be calculated for the passband ripple factor using the following set of equations:

$$\left.\begin{aligned} p_0 &= \sqrt{\hat{\Omega}_s / \Omega_p} \\ p_{i+1} &= p_i^2 + \sqrt{p_i^4 - 1},\ i = 0, 1, 2, 3 \\ q_3 &= \tfrac{1}{2}\left(\sqrt{2p_4}\right)^N \\ q_{i-1} &= \sqrt{\tfrac{1}{2}\left(q_i + 1/q_i\right)},\ i = 3, 2, 1 \\ \varepsilon_{p1} &= \varepsilon_s / q_0^2 \end{aligned}\right\} \tag{87.132}$$

Once a value for passband ripple factor, $\hat{\varepsilon}_p$, has been chosen, the revised stopband ripple factor can be determined using $\hat{\varepsilon}_s = \hat{\varepsilon}_p q_0^2$.

Calculation of Filter (Adaptor) Coefficients. Having determined the final values of all the filter parameters (denoted by hats on the variables), the coefficients, $\{\beta_i\}$, can now be computed. First, Gazsi defines some auxiliary variables:

$$\left.\begin{aligned} v_1 &= \hat{\varepsilon}_p^{-1} + \sqrt{\hat{\varepsilon}_p^{-2} + 1} \\ v_{i+1} &= q_i v_i + \sqrt{1 + \left(q_i v_i\right)^2},\ i = 1, 2 \\ w_5 &= \sqrt[N]{\frac{q_3}{v_3} + \sqrt{\left(\frac{q_3}{v_3}\right)^2 + 1}} \\ w_{i-1} &= \frac{1}{2p_{i-1}}\left(w_i - 1/w_i\right),\ i = 5, 4, 3, 2, 1 \end{aligned}\right\} \tag{87.133}$$

from which the coefficient of the first-order section can be determined thus:

$$\beta_0 = \frac{1 + w_0 p_0 \Omega_p}{1 - w_0 p_0 \Omega_p} \tag{87.134}$$

© 2003 by CRC Press LLC

To calculate the coefficients of the second-order sections, further auxiliary variables are required as follows:

$$\left.\begin{aligned} c_{4,i} &= \frac{p_4}{\sin\left(i\pi/N\right)} \\ c_{j-1,i} &= \frac{1}{2p_{j-1}}\left(c_{j,i} + 1/c_{j,i}\right), j = 4,3,2,1 \\ y_i &= 1/c_{0,i} \\ B_i &= \frac{w_0^2 + y_i^2}{1+\left(w_0 y_i\right)^2}\left(p_0\Omega_p\right)^2 \\ A_i &= \frac{-2w_0 p_0 \Omega_p}{1+\left(w_0 y_i\right)^2}\sqrt{1-\left(p_0^2 + 1/p_0^2 - y_i^2\right)y_i^2} \end{aligned}\right\} \tag{87.135}$$

for $i = 1, 2, \ldots, (N-1)/2$. Finally, the coefficients for each second-order section may be calculated in turn from the following formulae:

$$\left.\begin{aligned} \beta_{2i-1} &= \frac{A_i - B_i - 1}{A_i + B_i + 1} \\ \beta_{2i} &= \frac{1 - B_i}{1 + B_i} \end{aligned}\right\} \tag{87.136}$$

Figure 87.41 shows a ninth-order lattice WDF structure and the coefficient numbering scheme. The difference in order between the upper and lower arms should never exceed one.

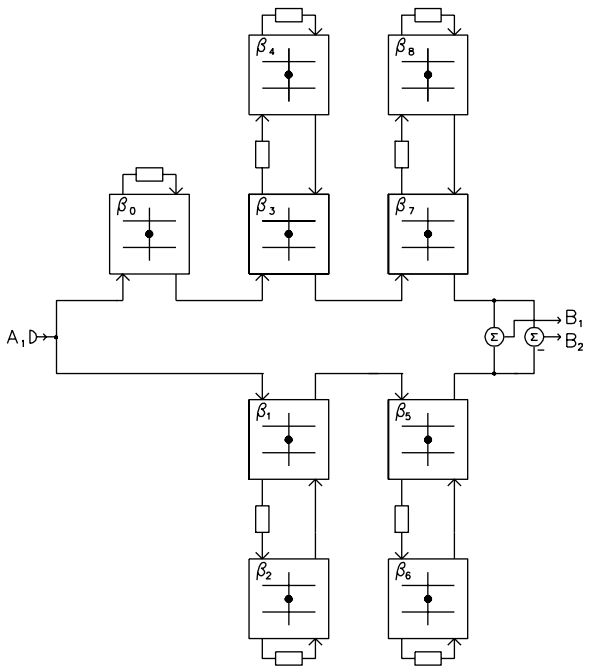

FIGURE 87.41 Lattice WDF structure showing first- and second-order sections and coefficient labeling scheme.

Optimization

In some design problems, the specifications cannot be met by the classical filter approximations. For example, it may be necessary to have an approximately linear phase (ALP) passband characteristic. FIR filters can, of course, be used to give exact linear phase, but generally, the filter order is high. Recursive filters and WDF's in particular, offer an attractive alternative. The lattice WDF structure introduced earlier can be used for the design of ALP filters. However, the design problem must be formulated as the minimization of some error function subject to constraints. We can then use existing optimization methods. An L_2 error norm defined as follows has been found to be useful:

$$\varepsilon(\underline{\alpha}) = \sum_{i=1}^{n} W_i^g \xi_i^2 + \sum_{i=1}^{m} W_i^d \psi_i^2 \tag{87.137}$$

where $\underline{\alpha}$ is the vector of filter coefficients, ξ_i, ψ_i are, respectively, the gain and delay errors at the ith frequency point, and W_i^g, W_i^d are the weights, respectively, for the gain and delay errors at point i. The gain error is normally defined as the difference between the computed and desired gain, normally unity in the passband and zero in the stopband. Similarly the delay error is the difference between the computed and desired delay. The desired delay is not fixed but is used as an additional optimization parameter. However, there may be cases in which the delay is specified to be less than some pre-specified value. This can be accommodated by an additional constraint. If we had used phase instead of delay, then the additional optimization parameter would have been the phase gradient. Finally, n and m are the number of frequency points used in gain and delay error calculations, respectively.

The design objective is to find the value of the coefficient vector $\underline{\alpha}$ that minimizes the error function, $\varepsilon(\underline{\alpha})$ subject to a stability constraint. To satisfy this constraint, it is necessary that $|\alpha_i| < 1$, $\forall i$. Many optimization techniques can be applied to this problem, such as quasi-Newton, linear and quadratic programming, simulated annealing, and genetic algorithms. We will look at a design example using optimization in the next section.

Least-Squares Method for Wave Digital Lattice Filters

The lattice structure of Fig. 87.37 is essentially a parallel combination of all-pass filters (PCAS). Design techniques for filters using this PCAS structure have been developed independently of those for lattice WDF's. In particular, it has been observed that the transfer function of an all-pass filter has a form making it possible to generate a set of linear equations in the coefficients, which can then be solved using the method of least-squares with excellent results.

Consider the Nth order all-pass subfilter with transfer function $G(z)$, given by the following:

$$G(z) = \frac{\sum_{n=0}^{N} c_n z^{n-N}}{\sum_{n=0}^{N} c_n z^{-n}} \tag{87.138}$$

The corresponding phase function can be expressed as follows:

$$\phi(\omega) = -N\omega + 2\arctan\left(\frac{\sum_{k=0}^{N} c_k \sin k\omega}{\sum_{k=0}^{N} c_k \cos k\omega}\right) \tag{87.139}$$

After some algebraic manipulation we find that

$$\sum_{k=1}^{N} c_k \sin\left(\tfrac{1}{2}(\phi + N\omega) + k\omega\right) = -\sin\left(\tfrac{1}{2}(\phi + N\omega)\right) \tag{87.140}$$

© 2003 by CRC Press LLC

for Nth order all-pass filter with phase response $\phi(\omega)$. This equation is linear in $\{c_k\}$ and so can form the basis of a set of linear simultaneous equations to determine the coefficients. The set is generated by choosing equi-spaced frequency points $\{\omega_i\}$ on a grid in the bands of interest. The number of grid points, equal to the number of equations, will generally be greater than N, so the system may be solved in the least-squares sense.

This technique can be extended simply to filters with two all-pass filters in parallel and be used in the situation where approximately linear phase is required. Referring to Fig. 87.37 again, it is known that the magnitude and phase of the transfer functions $G(z) = B_1/A_1$ and $H(z) = B_2/A_1$ are given, respectively, by the following:

$$\left.\begin{aligned} M_1(\omega) &= \left|\cos\left\{\left(\phi_1(\omega)-\phi_2(\omega)\right)/2\right\}\right| \\ \varphi_1(\omega) &= \left(\phi_1(\omega)+\phi_2(\omega)\right)/2 \\ M_2(\omega) &= \left|\sin\left\{\left(\phi_1(\omega)-\phi_2(\omega)\right)/2\right\}\right| \\ \varphi_2(\omega) &= \left(\phi_1(\omega)+\phi_2(\omega)+\pi\right)/2 \end{aligned}\right\} \tag{87.141}$$

where $\phi_1(\omega)$, $\phi_2(\omega)$ are the phase functions of the upper and lower branches, respectively. In practice, $G(z)$ will be lowpass while $H(z)$ will be highpass.

From (87.141) we can find that in the passband of $G(z)$, $\phi_1(\omega) \cong \phi_2(\omega)$ and in the stopband that $\phi_1(\omega) \cong \phi_2(\omega) \pm\pi$.

Design Examples

Example I: Lowpass Ladder WDF

An elliptic lowpass filter is to be designed with the following specification $f_p = 0.1$, $f_s = 0.13$, $a_p = 0.1dB$, and $a_s = 60dB$. The sampling frequency is normalized to unity. To calculate the minimum order we need to find the pre-warped edge frequencies using the bilinear transform of (87.130). On using (87.128), we find that a seventh-order filter will meet the specification. The next stage is to determine the component values of the reference filter using analog filter design tables such as those of Saal or Zverev. These tables are tabulated according to reflection coefficient ρ that is related to a_p by the relationship $a_p = -20 \log (\sqrt{1-\rho^2})$. The stopband edge frequency Ω_s relative to the passband edge frequency is 1.3319. The tables yield a design C071549, meaning seventh-order, $\rho = 0.15$ and $\theta = \arcsin(1/\Omega_s) = 49°$. The minimum stopband attenuation will be 61.17 dB. The analog component values are given in Table 87.3.

TABLE 87.3 Reference Filter Component Values for Example I

$R_s = 1$	$C_1 = 1.08511$
$C_2 = 0.11338$	$L_2 = 1.29868$
$C_3 = 1.63031$	
$C_4 = 0.54952$	$L_4 = 1.00291$
$C_5 = 1.47376$	
$C_6 = 0.39771$	$L_6 = 1.01201$
$C_7 = 0.86396$	$R_L = 1.0$

The ladder WDF coefficient values are computed using the design equations of (87.124) and are shown in Table 87.4. The final structure in block diagram form is shown in Fig. 87.42.

TABLE 87.4 Ladder Wave Digital Filter Coefficient Values for Example I

$\alpha_1 = 0.4796$	$\alpha_2 = 0.2976$
$\alpha_3 = 0.7433$	$\alpha_4 = 0.2757$
$\alpha_5 = 0.4073$	$\alpha_6 = 0.2894$
$\alpha_7 = 0.3835$	$\alpha_8 = 0.3670$
$\alpha_9 = 0.4260$	$\alpha_{10} = 0.5038$

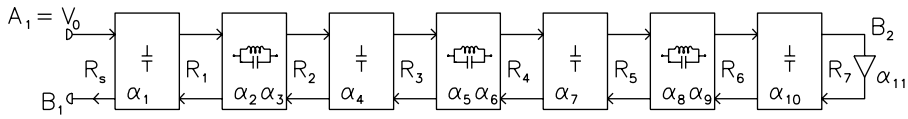

FIGURE 87.42 Block diagram of seventh-order ladder WDF designed from the source-end.

Example II: Lowpass Unit Element WDF

The next example is the design of a WDF based on a cascade of unit elements, the structure for which was shown in Fig. 87.40. Although design can be performed from the source or from the load end, the final structure is the same.

The transfer function that can be achieved with this structure will be all-pole and the frequency response will be periodic. Levy has produced tables of characteristic impedances for lowpass odd order double-terminated filters based on the Chebyshev approximation, the magnitude-squared function for which is,

$$\left|G(\theta)\right|^2 = \frac{1}{1+h^2T_n^2\left(\sin\theta/\sin\theta_p\right)} \tag{87.142}$$

where T_n denotes the nth order Chebyshev polynomial and θ_p is the cut-off parameter. Note that $|G(\theta)|^2$ does not fall to zero in the stopband as it would for lumped filters.

The relationship between θ and the discrete-time frequency variable, ω, is $\theta = \omega T/2$ which is linear; thus, no pre-distortion of the edge frequencies is required. To estimate the filter order, N, we use the following expression:

$$N = \frac{\log\left(2\varepsilon_s\right) - \log\left(\varepsilon_p\right)}{\log\left\{2\sin\left(\theta_s\right)\right\} - \log\left\{\sin\left(\theta_p\right)\right\}} \tag{87.143}$$

where $\theta_p = \pi f_p/F$ is the passband edge parameter and $\theta_s = \pi f_s/F$ is the stopband edge parameter, F is the sampling frequency, and other terms are as defined in a previous section.

To use Levy's tables, two further parameters need to be evaluated. The first is bandwidth, BW, defined as $BW = 4f_p/F$ and the second is VSWR, S, which is related to passband ripple by $S = 2\varepsilon - 1 + 2\sqrt{\varepsilon(\varepsilon-1)}$ where $a_p = 10\log(\varepsilon)$. The characteristic impedances have symmetry according to the following relationship $Z_k = Z_{N-k+1}$ for $k = 1, \ldots, (N-1)/2$. In addition, $Z_0 = R_s = 1$ and $Z_{N+1} = R_L = 1$.

Having determined the characteristic impedances, the adaptor multiplier coefficients can be computed using the following expression, for $k = 1, \ldots, (N+1)$:

$$\alpha_k = \frac{Z_{k-1} - Z_k}{Z_{k-1} + Z_k} \tag{87.144}$$

The specification for a lowpass UE WDF is as follows: $f_p = 0.1$, $f_s = 0.2$, $a_p = 0.5dB$, and $a_s = 60dB$. Using (87.143), the minimum filter order is 7. BW is 0.4 and $S = 1.98$. The closest tabulated design is for $S = 2$.

The characteristic impedances are as follows:

$$Z_0 = Z_8 = 1$$

$$Z_1 = Z_7 = 5.622$$

$$Z_2 = Z_6 = 0.2557$$

$$Z_3 = Z_5 = 8.329$$

$$Z_4 = 0.2373$$

© 2003 by CRC Press LLC

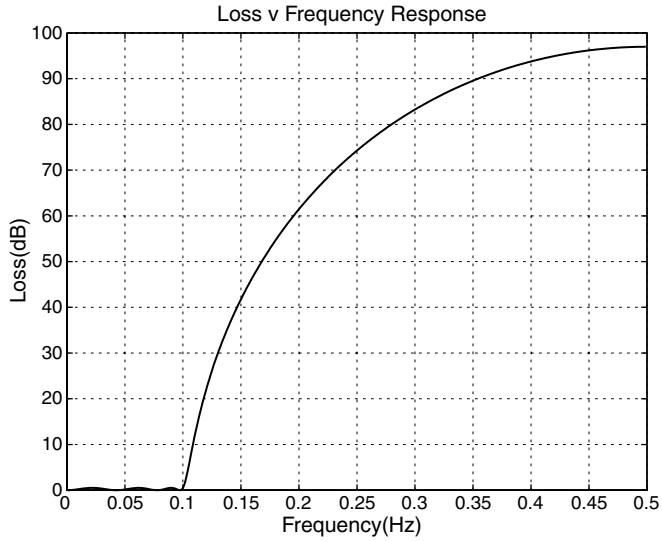

FIGURE 87.43 Loss vs. frequency response for UEWDF of Example II.

Using (87.144), we find the multiplier coefficients to be as follows:

$$\alpha_1 = -\alpha_8 = -0.69798$$

$$\alpha_2 = -\alpha_7 = 0.91299$$

$$\alpha_3 = -\alpha_6 = -0.94043$$

$$\alpha_4 = -\alpha_5 = 0.94460$$

The resulting UEWDF network was analyzed in the frequency domain and its loss vs. frequency response is shown in Fig. 87.43.

Example III: Lowpass Lattice WDF

Using the same specification as in Example I, a lattice WDF will be designed using Gazsi's method. The minimum order will be 7 and, applying the various formulae given in an earlier section, the coefficients are found to be as follows:

$$\beta_0 = 0.72666, \beta_1 = -0.62455$$

$$\beta_2 = 0.90358, \beta_3 = -0.80128$$

$$\beta_4 = 0.83318, \beta_5 = -0.94151$$

$$\beta_6 = 0.79789$$

In the design process a design margin is created for the stopband frequency between 0.1279 and 0.13; a value of 0.13 was chosen. In addition, a design margin for the passband ripple between 0.081654 and 0.1 was created and a value of 0.09 was chosen. The loss vs. frequency response is shown in Fig. 87.44.

Example IV: Approximately Linear Phase (ALP) Bandpass Lattice WDF

The next design is that of an ALP bandpass lattice WDF. As no explicit equations for the coefficients exist in this case, some form of optimization is required. The specifications are as follows: $f_{p1} = 0.2$, $f_{p2} = 0.3$, $f_{s1} = 0.15$, and $f_{s2} = 0.35$. The group delay is required to be constant in the interval [0.175,0.325]. The passband ripple should be less than 0.1 dB and the minimum stopband attenuation greater than 50 dB.

© 2003 by CRC Press LLC

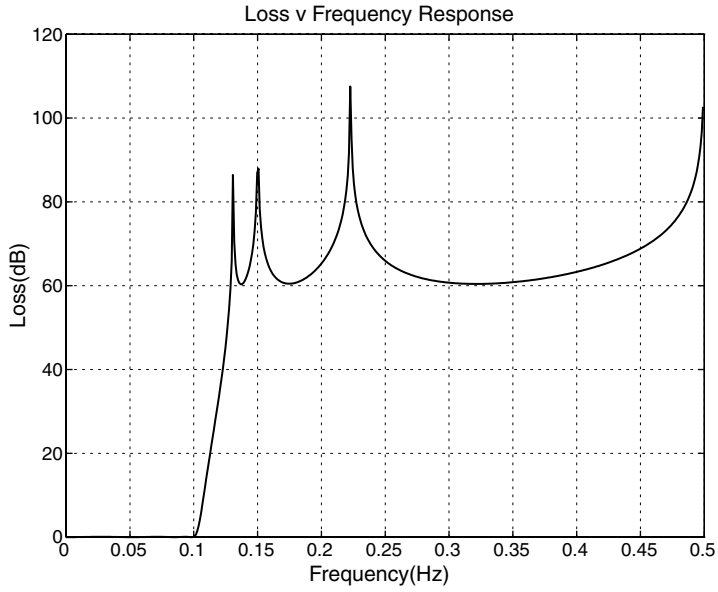

FIGURE 87.44 Loss vs. frequency response for LTWDF of Example III.

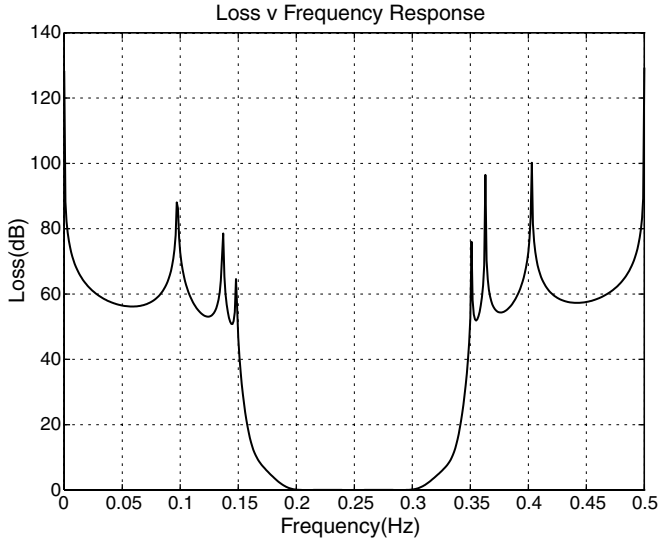

FIGURE 87.45 Loss vs. frequency response for Example IV.

No expression exists for the order of ALP filters, but a lower bound would be the order of a minimum phase design which, in this case, would be 10. To meet the magnitude specifications as well as maintaining a flat delay requires considerably greater order. In fact, in this case an order of 22 yields a fairly good result. The loss vs. frequency response is shown in Fig. 87.45 while the delay characteristic is found in Fig. 87.46. The delay error, defined as $200(1 - \lambda)/(1 + \lambda)$ where $\lambda = \tau_{min}/\tau_{max}$, is 8.9%. The optimization technique was based on a sequential quadratic programming technique. In 495 function calls, the objective function was reduced from 12 375 to 0.4. Numerical techniques tend to be successful when the filter designer adds a wealth of experience to the process. For example, the choice of initial coefficient values and constraints on the coefficient values, e.g., for stability, are important to incorporate into the design method.

Final Comments

In this section we have looked at the basic theory and design of wave digital filters together with some examples of the design process. These filters are useful because of their low roundoff noise characteristics, which are a result of using particular analog reference filters together with wave variables. In particular, the lattice WDF has the additional advantage of low complexity.

Wave digital filters can be implemented in software for use in digital signal processing chips or in hardware as VLSI integrated circuits, such as FPGAs, PLDs, or ASICs. To minimize hardware, several optimization methods have been developed to find sets of short wordlength coefficients or coefficients with a small number of non-zero bits to meet a given specification. Hardware designs have concentrated on searching for efficient VLSI architectures such as bit-level arrays that have a regular structure and some degree of pipelining to increase the throughput. With current CMOS technology, sampling rates in the tens of megahertz are feasible for programmable filters. However, for fixed coefficient filters, more can be done to minimize the arithmetic required and so rates in the hundreds of megahertz can be expected.

The WDF lattice filter, in its bi-reciprocal form, has been used as a building block in iterated filter banks (Fig. 87.47). This form is also known as a quadrature-mirror filter (QMF) because the low and high-pass responses are mirror images about a vertical line through $f = 1/2$ (Fig. 87.48). Such filter banks,

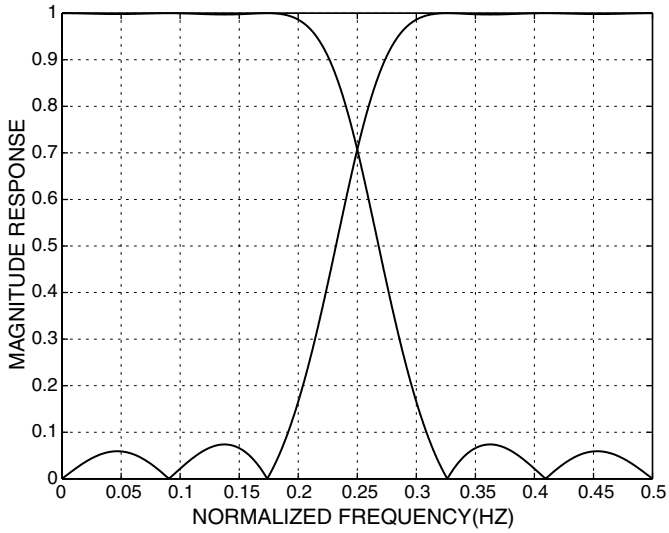

FIGURE 87.48 Typical magnitude responses for low- and high-pass outputs.

particularly those using a wavelet decomposition, have an important application in image compression techniques. More detailed discussions on wavelets and filter banks are to be found in Chapters 6 and 89 of this handbook, respectively.

In conclusion, the wave digital filter concept has been generalized in the 1-D case, used also for multirate filtering, and extended successfully to 2-D and higher dimensions. A fruitful and relatively new area is their use in modeling physical systems described by sets of partial differential equations.

Readers who are interested in obtaining various software packages for the design, analysis, and simulation of WDF's are invited to contact the author, whose email address is ssl eng.warwick.ac.uk.

87.4 Lattice Filters [1]-[3]

Y. C. Lim

Lattice Filters

There are several families of lattice structures for the implementation of IIR filters. Two of the most commonly encountered families are the tapped numerator structure shown in Fig. 87.49 [3] and the injected numerator structure shown in Fig. 87.50 [3]. It should be noted that not all the taps and injectors of the filters are nontrivial. For example, if $\lambda_i = 0$ for all i, the structure of Fig. 87.49 simplifies to that of Fig. 87.51 [1]. If $\phi_i =$ for $i \leq 1$, the structure of Fig. 87.50 reduces to that of Fig. 87.52. For both families, the denominator of the filter's transfer function is synthesized using a lattice network. The transfer function's numerator of the tapped numerator structure is realized by a weighted sum of the signals tapped from $N + 1$ appropriate points of the lattice. For the injected numerator structure, the transfer function's numerator is realized by weighting and injecting the input into $N + 1$ appropriate points on the lattice. The lattice itself may appear in several forms as shown in Fig. 87.53 [1]. Figure 87.54 shows the structure of a third-order injected numerator filter synthesized using the one-multiplier lattice.

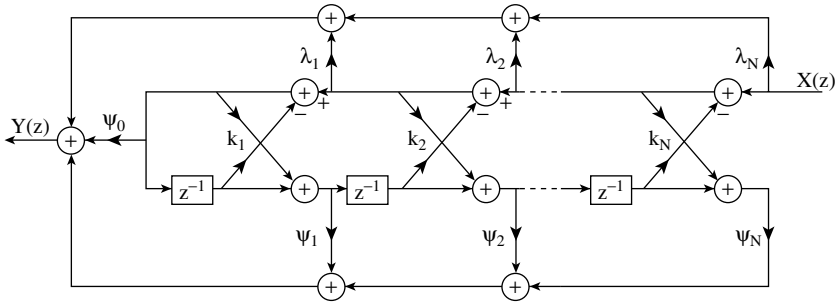

FIGURE 87.49 The general structure of a topped numerator filter.

Evaluation of the Reflection Coefficients k_n [2]

The nth reflection coefficient k_n for both families of filters may be evaluated as follows. Let the transfer function of the filter $H(z)$ be given by

© 2003 by CRC Press LLC

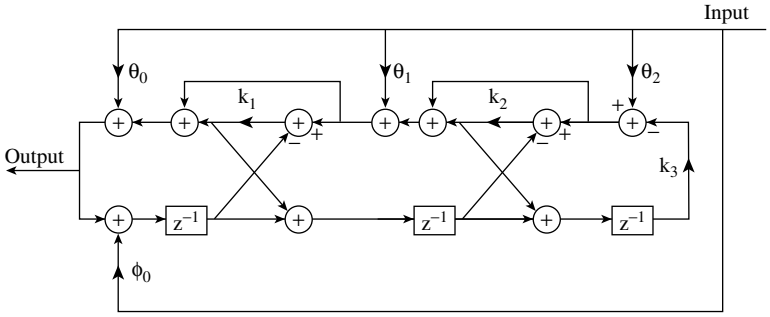

FIGURE. 83.54 A third-order one-multiplier lattice injected numerator filter.

$$H(z)=\frac{B(z)}{A(z)} \tag{87.145}$$

where

$$B(z)=\sum_{n=0}^{N} b_n z^{-n} \tag{87.146}$$

$$A(z)=1+\sum_{n=1}^{N} a_n z^{-n} \tag{87.147}$$

Define

$$D_N(z)=A(z) \tag{87.148}$$

$$D_{n-1}(z)=\frac{D_n(z)-k_n z^{-n} D_n\left(z^{-1}\right)}{1-k_n^2} \tag{87.149}$$

$$=1+\sum_{r=1}^{n-1} d_{n-1}(r) z^{-r} \tag{87.150}$$

1. Set $n = N$.
2. Compute $D_n(z)$.
3. $k_n = d_n(n)$
4. Decrement n.
5. If $n = 0$, stop; otherwise, go to 2.

Evaluation of the Tap Gains ψ_n and λ_n [3]

For the tapped numerator filters, ψ_n and λ_n may be computed as follows. Define

$$\mathbf{\Gamma}_N(z)=B(z) \tag{87.151}$$

$$\mathbf{\Gamma}_{n-1}(z)=\mathbf{\Gamma}_n(z)-\lambda_n D_n(z)-\psi_n z^{-n} D_n\left(z^{-1}\right) \tag{87.152}$$

$$=\sum_{r=0}^{n-1} \gamma_{n-1}(r) z^{-r} \tag{87.153}$$

© 2003 by CRC Press LLC

1. Set $n = N$.
2. Compute $\Gamma_n(z)$.
   Set either $\psi_n = 0$ or $\lambda_n = 0$.
   If $\psi_n = 0$, $\lambda_n = \gamma_n(n)/k_n$.
   If $\lambda_n = 0$, $\psi_n = \gamma_n(n)$.
3. Decrement n.
4. If $n = -1$, stop; otherwise, go to 2.

Evaluation of the Injector Gains θ_n and ϕ_n [3]

For the injected numerator filters, θ_n and ϕ_n may be computed as follows. Define

$$L_0^0(z) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \tag{87.154}$$

$$L_m^n(z) = \begin{bmatrix} 1 & k_n z^{-1} \\ k_n & z^{-1} \end{bmatrix} L_m^{n-1}(z), \qquad n > m \tag{87.155}$$

$$= \begin{bmatrix} P_m^n(z) & Q_m^n(z) \\ R_m^n(z) & S_m^n(z) \end{bmatrix} \tag{87.156}$$

$$P_m^n(z) = 1 + \sum_{r=1}^{n-m-1} p_m^n(r) z^{-r} \tag{87.157}$$

$$Q_m^n(z) = \sum_{r=1}^{n-m} q_m^n(r) z^{-r} \tag{87.158}$$

$$\Xi_{N-1} = B(z) + \phi_0 Q_0^N(z) \tag{87.159}$$

$$\Xi_{n-1}(z) = \Xi_n(z) + \phi_{N-n} Q_{N-n}^N(z) - \theta_{N-n-1} P_{N-n-1}^N(z) \tag{87.160}$$

$$= \sum_{r=0}^{n-1} \xi_{n-1}(r) z^{-r} \tag{87.161}$$

1. $\phi_0 = -b_N / q_0^N(N)$.
   Set $n = 0$.
2. Increment n.
   Compute $\Xi_{N-n}(z)$.
   Set either $\phi_n = 0$ or $\theta_{n-1} = 0$.
   If $\phi_n = 0$, $\theta_{n-1} = \xi_{N-n}(N-n)/p_{n-1}^N(N-n)$.
   If θ_{n-1}, $\phi_n = -\xi_{N-n}(N-n)/q_{n-1}^N(N-n)$.
3. If $n = N - 1$ go to 4; otherwise, go to 2.
4. $\theta_{N-1} = \xi_0(0)$. Stop.

Bruce W. Bomar
University of Tennessee Space Institute

Practical digital filters must be implemented with finite precision numbers and arithmetic. As a result, both the filter coefficients and the filter input and output signals are in discrete form. This leads to four types of finite wordlength effects.

Discretization (quantization) of the filter coefficients has the effect of perturbing the location of the filter poles and zeros. As a result, the actual filter response differs slightly from the ideal response. This *deterministic* frequency response error is referred to as **coefficient quantization error**.

The use of finite precision arithmetic makes it necessary to quantize filter calculations by rounding or truncation. **Roundoff noise** is that error in the filter output that results from rounding or truncation calculations within the filter. As the name implies, this error looks like low-level noise at the filter output.

Quantization of the filter calculations also renders the filter slightly nonlinear. For large signals this nonlinearity is negligible and roundoff noise is the major concern. However, for recursive filters with a zero or constant input, this nonlinearity can cause spurious oscillations called **limit cycles**.

With fixed-point arithmetic it is possible for filter calculations to **overflow**. The term **overflow oscillation**, sometimes also called **adder overflow limit cycle**, refers to a high-level oscillation that can exist in an otherwise stable filter due to the nonlinearity associated with the overflow of internal filter calculations.

In this chapter, we examine each of these finite wordlength effects. Both fixed-point and floating-point number representations are considered.

88.1 Number Representation

In digital signal processing, $(B + 1)$-bit fixed-point numbers are usually represented as two's-complement signed fractions in the format

$$b_0 \cdot b_{-1} b_{-2} \cdots b_{-B}$$

© 2003 by CRC Press LLC

The number represented is then

$$X = -b_0 + b_{-1}2^{-1} + b_{-2}2^{-2} + \cdots + b_{-B}2^{-B} \tag{88.1}$$

where b_0 is the sign bit and the number range is $-1 \le X < 1$. The advantage of this representation is that the product of two numbers in the range from –1 to 1 is another number in the same range.

Floating-point numbers are represented as

$$X = (-1)^s m 2^c \tag{88.2}$$

where s is the *sign bit, m* is the mantissa, and c is the *characteristic* or *exponent.* To make the representation of a number unique, the mantissa is *normalized* so that $0.5 \le m < 1$.

Although floating-point numbers are always represented in the form of (88.2), the way in which this representation is actually *stored* in a machine may differ. Since $m \ge 0.5$, it is not necessary to store the 2^{-1}-weight bit of m, which is always set. Therefore, in practice numbers are usually stored as

$$X = (-1)^s (0.5 + f) 2^c \tag{88.3}$$

where f is an unsigned fraction, $0 \le f < 0.5$.

Most floating-point processors now use the IEEE Standard 754 32-bit floating-point format for storing numbers. According to this standard the exponent is stored as an unsigned integer p where

$$p = c + 126 \tag{88.4}$$

Therefore, a number is stored as

$$X = (-1)^s (0.5 + f) 2^{p-126} \tag{88.5}$$

where s is the sign bit, f is a 23-b unsigned fraction in the range $0 \le f < 0.5$, and p is an 8-b unsigned integer in the range $0 \le p \le 255$. The total number of bits is 1 + 23 + 8 = 32. For example, in IEEE format 3/4 is written $(-1)^0\ (0.5 + 0.25)2^0$ so $s = 0$, $p = 126$, and $f = 0.25$. The value $X = 0$ is a unique case and is represented by all bits zero (i.e., $s = 0$, $f = 0$, and $p = 0$). Although the 2^{-1}-weight mantissa bit is not actually stored, it does exist so the mantissa has 24 b plus a sign bit.

88.2 Fixed-Point Quantization Errors

In fixed-point arithmetic, a multiply doubles the number of significant bits. For example, the product of the two 5-b numbers 0.0011 and 0.1001 is the 10-b number 00.00011011. The extra bit to the left of the decimal point can be discarded without introducing any error. However, the least significant four of the remaining bits must ultimately be discarded by some form of quantization so that the result can be stored to 5 b for use in other calculations. In the example above this results in 0.0010 (quantization by rounding) or 0.0001 (quantization by truncating). When a sum of products calculation is performed, the quantization can be performed either after each multiply or after all products have been summed with double-length precision.

We will examine three types of fixed-point quantization — rounding, truncation, and magnitude truncation. If X is an exact value then the rounded value will be denoted $Q_r(X)$, the truncated value $Q_t(X)$, and the magnitude truncated value $Q_{mt}(X)$. If the quantized value has B bits to the right of the decimal point, the quantization step size is

$$\Delta = 2^{-B} \tag{88.6}$$

© 2003 by CRC Press LLC

Since rounding selects the quantized value nearest the unquantized value, it gives a value which is never more than ±Δ/2 away from the exact value. If we denote the rounding error by

$$\epsilon_r = Q_r(X) - X \tag{88.7}$$

then

$$-\frac{\Delta}{2} \le \epsilon_r \le \frac{\Delta}{2} \tag{88.8}$$

Truncation simply discards the low-order bits giving a quantized value that is always less than or equal to the exact value so

$$-\Delta < \epsilon_t \le 0 \tag{88.9}$$

Magnitude truncation chooses the nearest quantized value that has a magnitude less than or equal to the exact value so

$$-\Delta < \epsilon_{mt} < \Delta \tag{88.10}$$

The error resulting from quantization can be modeled as a random variable uniformly distributed over the appropriate error range. Therefore, calculations with roundoff error can be considered error-free calculations that have been corrupted by additive white noise. The mean of this noise for rounding is

$$m_{\epsilon_r} = E\{\epsilon_r\} = \frac{1}{\Delta}\int_{-\Delta/2}^{\Delta/2} \epsilon_r \, d\epsilon_r = 0 \tag{88.11}$$

where $E\{\ \}$ represents the operation of taking the expected value of a random variable. Similarly, the variance of the noise for rounding is

$$\sigma_{\epsilon_r}^2 = E\left\{\left(\epsilon_r - m_{\epsilon_r}\right)^2\right\} = \frac{1}{\Delta}\int_{-\Delta/2}^{\Delta/2}\left(\epsilon_r - m_{\epsilon_r}\right)^2 \, d\epsilon_r = \frac{\Delta^2}{12} \tag{88.12}$$

Likewise, for truncation,

$$\begin{aligned} m_{\epsilon_t} &= E\{\epsilon_t\} = -\frac{\Delta}{2} \\ \sigma_{\epsilon_t}^2 &= E\left\{\left(\epsilon_t - m_{\epsilon_t}\right)^2\right\} = \frac{\Delta^2}{12} \end{aligned} \tag{88.13}$$

and, for magnitude truncation

$$\begin{aligned} m_{\epsilon_{mt}} &= E\{\epsilon_{mt}\} = 0 \\ \sigma_{\epsilon_{mt}}^2 &= E\left\{\left(\epsilon_{mt} - m_{\epsilon_{mt}}\right)^2\right\} = \frac{\Delta^2}{3} \end{aligned} \tag{88.14}$$

88.3 Floating-Point Quantization Errors

With floating-point arithmetic it is necessary to quantize after both multiplications and additions. The addition quantization arises because, prior to addition, the mantissa of the smaller number in the sum is shifted right until the exponent of both numbers is the same. In general, this gives a sum mantissa that is too long and so must be quantized.

© 2003 by CRC Press LLC

We will assume that quantization in floating-point arithmetic is performed by rounding. Because of the exponent in floating-point arithmetic, it is the relative error that is important. The relative error is defined as

$$\varepsilon_r = \frac{Q_r(X) - X}{X} = \frac{\epsilon_r}{X} \tag{88.15}$$

Since $X = (-1)^s m 2^c$, $Q_r(X) = (-1)^s Q_r(m) 2^c$ and

$$\varepsilon_r = \frac{Q_r(m) - m}{m} = \frac{\epsilon}{m} \tag{88.16}$$

If the quantized mantissa has B bits to the right of the decimal point, $|\epsilon| < \Delta/2$ where, as before, $\Delta = 2^{-B}$. Therefore, since $0.5 \le m < 1$,

$$|\varepsilon_r| < \Delta \tag{88.17}$$

If we assume that ϵ is uniformly distributed over the range from $-\Delta/2$ to $\Delta/2$ and m is uniformly distributed over 0.5 to 1,

$$\begin{aligned} m_{\varepsilon_r} &= E\left\{\frac{\epsilon}{m}\right\} = 0 \\ \sigma^2_{\varepsilon_r} &= E\left\{\left(\frac{\epsilon}{m}\right)^2\right\} = \frac{2}{\Delta}\int_{1/2}^{1}\int_{-\Delta/2}^{\Delta/2}\frac{\epsilon^2}{m^2}\, d\epsilon\, dm \\ &= \frac{\Delta^2}{6} = (0.167)2^{-2B} \end{aligned} \tag{88.18}$$

In practice, the distribution of m is not exactly uniform. Actual measurements of roundoff noise in [1] suggested that

$$\sigma^2_{\varepsilon_r} \approx 0.23\Delta^2 \tag{88.19}$$

while a detailed theoretical and experimental analysis in [2] determined

$$\sigma^2_{\varepsilon_r} \approx 0.18\Delta^2 \tag{88.20}$$

From (88.15) we can represent a quantized floating-point value in terms of the unquantized value and the random variable ε_r using

$$Q_r(X) = X(1 + \varepsilon_r) \tag{88.21}$$

Therefore, the finite-precision product $X_1 X_2$ and the sum $X_1 + X_2$ can be written

$$fl(X_1 X_2) = X_1 X_2(1 + \varepsilon_r) \tag{88.22}$$

and

$$fl(X_1 + X_2) = (X_1 + X_2)(1 + \varepsilon_r) \tag{88.23}$$

where ε_r is zero-mean with the variance of (88.20).

© 2003 by CRC Press LLC

88.4 Roundoff Noise

To determine the roundoff noise at the output of a digital filter we will assume that the noise due to a quantization is stationary, white, and uncorrelated with the filter input, output, and internal variables. This assumption is good if the filter input changes from sample to sample in a sufficiently complex manner. It is not valid for zero or constant inputs for which the effects of rounding are analyzed from a limit cycle perspective.

To satisfy the assumption of a sufficiently complex input, roundoff noise in digital filters is often calculated for the case of a zero-mean white noise filter input signal $x(n)$ of variance σ_x^2. This simplifies calculation of the output roundoff noise because expected values of the form $E\{x(n)x(n-k)\}$ are zero for $k \neq 0$ and give σ_x^2 when $k = 0$. This approach to analysis has been found to give estimates of the output roundoff noise that are close to the noise actually observed for other input signals.

Another assumption that will be made in calculating roundoff noise is that the product of two quantization errors is zero. To justify this assumption, consider the case of a 16-b fixed-point processor. In this case a quantization error is of the order 2^{-15}, while the product of two quantization errors is of the order 2^{-30}, which is negligible by comparison.

If a linear system with impulse response $g(n)$ is excited by white noise with mean m_x and variance σ_x^2, the output is noise of mean [3, pp. 788–790]

$$m_y = m_x \sum_{n=-\infty}^{\infty} g(n) \tag{88.24}$$

and variance

$$\sigma_y^2 = \sigma_x^2 \sum_{n=-\infty}^{\infty} g^2(n) \tag{88.25}$$

Therefore, if $g(n)$ is the impulse response from the point where a roundoff takes place to the filter output, the contribution of that roundoff to the variance (mean-square value) of the output roundoff noise is given by (88.25) with σ_x^2 replaced with the variance of the roundoff. If there is more than one source of roundoff error in the filter, it is assumed that the errors are uncorrelated so the output noise variance is simply the sum of the contributions from each source.

Roundoff Noise in FIR Filters

The simplest case to analyze is a finite impulse response (FIR) filter realized via the convolution summation

$$y(n) = \sum_{k=0}^{N-1} h(k)x(n-k) \tag{88.26}$$

When fixed-point arithmetic is used and quantization is performed after each multiply, the result of the N multiplies is N-times the quantization noise of a single multiply. For example, rounding after each multiply gives, from (88.6) and (88.12), an output noise variance of

$$\sigma_o^2 = N\frac{2^{-2B}}{12} \tag{88.27}$$

Virtually all digital signal processor integrated circuits contain one or more double-length accumulator registers which permit the sum-of-products in (88.26) to be accumulated without quantization. In this case only a single quantization is necessary following the summation and

© 2003 by CRC Press LLC

$$\sigma_o^2 = \frac{2^{-2B}}{12} \tag{88.28}$$

For the floating-point roundoff noise case we will consider (88.26) for $N = 4$ and then generalize the result to other values of N. The finite-precision output can be written as the exact output plus an error term $e(n)$. Thus,

$$\begin{aligned} y(n)+e(n) = \Big(\Big\{\Big[h(0)x(n)\Big[1+\varepsilon_1(n)\Big] \\ + h(1)x(n-1)\Big[1+\varepsilon_2(n)\Big]\Big[1+\varepsilon_3(n)\Big] \\ + h(2)x(n-2)\Big[1+\varepsilon_4(n)\Big]\Big\}\Big\{1+\varepsilon_5(n)\Big\} \\ + h(3)x(n-3)\Big[1+\varepsilon_6(n)\Big]\Big)\Big[1+\varepsilon_7(n)\Big] \end{aligned} \tag{88.29}$$

In (88.29), $\varepsilon_1(n)$ represents the error in the first product, $\varepsilon_2(n)$ the error in the second product, $\varepsilon_3(n)$ the error in the first addition, etc. Notice that it has been assumed that the products are summed in the order implied by the summation of (88.26).

Expanding (88.29), ignoring products of error terms, and recognizing $y(n)$ gives

$$\begin{aligned} e(n) = h(0)x(n)\Big[\varepsilon_1(n)+\varepsilon_3(n)+\varepsilon_5(n)+\varepsilon_7(n)\Big] \\ + h(1)x(n-1)\Big[\varepsilon_2(n)+\varepsilon_3(n)+\varepsilon_5(n)+\varepsilon_7(n)\Big] \\ + h(2)x(n-2)\Big[\varepsilon_4(n)+\varepsilon_5(n)+\varepsilon_7(n)\Big] \\ + h(3)x(n-3)\Big[\varepsilon_6(n)+\varepsilon_7(n)\Big] \end{aligned} \tag{88.30}$$

Assuming that the input is white noise of variance σ_x^2 so that $E\{x(n)x(n-k)\}$ is zero for $k \neq 0$, and assuming that the errors are uncorrelated,

$$E\Big\{e^2(n)\Big\} = \Big[4h^2(0)+4h^2(1)+3h^2(2)+2h^2(3)\Big]\sigma_x^2\sigma_{\varepsilon_r}^2 \tag{88.31}$$

In general, for any N,

$$\sigma_o^2 = E\Big\{e^2(n)\Big\} = \left[Nh^2(0)+\sum_{k=1}^{N-1}(N+1-k)h^2(k)\right]\sigma_x^2\sigma_{\varepsilon_r}^2 \tag{88.32}$$

Notice that if the order of summation of the product terms in the convolution summation is changed, then the order in which the $h(k)$'s appear in (88.32) changes. If the order is changed so that the $h(k)$ with smallest magnitude is first, followed by the next smallest, etc., then the roundoff noise variance is minimized. However, performing the convolution summation in nonsequential order greatly complicates data indexing and so may not be worth the reduction obtained in roundoff noise.

Roundoff Noise in Fixed-Point IIR Filters

To determine the roundoff noise of a fixed-point infinite impulse response (IIR) filter realization, consider a causal first-order filter with impulse response

$$h(n) = a^n u(n) \tag{88.33}$$

© 2003 by CRC Press LLC

realized by the difference equation

$$y(n) = ay(n-1) + x(n) \tag{88.34}$$

Due to roundoff error, the output actually obtained is

$$\hat{y}(n) = Q\{ay(n-1) + x(n)\} = ay(n-1) + x(n) + e(n) \tag{88.35}$$

where $e(n)$ is a random roundoff noise sequence. Since $e(n)$ is injected at the same point as the input, it propagates through a system with impulse response $h(n)$. Therefore, for fixed-point arithmetic with rounding, the output roundoff noise variance from (88.6), (88.12), (88.25), and (88.33) is

$$\sigma_o^2 = \frac{\Delta^2}{12}\sum_{n=-\infty}^{\infty} h^2(n) = \frac{\Delta^2}{12}\sum_{n=0}^{\infty} a^{2n} = \frac{2^{-2B}}{12}\frac{1}{1-a^2} \tag{88.36}$$

With fixed-point arithmetic there is the possibility of overflow following addition. To avoid overflow it is necessary to restrict the input signal amplitude. This can be accomplished by either placing a *scaling* multiplier at the filter input or by simply limiting the maximum input signal amplitude. Consider the case of the first-order filter of (88.34). The transfer function of this filter is

$$H(e^{j\omega}) = \frac{Y(e^{j\omega})}{X(e^{j\omega})} = \frac{1}{e^{j\omega} - a} \tag{88.37}$$

so

$$\left|H(e^{j\omega})\right|^2 = \frac{1}{1 + a^2 - 2a\cos(\omega)} \tag{88.38}$$

and

$$\left|H(e^{j\omega})\right|_{\max} = \frac{1}{1-|a|} \tag{88.39}$$

The peak gain of the filter is $1/(1 - |a|)$ so limiting input signal amplitudes to $|x(n)| \le 1 - |a|$ will make overflows unlikely.

An expression for the output roundoff noise-to-signal ratio can easily be obtained for the case where the filter input is white noise, uniformly distributed over the interval from $-(1 - |a|)$ to $(1 - |a|)$ [4], [5]. In this case

$$\sigma_x^2 = \frac{1}{2(1-|a|)}\int_{-(1-|a|)}^{1-|a|} x^2 dx = \frac{1}{3}(1-|a|)^2 \tag{88.40}$$

so, from (88.25),

$$\sigma_y^2 = \frac{1}{3}\frac{(1-|a|)^2}{1-a^2} \tag{88.41}$$

Combining (88.36) and (88.41) then gives

$$\frac{\sigma_o^2}{\sigma_y^2} = \left(\frac{2^{-2B}}{12}\frac{1}{1-a^2}\right)\left(3\frac{1-a^2}{(1-|a|)^2}\right) = \frac{2^{-2B}}{12}\frac{3}{(1-|a|)^2} \tag{88.42}$$

Notice that the noise-to-signal ratio increases without bound as $|a| \to 1$.

© 2003 by CRC Press LLC

Similar results can be obtained for the case of the causal second-order filter realized by the difference equation

$$y(n) = 2r\cos(\theta)y(n-1) - r^2 y(n-2) + x(n) \tag{88.43}$$

This filter has complex-conjugate poles at $re^{\pm j\theta}$ and impulse response

$$h(n) = \frac{1}{\sin(\theta)} r^n \sin\left[(n+1)\theta\right] u(n) \tag{88.44}$$

Due to roundoff error, the output actually obtained is

$$\hat{y}(n) = 2r\cos(\theta)y(n-1) - r^2 y(n-2) + x(n) + e(n) \tag{88.45}$$

There are two noise sources contributing to $e(n)$ if quantization is performed after each multiply, and there is one noise source if quantization is performed after summation. Since

$$\sum_{n=-\infty}^{\infty} h^2(n) = \frac{1+r^2}{1-r^2} \frac{1}{\left(1+r^2\right)^2 - 4r^2\cos^2(\theta)} \tag{88.46}$$

the output roundoff noise is

$$\sigma_o^2 = \nu \frac{2^{-2B}}{12} \frac{1+r^2}{1-r^2} \frac{1}{\left(1+r^2\right)^2 - 4r^2\cos^2(\theta)} \tag{88.47}$$

where $\nu = 1$ for quantization after summation, and $\nu = 2$ for quantization after each multiply.

To obtain an output noise-to-signal ratio we note that

$$H\left(e^{j\omega}\right) = \frac{1}{1 - 2r\cos(\theta)e^{-j\omega} + r^2 e^{-j2\omega}} \tag{88.48}$$

and, using the approach of [6],

$$\left|H\left(e^{j\omega}\right)\right|^2_{\max} = \frac{1}{4r^2\left\{\left[\text{sat}\left(\frac{1+r^2}{2r}\cos(\theta)\right) - \frac{1+r^2}{2r}\cos(\theta)\right]^2 + \left[\frac{1-r^2}{2r}\sin(\theta)\right]^2\right\}} \tag{88.49}$$

where

$$\text{sat}(\mu) = \begin{cases} 1 & \mu > 1 \\ \mu & -1 \le \mu \le 1 \\ -1 & \mu < -1 \end{cases} \tag{88.50}$$

Following the same approach as for the first-order case then gives

$$\frac{\sigma_o^2}{\sigma_y^2} = \nu \frac{2^{-2B}}{12} \frac{1+r^2}{1-r^2} \frac{3}{\left(1+r^2\right)^2 - 4r^2\cos^2(\theta)} \times \frac{1}{4r^2\left\{\left[\text{sat}\left(\frac{1+r^2}{2r}\cos(\theta)\right) - \frac{1+r^2}{2r}\cos(\theta)\right]^2 + \left[\frac{1-r^2}{2r}\sin(\theta)\right]^2\right\}} \tag{88.51}$$

© 2003 by CRC Press LLC

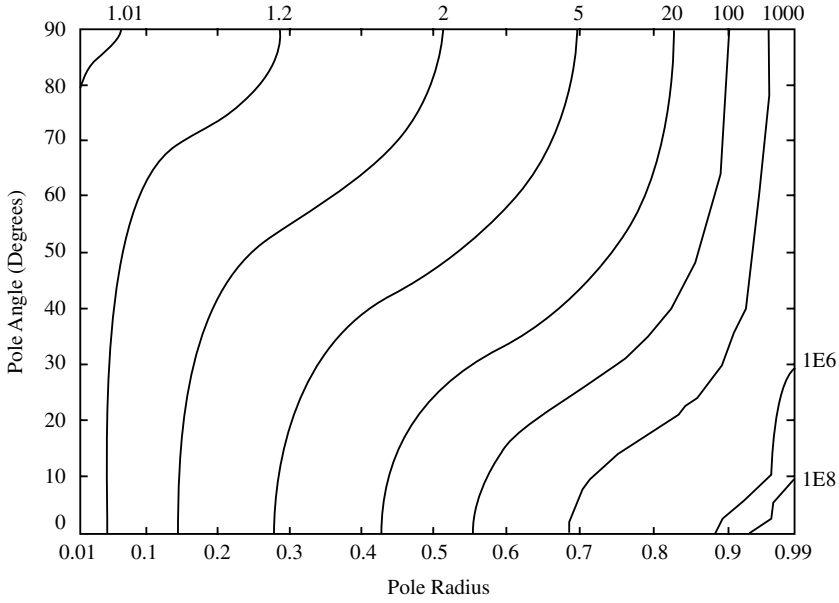

FIGURE 88.1 Normalized fixed-point roundoff noise variance.

Figure 88.1 is a contour plot showing the noise-to-signal ratio of (88.51) for $\nu = 1$ in units of the noise variance of a single quantization $2^{-2B}/12$. The plot is symmetrical about $\theta = 90°$, so only the range from 0° to 90° is shown. Notice that as $r \to 1$, the roundoff noise increases without bound. Also notice that the noise increases as $\theta \to 0°$.

It is possible to design state-space filter realizations that minimize fixed-point roundoff noise [7]–[10]. Depending on the transfer function being realized, these structures may provide a roundoff noise level that is orders-of-magnitude lower than for a nonoptimal realization. The price paid for this reduction in roundoff noise is an increase in the number of computations required to implement the filter. For an Nth-order filter the increase is from roughly $2N$ multiplies for a direct form realization to roughly $(N + 1)^2$ for an optimal realization. However, if the filter is realized by the parallel or cascade connection of first- and second-order optimal subfilters, the increase is only to about $4N$ multiplies. Furthermore, near-optimal realizations exist that increase the number of multiplies to only about $3N$ [10].

Roundoff Noise in Floating-Point IIR Filters

For floating-point arithmetic it is first necessary to determine the injected noise variance of each quantization. For the first-order filter this is done by writing the computed output as

$$y(n) + e(n) = \left[ay(n-1)\left(1+\varepsilon_1(n)\right) + x(n)\right]\left(1+\varepsilon_2(n)\right) \tag{88.52}$$

where $\varepsilon_1(n)$ represents the error due to the multiplication and $\varepsilon_2(n)$ represents the error due to the addition. Neglecting the product of errors, (88.52) becomes

$$\begin{aligned} y(n) + e(n) \approx{}& ay(n-1) + x(n) + ay(n-1)\varepsilon_1(n) \\ &+ ay(n-1)\varepsilon_2(n) + x(n)\varepsilon_2(n) \end{aligned} \tag{88.53}$$

Comparing (88.34) and (88.53), it is clear that

$$e(n) = ay(n-1)\varepsilon_1(n) + ay(n-1)\varepsilon_2(n) + x(n)\varepsilon_2(n) \tag{88.54}$$

© 2003 by CRC Press LLC

Taking the expected value of $e^2(n)$ to obtain the injected noise variance then gives

$$\begin{aligned} E\{e^2(n)\} &= a^2 E\{y^2(n-1)\}E\{\varepsilon_1^2(n)\} + a^2 E\{y^2(n-1)\}E\{\varepsilon_2^2(n)\} \\ &\quad + E\{x^2(n)\}E\{\varepsilon_2^2(n)\} + E\{x(n)y(n-1)\}E\{\varepsilon_2^2(n)\} \end{aligned} \tag{88.55}$$

To carry this further it is necessary to know something about the input. If we assume the input is zero-mean white noise with variance σ_x^2, then $E\{x^2(n)\} = \sigma_x^2$ and the input is uncorrelated with past values of the output so $E\{x(n)y(n-1)\} = 0$ giving

$$E\{e^2(n)\} = 2a^2\sigma_y^2\sigma_{\varepsilon_r}^2 + \sigma_x^2\sigma_{\varepsilon_r}^2 \tag{88.56}$$

and

$$\begin{aligned} \sigma_o^2 &= \left(2a^2\sigma_y^2\sigma_{\varepsilon_r}^2 + \sigma_x^2\sigma_{\varepsilon_r}^2\right)\sum_{n=-\infty}^{\infty} h^2(n) \\ &= \frac{2a^2\sigma_y^2 + \sigma_x^2}{1-a^2}\sigma_{\varepsilon_r}^2 \end{aligned} \tag{88.57}$$

However,

$$\sigma_y^2 = \sigma_x^2\sum_{n=-\infty}^{\infty} h^2(n) = \frac{\sigma_x^2}{1-a^2} \tag{88.58}$$

$$\sigma_o^2 = \frac{1+a^2}{\left(1-a^2\right)^2}\sigma_{\varepsilon_r}^2\sigma_x^2 = \frac{1+a^2}{1-a^2}\sigma_{\varepsilon_r}^2\sigma_y^2 \tag{88.59}$$

and the output roundoff noise-to-signal ratio is

$$\frac{\sigma_o^2}{\sigma_y^2} = \frac{1+a^2}{1-a^2}\sigma_{\varepsilon_r}^2 \tag{88.60}$$

Similar results can be obtained for the second-order filter of (88.43) by writing

$$\begin{aligned} y(n) + e(n) &= \left(\left[2r\cos(\theta)y(n-1)\left(1+\varepsilon_1(n)\right) - r^2 y(n-2)\left(1+\varepsilon_2(n)\right)\right]\right. \\ &\quad \left.\times\left[1+\varepsilon_3(n)\right] + x(n)\right)\left(1+\varepsilon_4(n)\right) \end{aligned} \tag{88.61}$$

Expanding with the same assumptions as before gives

$$\begin{aligned} e(n) &\approx 2r\cos(\theta)y(n-1)\left[\varepsilon_1(n) + \varepsilon_3(n) + \varepsilon_4(n)\right] \\ &\quad - r^2 y(n-2)\left[\varepsilon_2(n) + \varepsilon_3(n) + \varepsilon_4(n)\right] + x(n)\varepsilon_4(n) \end{aligned} \tag{88.62}$$

and

$$\begin{aligned} E\{e^2(n)\} &= 4r^2\cos^2(\theta)\sigma_y^2\sigma_{\varepsilon_r}^2 + r^2\sigma_y^2 3\sigma_{\varepsilon_r}^2 \\ &\quad + \sigma_x^2\sigma_{\varepsilon_r}^2 - 8r^3\cos(\theta)\sigma_{\varepsilon_r}^2 E\{y(n-1)y(n-2)\} \end{aligned} \tag{88.63}$$

© 2003 by CRC Press LLC

However,

$$\begin{aligned} &E\{y(n-1)y(n-2)\} \\ &= E\{2r\cos(\theta)y(n-2) - r^2 y(n-3) + x(n-1)]y(n-2)\} \\ &= 2r\cos(\theta)E\{y^2(n-2)\} - r^2 E\{y(n-2)y(n-3)\} \\ &= 2r\cos(\theta)E\{y^2(n-2)\} - r^2 E\{y(n-1)y(n-2)\} \\ &= \frac{2r\cos(\theta)}{1+r^2}\sigma_y^2 \end{aligned} \tag{88.64}$$

so

$$E\{e^2(n)\} = \sigma_{\varepsilon_r}^2\sigma_x^2 + \left[3r^4 + 12r^2\cos^2(\theta) - \frac{16r^4\cos^2(\theta)}{1+r^2}\right]\sigma_{\varepsilon_r}^2\sigma_y^2 \tag{88.65}$$

and

$$\begin{aligned} \sigma_o^2 &= E(n)\sum_{n=-\infty}^{\infty} h^2(n) \\ &= \xi\left[\sigma_{\varepsilon_r}^2\sigma_x^2 + \left[3r^4 + 12r^2\cos^2(\theta) - \frac{16r^4\cos^2(\theta)}{1+r^2}\right]\sigma_{\varepsilon_r}^2\sigma_y^2\right] \end{aligned} \tag{88.66}$$

where from (88.46),

$$\xi = \sum_{n=-\infty}^{\infty} h^2(n) = \frac{1+r^2}{1-r^2}\,\frac{1}{\left(1+r^2\right)^2 - 4r^2\cos^2(\theta)} \tag{88.67}$$

Since $\sigma_y^2 = \xi\sigma_x^2$, the output roundoff noise-to-signal ratio is then

$$\frac{\sigma_o^2}{\sigma_y^2} = \xi\left[1 + \xi\left[3r^4 + 12r^2\cos^2(\theta) - \frac{16r^4\cos^2(\theta)}{1+r^2}\right]\right]\sigma_{\varepsilon_r}^2 \tag{88.68}$$

Figure 88.2 is a contour plot showing the noise-to-signal ratio of (88.68) in units of the noise variance of a single quantization $\sigma_{\varepsilon_r}^2$. The plot is symmetrical about $\theta = 90°$, so only the range from 0° to 90° is shown. Notice the similarity of this plot to that of Fig. 88.1 for the fixed-point case. It has been observed that filter structures generally have very similar fixed-point and floating-point roundoff characteristics [2]. Therefore, the techniques of [7]–[10], which were developed for the fixed-point case, can also be used to design low-noise floating-point filter realizations. Furthermore, since it is not necessary to scale the floating-point realization, the low-noise realizations need not require significantly more computation than the direct form realization.

88.5 Limit Cycles

A limit cycle, sometimes referred to as a **multiplier roundoff limit cycle**, is a low-level oscillation that can exist in an otherwise stable filter as a result of the nonlinearity associated with rounding (or truncating) internal filter calculations. [11]. Limit cycles require recursion to exist and do not occur in nonrecursive FIR filters.

© 2003 by CRC Press LLC

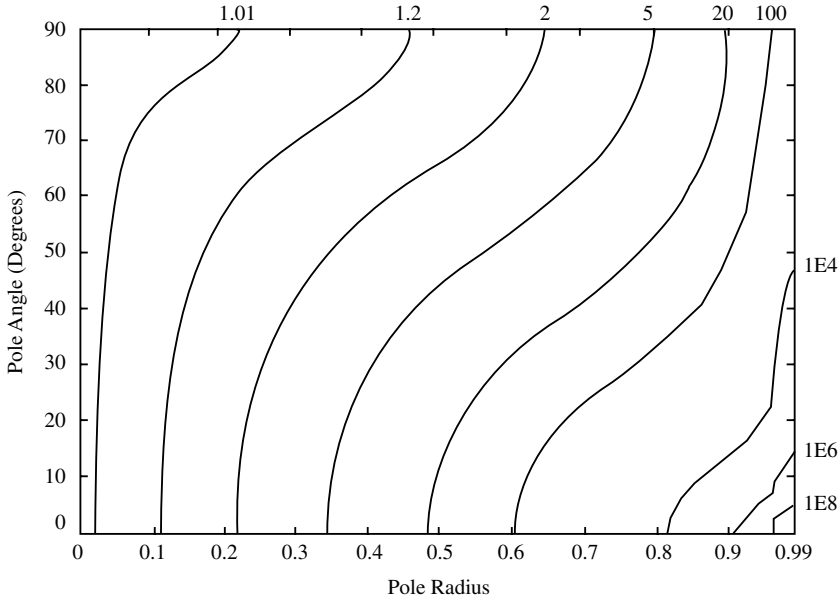

FIGURE 88.2 Normalized floating-point roundoff noise variance.

As an example of a limit cycle, consider the second-order filter realized by

$$y(n) = Q_r\left\{\frac{7}{8}y(n-1) - \frac{5}{8}y(n-2) + x(n)\right\} \tag{88.69}$$

where $Q_r\{\ \}$ represents quantization by rounding. This is a stable filter with poles at $0.4375 \pm j0.6585$. Consider the implementation of this filter with 4-b (3 b and a sign bit) two's complement fixed-point arithmetic, zero initial conditions ($y(-1) = y(-2) = 0$), and an input sequence $x(n) = \frac{3}{8}\delta(n)$, where $\delta(n)$ is the unit impulse or unit sample. The following sequence is obtained:

$$\begin{aligned}
y(0) &= Q_r\left\{\frac{3}{8}\right\} = \frac{3}{8} \\
y(1) &= Q_r\left\{\frac{21}{64}\right\} = \frac{3}{8} \\
y(2) &= Q_r\left\{\frac{3}{32}\right\} = \frac{1}{8} \\
y(3) &= Q_r\left\{-\frac{1}{8}\right\} = -\frac{1}{8} \\
y(4) &= Q_r\left\{-\frac{3}{16}\right\} = -\frac{1}{8} \\
y(5) &= Q_r\left\{-\frac{1}{32}\right\} = 0 \\
y(6) &= Q_r\left\{\frac{5}{64}\right\} = \frac{1}{8}
\end{aligned} \tag{88.70}$$

© 2003 by CRC Press LLC

$$y(7) = Q_r\left\{\frac{7}{64}\right\} = \frac{1}{8}$$

$$y(8) = Q_r\left\{\frac{1}{32}\right\} = 0$$

$$y(9) = Q_r\left\{-\frac{5}{64}\right\} = -\frac{1}{8}$$

$$y(10) = Q_r\left\{-\frac{7}{64}\right\} = -\frac{1}{8}$$

$$y(10) = Q_r\left\{-\frac{1}{32}\right\} = 0$$

$$y(12) = Q_r\left\{\frac{5}{64}\right\} = \frac{1}{8}$$

$$\vdots$$

Notice that while the input is zero except for the first sample, the output oscillates with amplitude 1/8 and period 6.

Limit cycles are primarily of concern in fixed-point recursive filters. As long as floating-point filters are realized as the parallel or cascade connection of first- and second-order subfilters, limit cycles will generally not be a problem since limit cycles are practically not observable in first- and second-order systems implemented with 32-b floating-point arithmetic [12]. It has been shown that such systems must have an extremely small margin of stability for limit cycles to exist at anything other than underflow levels, which are at an amplitude of less than 10^{-38} [12].

There are at least three ways of dealing with limit cycles when fixed-point arithmetic is used. One is to determine a bound on the maximum limit cycle amplitude, expressed as an integral number of quantization steps [13]. It is then possible to choose a word length that makes the limit cycle amplitude acceptably low. Alternately, limit cycles can be prevented by randomly rounding calculations up or down [14]. However, this approach is complicated to implement. The third approach is to properly choose the filter realization structure and then quantize the filter calculations using magnitude truncation [15], [16]. This approach has the disadvantage of producing more roundoff noise than truncation or rounding [see (88.12)–(88.14)].

88.6 Overflow Oscillations

With fixed-point arithmetic it is possible for filter calculations to overflow. This happens when two numbers of the same sign add to give a value having magnitude greater than one. Since numbers with magnitude greater than one are not representable, the result overflows. For example, the two's complement numbers 0.101 (5/8) and 0.100 (4/8) add to give 1.001 which is the two's complement representation of –7/8.

The overflow characteristic of two's complement arithmetic can be represented as $R\{\ \}$ where

$$R\{X\} = \begin{cases} X-2 & X \geq 1 \\ X & -1 \leq X < -1 \\ X+2 & X < -1 \end{cases} \tag{88.71}$$

For the example just considered, $R\{9/8\} = -7/8$.

© 2003 by CRC Press LLC

An overflow oscillation, sometimes also referred to as an *adder overflow limit cycle,* is a high-level oscillation that can exist in an otherwise stable fixed-point filter due to the gross nonlinearity associated with the overflow of internal filter calculations [17]. Like limit cycles, overflow oscillations require recursion to exist and do not occur in nonrecursive FIR filters. Overflow oscillations also do not occur with floating-point arithmetic due to the virtual impossibility of overflow.

As an example of an overflow oscillation, once again consider the filter of (88.69) with 4-b fixed-point two's complement arithmetic and with the two's complement overflow characteristic of (88.71):

$$y(n) = Q_r\left\{R\left[\frac{7}{8}y(n-1) - \frac{5}{8}y(n-2) + x(n)\right]\right\} \tag{88.72}$$

In this case we apply the input

$$\begin{aligned} x(n) &= -\frac{3}{4}\delta(n) - \frac{5}{8}\delta(n-1) \\ &= \left\{-\frac{3}{4}, -\frac{5}{8}, 0, 0, \ldots\right\}, \end{aligned} \tag{88.73}$$

giving the output sequence

$$\begin{aligned} y(0) &= Q_r\left\{R\left[-\frac{3}{4}\right]\right\} = Q_r\left\{-\frac{3}{4}\right\} = -\frac{3}{4} \\ y(1) &= Q_r\left\{R\left[-\frac{41}{32}\right]\right\} = Q_r\left\{\frac{23}{32}\right\} = \frac{3}{4} \\ y(2) &= Q_r\left\{R\left[\frac{9}{8}\right]\right\} = Q_r\left\{-\frac{7}{8}\right\} = -\frac{7}{8} \\ y(3) &= Q_r\left\{R\left[-\frac{79}{64}\right]\right\} = Q_r\left\{\frac{49}{64}\right\} = \frac{3}{4} \\ y(4) &= Q_r\left\{R\left[\frac{77}{64}\right]\right\} = Q_r\left\{-\frac{51}{64}\right\} = -\frac{3}{4} \\ y(5) &= Q_r\left\{R\left[-\frac{9}{8}\right]\right\} = Q_r\left\{\frac{7}{8}\right\} = \frac{7}{8} \\ y(6) &= Q_r\left\{R\left[\frac{79}{64}\right]\right\} = Q_r\left\{\frac{-49}{64}\right\} = -\frac{3}{4} \\ y(7) &= Q_r\left\{R\left[-\frac{77}{64}\right]\right\} = Q_r\left\{\frac{51}{64}\right\} = \frac{3}{4} \\ y(8) &= Q_r\left\{R\left[\frac{9}{8}\right]\right\} = Q_r\left\{-\frac{7}{8}\right\} = -\frac{7}{8} \\ &\vdots \end{aligned} \tag{88.74}$$

This is a large-scale oscillation with nearly full-scale amplitude.

© 2003 by CRC Press LLC

There are several ways to prevent overflow oscillations in fixed-point filter realizations. The most obvious is to scale the filter calculations so as to render overflow impossible. However, this may unacceptably restrict the filter dynamic range. Another method is to force completed sums-of-products to saturate at ±1, rather than overflowing [18], [19]. It is important to saturate only the completed sum, since intermediate overflows in two's complement arithmetic do not affect the accuracy of the final result. Most fixed-point digital signal processors provide for automatic saturation of completed sums if their *saturation arithmetic* feature is enabled. Yet another way to avoid overflow oscillations is to use a filter structure for which any internal filter transient is guaranteed to decay to zero [20]. Such structures are desirable anyway, since they tend to have low roundoff noise and be insensitive to coefficient quantization [21].

88.7 Coefficient Quantization Error

Each filter structure has its own finite, generally nonuniform grids of realizable pole and zero locations when the filter coefficients are quantized to a finite word length. In general the pole and zero locations desired in a filter do not correspond exactly to the realizable locations. The error in filter performance (usually measured in terms of a frequency response error) resulting from the placement of the poles and zeros at the nonideal but realizable locations is referred to as coefficient quantization error.

Consider the second-order filter with complex-conjugate poles

$$\begin{aligned}\lambda &= re^{\pm j\theta} \\ &= \lambda_r \pm j\lambda_i \\ &= r\cos(\theta) \pm jr\sin(\theta)\end{aligned} \tag{88.75}$$

and transfer function

$$H(z) = \frac{1}{1-2r\cos(\theta)z^{-1}+r^2z^{-2}} \tag{88.76}$$

realized by the difference equation

$$y(n) = 2r\cos(\theta)y(n-1) - r^2y(n-2) + x(n) \tag{88.77}$$

Figure 88.3 from [5] shows that quantizing the difference equation coefficients results in a nonuniform grid of realizable pole locations in the z plane. The grid is defined by the intersection of vertical lines corresponding to quantization of $2\lambda_r$ and concentric circles corresponding to quantization of $-r^2$. The sparseness of realizable pole locations near $z = \pm 1$ will result in a large coefficient quantization error for poles in this region.

Figure 88.4 gives an alternative structure to (88.77) for realizing the transfer function of (88.76). Notice that quantizing the coefficients of this structure corresponds to quantizing λ_r and λ_i. As shown in Fig. 88.5 from [5], this results in a uniform grid of realizable pole locations. Therefore, large coefficient quantization errors are avoided for all pole locations.

It is well established that filter structures with low roundoff noise tend to be robust to coefficient quantization, and vice versa [22]–[24]. For this reason, the uniform grid structure of Fig. 88.4 is also popular because of its low roundoff noise. Likewise, the low-noise realizations of [7]–[10] can be expected to be relatively insensitive to coefficient quantization, and digital wave filters and lattice filters that are derived from low-sensitivity analog structures tend to have not only low coefficient sensitivity, but also low roundoff noise [25], [26].

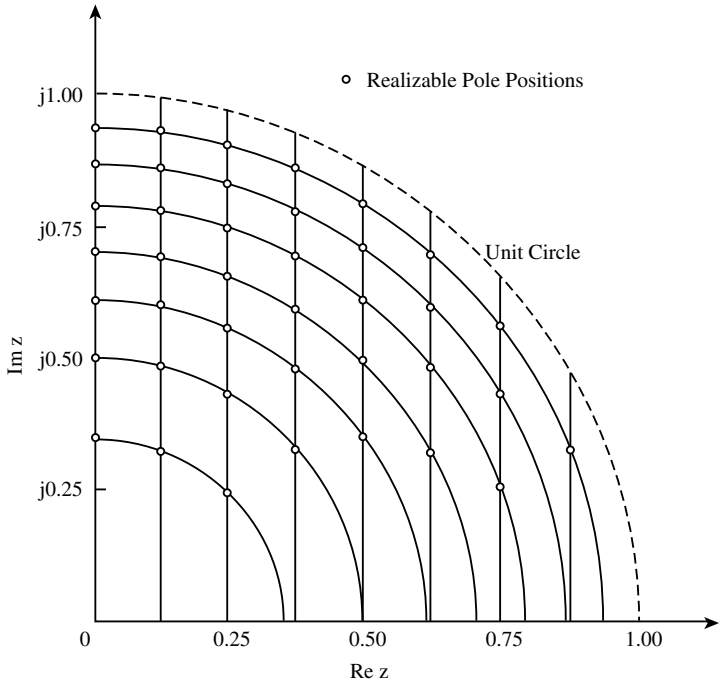

FIGURE 88.3 Realizable pole locations for the difference equation of (88.76).

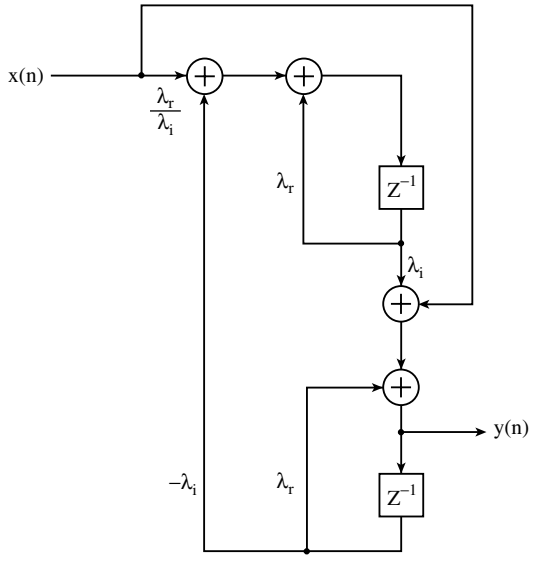

FIGURE 88.4 Alternate realization structure.

It is well known that in a high-order polynomial with clustered roots, the root location is a very sensitive function of the polynomial coefficients. Therefore, filter poles and zeros can be much more accurately controlled if higher order filters are realized by breaking them up into the parallel or cascade connection of first- and second-order subfilters. One exception to this rule is the case of linear-phase

© 2003 by CRC Press LLC

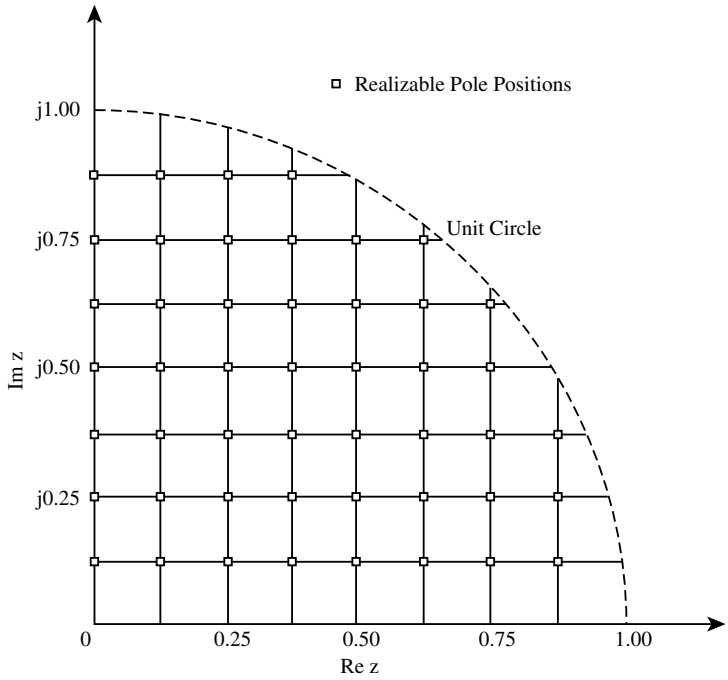

FIGURE 88.5 Realizable pole locations for the alternate realization structure.

FIR filters in which the symmetry of the polynomial coefficients and the spacing of the filter zeros around the unit circle usually permits an acceptable direct realization using the convolution summation.

Given a filter structure it is necessary to assign the ideal pole and zero locations to the realizable locations. This is generally done by simply rounding or truncating the filter coefficients to the available number of bits, or by assigning the ideal pole and zero locations to the nearest realizable locations. A more complicated alternative is to consider the original filter design problem as a problem in discrete optimization, and choose the realizable pole and zero locations that give the best approximation to the desired filter response [27]–[30].

88.8 Realization Considerations

Linear-phase FIR digital filters can generally be implemented with acceptable coefficient quantization sensitivity using the direct convolution sum method. When implemented in this way on a digital signal processor, fixed-point arithmetic is not only acceptable but may actually be preferable to floating-point arithmetic. Virtually all fixed-point digital signal processors accumulate a sum of products in a double-length accumulator. This means that only a single quantization is necessary to compute an output. Floating-point arithmetic, on the other hand, requires a quantization after every multiply and after every add in the convolution summation. With 32-b floating-point arithmetic these quantizations introduce a small enough error to be insignificant for many applications.

When realizing IIR filters, either a parallel or cascade connection of first- and second-order subfilters is almost always preferable to a high-order direct-form realization. With the availability of very low-cost floating-point digital signal processors, like the Texas Instruments TMS320C32, it is highly recommended that floating-point arithmetic be used for IIR filters. Floating-point arithmetic simultaneously eliminates most concerns regarding scaling, limit cycles, and overflow oscillations. Regardless of the arithmetic employed, a low roundoff noise structure should be used for the second-order sections. Good choices are given in [2] and [10]. Recall that realizations with low fixed-point roundoff noise also have low

© 2003 by CRC Press LLC

floating-point roundoff noise. The use of a low roundoff noise structure for the second-order sections also tends to give a realization with low coefficient quantization sensitivity. First-order sections are not as critical in determining the roundoff noise and coefficient sensitivity of a realization, and so can generally be implemented with a simple direct form structure.

89.1 Introduction

In this chapter, we present the theory and design of *aliasing-free* and *perfect-reconstruction* filter banks. Section 89.2 covers the fundamentals of multirate systems including downsampling/upsampling, delay chains, serial-parallel/parallel-serial converters, polyphase representations, noble identities, decimation, and interpolation filters. These multirate components are essential in the theory and implementation of filter banks.

The basic operations of and the reconstruction errors in a maximally decimated uniform filter bank are discussed in Section 89.3. By using the polyphase representation, the necessary and sufficient conditions for aliasing-free filter banks are given in Section 89.3. Moreover, several examples of alias-free filter banks such as the two-channel quadrature-mirror-filter (QMF) bank, the two-channel allpass-based IIR filter bank, and the *M*-channel DFT filter bank are elaborated in detail.

Section 89.4 presents the theory and lattice structures for perfect-reconstruction (PR) filter banks. The section is divided into three subsections: paraunitary filter bank, linear-phase filter bank, and cosine-modulated filter bank.

The design methods for filter banks are discussed in Section 89.5. The first subsection considers the design method based on lattice structure realization and the next subsection presents an alternative method based on filter coefficients in the form of quadratic-constrained least-squares (QCLS) optimization.

Compactly supported wavelet is closely related to the two-channel filter bank. It can be obtained by iterating on a two-channel digital filter bank. Chapter 4 discusses this relation in detail. Other issues on wavelets such as regularity, maximally flat filter, tight frames, M-band wavelets, wavelet packets, etc. are also presented in Chapter 4.

Notations. The variable ω is used as the frequency variable, whereas the term "normalized frequency" is used to denote $f = \omega/2\pi$. Boldfaced quantities denote matrices and column vectors, with upper case used for the former and lower case for the latter, as in **A**, **h**(z), etc. The superscripts (T) and $(^\dagger)$ stand for matrix transposition and transposition with coefficient conjugation, respectively. $\tilde{\mathbf{E}}(z) = \mathbf{E}^\dagger(z^{-1})$. The k by k identity matrix is denoted $\mathbf{I}_k$ and the exchange matrix **J** is defined to be

$$\mathbf{J} = \begin{pmatrix} 0 & \cdots & 0 & 1 \\ 0 & \cdots & 1 & 0 \\ \vdots & \iddots & \vdots & \vdots \\ 1 & \cdots & 0 & 0 \end{pmatrix}$$

89.2 Fundamentals of a Multirate System

Downsampling [26], [29]

Figure 89.1 shows the block diagram of a downsampler by a factor of M. The output signal $y_D(n)$ in terms of $x(n)$ is

$$\begin{cases} y_D(n) = x(nM) \\ Y_D(z) = \dfrac{1}{M}\displaystyle\sum_{k=0}^{M-1} X\left(z^{1/M} W_M^k\right) \qquad W_M = e^{-j2\pi/M} \\ Y_D\left(e^{j\omega}\right) = \dfrac{1}{M}\displaystyle\sum_{k=0}^{M-1} X\left(e^{(j/M)(\omega - 2\pi k)}\right) \end{cases} \tag{89.1}$$

It is clear from the above expression that the output of a downsampler has M copies of the *stretched* input spectrum. The first term in the summation is the input spectrum $X(e^{j(\omega/M)})$ $(k = 0)$ and the remaining $(M - 1)$ terms are the aliased versions of $X(e^{j(\omega/M)})$, $1 \le k \le M - 1$. If the input spectrum

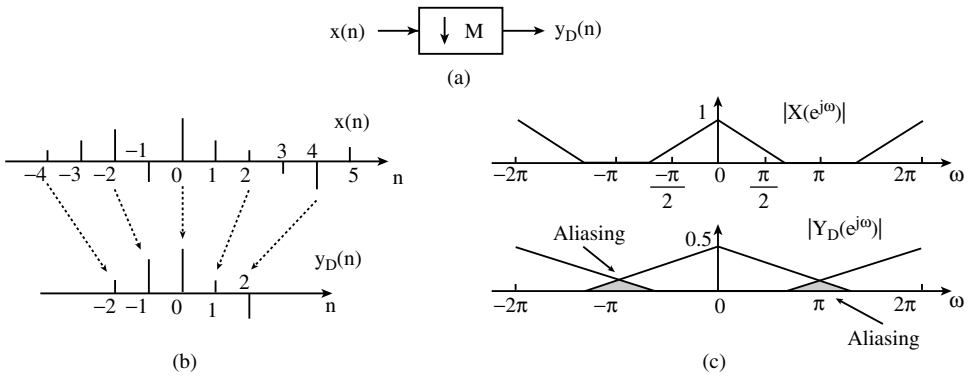

FIGURE 89.1 Downsampling: (a) Block diagram; (b), (c) time and frequency-domain example for $M = 2$.

© 2003 by CRC Press LLC

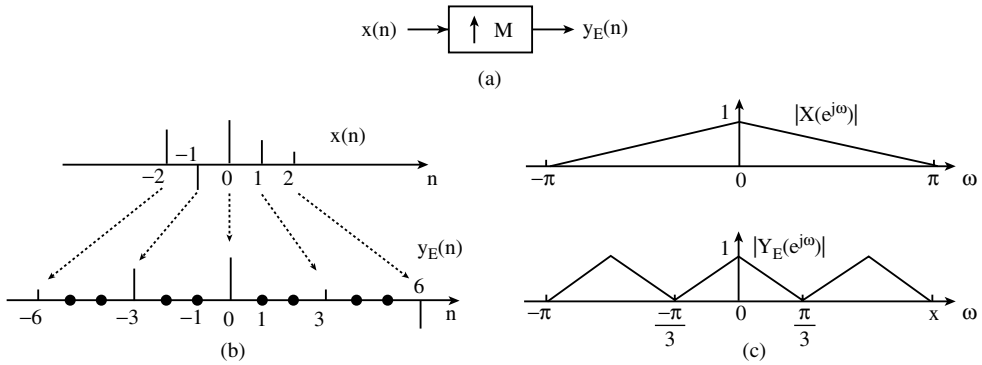

FIGURE 89.2 Upsampling: (a) Block diagram; (b), (c) time and frequency-domain example for $M = 3$.

$X(e^{j\omega} =)$ *is bandlimited to* $-\pi/M < \omega < \pi/M$, then there is no contribution from the aliased versions in the frequency range $-\pi < \omega \le \pi$. On the other hand, if $X(e^{j\omega})$ is not bandlimited to the above frequency range, then the downsampled output is aliased. This is the main reason for low-pass filtering the input signal before downsampling. An example for $M = 2$, where $X(e^{j\omega})$ is not bandlimited, is shown in Fig. 89.1(b) and (c).

Upsampling [26], [29]

Figure 89.2(a) shows the block diagram of an upsampler by a factor of M. The output signal $y_E(n)$ in terms of $x(n)$ is

$$y_E(n) = \begin{cases} x(n/M) & n \text{ is a multiple of } M \\ 0 & \text{otherwise} \end{cases} \qquad Y_E(z) = X(z^M) \quad Y_E(e^{j\omega}) = X(e^{jM\omega}) \tag{89.2}$$

The output $y_E(n)$ is a *compressed* copy of the output. Besides the original input spectrum, there are images repeated at $\omega_k = 2\pi k/M$. Consequently, it is necessary to low-pass the output to suppress the images. An example for $M = 3$ is shown in Fig. 89.2(b) and (c).

Delay Chain, Serial-Parallel Converter, Parallel-Serial Converter [29]

Figure 89.3(a) shows the block diagram of a delay chain where the transfer function from the input to the kth output is z^{-k}. By itself, the delay chain is not very interesting. However, using it in cascade with a set of decimators (or expanders), a serial-to-parallel (S/P) [or parallel-to serial (P/S)] converter can be implemented.

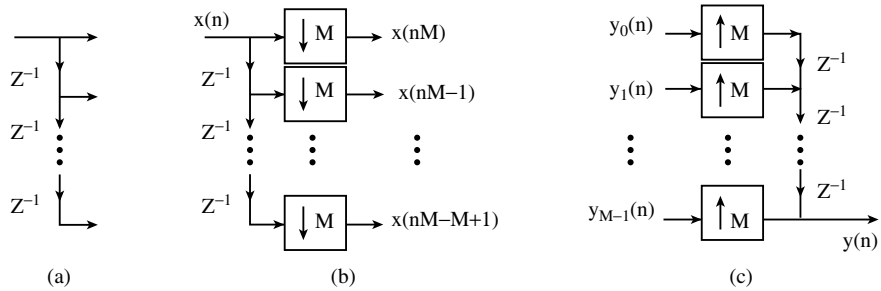

FIGURE 89.3 (a) Delay chain, (b) serial-parallel converter, (c) parallel-serial converter.

© 2003 by CRC Press LLC

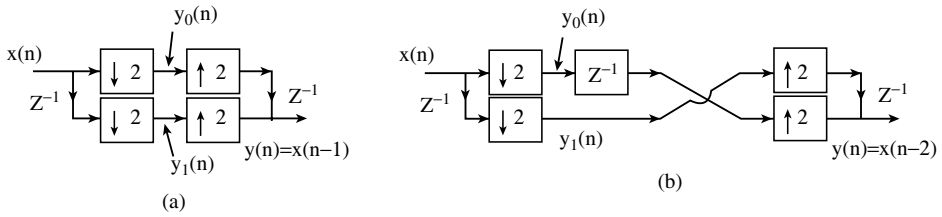

FIGURE 89.4 Simple perfect-reconstruction filter bank.

Figure 89.3(b) shows such implementation for a S/P converter. The output at the kth branch is $x(nM-k)$, which implies that the input sequence is selected in a *counterclockwise* fashion. In other words, the order for selecting the signals at the kth branch is

$$k=0,\ M-1,\ M-2,\ldots,2,\ 1,\ 0,\ M-1,\ M-2,\ldots \tag{89.3}$$

The output rate of a S/P converter is $1/M$ of the input rate.

On the other hand, a P/S converter can be obtained by cascading a set of expanders with a reverse-ordered delay chain, as depicted in Fig. 89.3(c). The output $y(n)$ is an interleaved combination of the signals $y_k(n)$, thus, its rate is M times the rate of $y_k(n)$. Assuming that $y_k(n)$ are causal, $y(n)$ is

$$y_{M-1}(0)y_{M-2}(0)\cdots y_0(0)y_{M-1}(1)y_{M-2}(1)\cdots y_0(1)\cdots \tag{89.4}$$

which implies $y_k(n)$ are selected in a *clockwise* fashion.

Simple Perfect-Reconstruction (PR) Multirate Systems

Figure 89.4 shows two simple multirate systems where the output signals are delayed versions of the input signal. The first system [Fig. 89.4(a)] blocks the input signal into the even-indexed and odd-indexed sequences $y_k(n)$ using a S/P converter and combines them together using a P/S converter. The overall delay for this system is one sample. On the other hand, if the orders of $y_k(n)$ are switched (after delaying $y_0(n)$ by a sample), as shown in Fig. 89.4(b), then it can be verified that the overall delay of the system is two samples.

The above simple PR filter banks do not process the subband signals $y_k(n)$, and thus are not useful filter banks in practice. They are, however, important in demonstrating the existence of PR filter banks.

Noble Identities [7], [29]

The components of a multirate system are filtering, decimators, expanders, S/P, and P/S converters. The two *noble identities* in this subsection allow interchangeability of the filtering decimators and expanders blocks, which are important and essential for the analysis of filter bank and multirate systems. The first identity, as depicted in Fig. 89.5(a), deals with the commutative property of a transfer function $H(z)$ and a decimator. One can verify that filtering with a transfer function $H(z^M)$ and then decimating the result is the same as decimating the input first and then filtering with the transfer function $H(z)$.The second identity [Fig. 8.5.5(b)] shows the equivalent operation between a transfer function $H(z)$ and an expander.

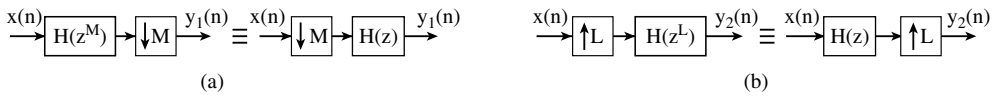

FIGURE 89.5 Noble identities.

© 2003 by CRC Press LLC

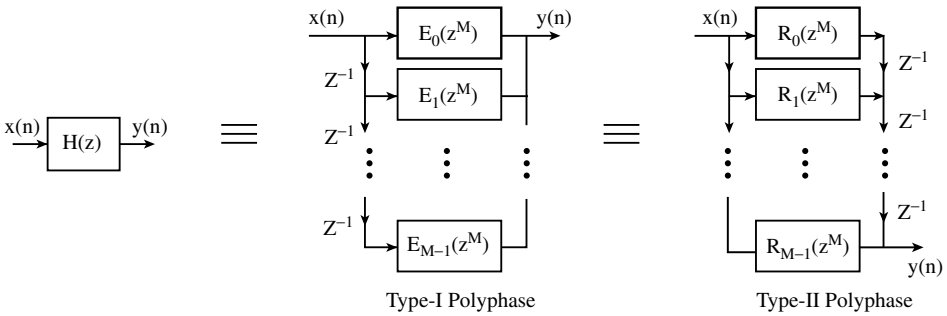

FIGURE 89.6 Polyphase representation: (a) type-I and (b) type-II.

Polyphase Representation [7], [26], [29]

Given a sequence $h(n)$ with length N, it can be represented by M distinct sequences $e_k(n)$ (type-I polyphase) or $r_k(n)$ (type-II polyphase) by choosing the appropriate sequences:

$$\begin{cases} e_k(n) = h(nM+k), & \text{type-I polyphase} \\ r_k(n) = h(nM+M-1-k) & \text{type-II polyphase} \end{cases} \qquad \begin{cases} 0 \le k \le M-1 \\ 0 \le n \le \left\lceil \dfrac{N}{M} \right\rceil \end{cases} \tag{89.5}$$

The equivalent z-domain representation is (as shown in Fig. 89.6):

$$H(z) = \sum_{k=0}^{M-1} z^{-k} E_k(z^M) \qquad H(z) = \sum_{k=0}^{M-1} z^{-(M-1-k)} R_k(z^M) \qquad R_k(z) = E_{M-1-k}(z) \tag{89.6}$$

type-I polyphase type-II polyphase

Example. Suppose that $h(n) = n$, $0 \le n \le 13$, then the polyphase representation $e_k(n)$ and $r_k(n)$ for $M = 3$ are

$$\begin{cases} e_0 = 0, 3, 6, 9, 12 \\ e_1 = 1, 4, 7, 10, 13 \\ e_2 = 2, 5, 8, 11 \end{cases} \qquad \begin{cases} r_0 = 2, 5, 8, 11 \\ r_1 = 1, 4, 7, 10, 13 \\ r_2 = 0, 3, 6, 9, 12 \end{cases} \tag{89.7}$$

type-I polyphase type-II polyphase

In summary, filtering by $H(z)$ is the same as filtering with the corresponding polyphase components $E_k(z)$ [or $R_k(z)$] of $H(z)$. Since the number of nonzero coefficients in $E_k(z)$ [or $R_k(z)$] is the same as that of $H(z)$, the above polyphase implementations do not offer any advantages. However, if $H(z)$ is proceeded (or preceded) with decimators (or expanders), as in a decimation (or interpolation) filter, then the polyphase implementations offer significant improvement on complexity, as elaborated in the next two subsections.

Decimation Filter [26], [29]

Figure 89.7 shows the decimation filter, its polyphase implementations, before and after using the noble identity. The equivalent operations for a decimation filter are thus, S/P converter, polyphase filtering (at the lower rate) and combining at the output. Comparing with the decimation filter in Fig. 89.7(a) which operates at the input signal rate, the equivalent polyphase implementation in Fig. 89.7(c) operates at $1/M$ the input signal rate.

© 2003 by CRC Press LLC

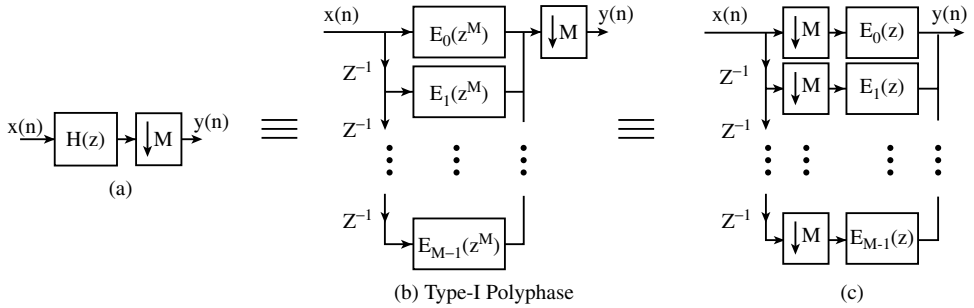

FIGURE 89.7 Decimation filtering and the efficient polyphase implementation.

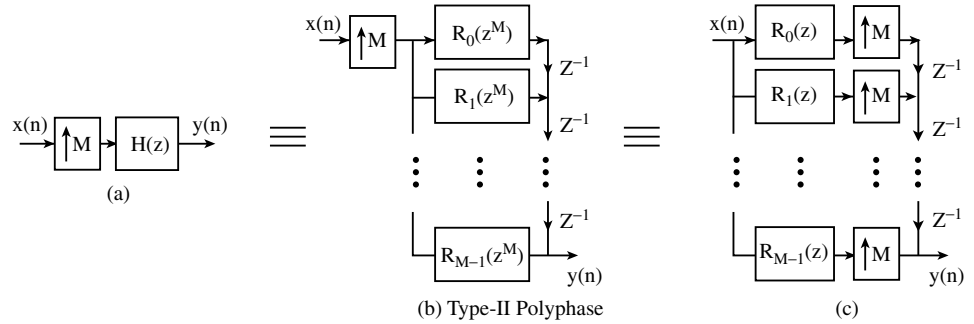

FIGURE 89.8 Interpolation filtering and the efficient polyphase implementation.

Interpolation Filter [26], [29]

Figure 89.8 shows the interpolation filter, its polyphase implementations, before and after using the noble identity. The equivalent operations for an interpolation filter are thus, polyphase filtering (at the lower rate), S/P converter, and combining at the output. Comparing to the interpolation filter in Fig. 89.8(a), which operates at M times the input signal rate, the equivalent polyphase implementation in Fig. 89.8(c) operates at the input signal rate.

89.3 Aliasing-Free Filter Bank

Digital filter banks have been getting popular in the last few years as a method to channelize the signal to many subbands, use the subband contents to extract essential information, and then reconstruct the original signal. A maximally decimated filter bank is shown in Fig. 89.9. The analysis bank channelizes the input signal into many subbands using a set of bandpass filters. Similarly, the synthesis bank reconstructs the subband signals using a set of bandpass filters. The forms of these filters depend on the applications and the dimensionality of the problem. The essential information is extracted from the subband signals in the processing block. Its form varies and depends on the applications. For example, in the audio/video compression system, the spectral contents of the subband signals are coded depending on their energies whereas in a radar system, the subband signals might be used to null out a narrowband interference adaptively. Filter banks found applications in audio/image compression, image analysis and enhancement, robotics, computer vision, echo-cancellation, radar, voice privacy, communications, etc.

Figure 89.9(a) illustrates a typical M-channel maximally decimated filter bank where $H_k(z)$ and $F_k(z)$, $0 \le k \le M-1$, are analysis and synthesis filters, respectively. Figure 89.9(b) shows the frequency responses of $H_k(e^{j\omega})$ and $F_k(e^{j\omega})$. The analysis filters $H_k(z)$ channelize the input signal $x(n)$ into M subband signals, which are downsampled (decimated) by a factor M. At the receiving end, the M subband signals are

© 2003 by CRC Press LLC

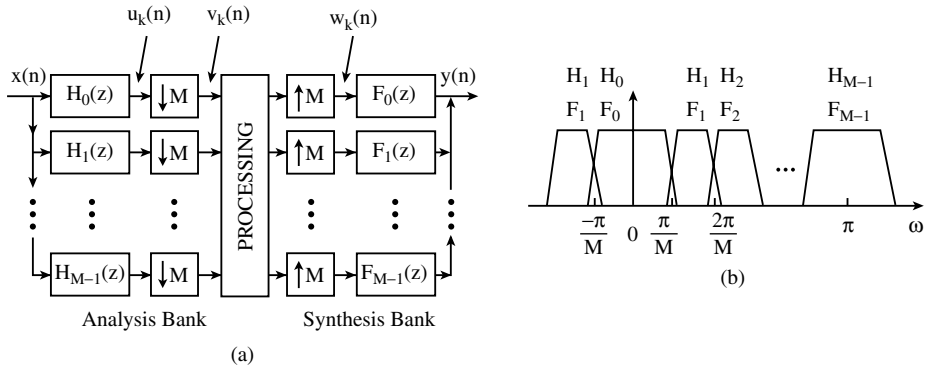

FIGURE 89.9 *M*-channel maximally decimated uniform filter bank.

decoded, interpolated, and recombined using a set of synthesis filters $F_k(z)$. The decimator, which decreases the sampling rate of the signal, and the expander, which increases the sampling rate of the signals, are denoted by the boxes with down-arrows and up-arrows, respectively, as shown in the figure.

Reconstructed Error [6], [7], [29]

Since the analysis filters $H_k(z)$ are not ideal bandpass filters, the signals $u_k(n)$ in Fig. 89.9(a) are not bandlimited to π/M, which implies that the signals $v_k(n)$ have aliased components of $u_k(n)$ (see the subsection on downsampling). The aliased levels at $v_k(n)$ depend on the stopband attenuation of $H_k(e^{j\omega})$ and their transition bands. The interpolated signals $w_k(n)$ have M "images" of the compressed spectrum $V_k(e^{j\omega})$ [assuming that no processing has been done on $v_k(n)$]. These images are filtered by the synthesis filters $F_k(z)$. There are two types of errors at the reconstructed output signal $y(n)$: *distortions* (magnitude and phase) and *aliasing*. The nonideal filtering characteristics of $H_k(z)$ and $F_k(z)$ contribute to both the distortions and aliasing errors, whereas the changes in sampling rates (decimation and interpolation) contribute to the aliasing error. A system with no aliasing error (i.e., aliasing cancellation) is called an alias-free filter bank and a system with no distortion and aliasing errors is called a perfect-reconstruction filter bank.

In terms of the input signal and the filters $H_k(z)$ and $F_k(z)$, $Y(z)$ is

$$Y(z) = \sum_{k=0}^{M-1} T_k(z) X(zW^k) \quad W = e^{-j2\pi/M} \tag{89.8}$$

where $T_k(z)$ are

$$T_k(z) = \frac{1}{M} \sum_{l=0}^{M-1} F_l(z) H_l(zW^k) \tag{89.9}$$

The transfer functions $T_0(z)$ and $T_k(z)$, $1 \le k \le M-1$ are the distortion and alias transfer functions, respectively. The objective in designing an alias-free filter bank or a PR filter bank is to find a set of filters $H_k(z)$ and $F_k(z)$ such that

$$T_k(z) = 0 \quad 1 \le k \le M-1 \qquad \text{or} \qquad \begin{cases} T_0(z) = z^{-n_0} \\ T_k(z) = 0 \qquad 1 \le k \le M-1 \end{cases} \tag{89.10}$$

alias-free perfect-reconstruction

Polyphase Representation of Filter Bank [7], [29]

Using type-I and type-II polyphase representations for the analysis and synthesis bank yields

$$\begin{bmatrix} H_0(z) \\ H_1(z) \\ \vdots \\ H_{M-1}(z) \end{bmatrix} = \begin{bmatrix} E_{00}(z^M) & E_{01}(z^M) & \cdots & E_{0,M-1}(z^M) \\ E_{10}(z^M) & E_{11}(z^M) & \cdots & E_{1,M-1}(z^M) \\ \vdots & \vdots & \ddots & \vdots \\ E_{M-1,0}(z^M) & E_{M-1,1}(z^M) & \cdots & E_{M-1,M-1}(z^M) \end{bmatrix} \begin{bmatrix} 1 \\ z^{-1} \\ \vdots \\ z^{-(M-1)} \end{bmatrix}$$

$$= \mathbf{E}(z^M) \begin{bmatrix} 1 \\ z^{-1} \\ \vdots \\ z^{-(M-1)} \end{bmatrix} \tag{89.11}$$

$$\left[F_0(z)\, F_1(z) \cdots F_{M-1}(z)\right] = \left(z^{-(M-1)} \cdots z^{-1}\ 1\right) \mathbf{R}(z^M)$$

Here, $\mathbf{E}(z)$ and $\mathbf{R}(z)$ are the polyphase transfer matrices of the analysis and synthesis filter banks, respectively. Given any sets of analysis and synthesis filters, one can always find the corresponding transfer matrices $\mathbf{E}(z)$ (type-I polyphase) and $\mathbf{R}(z)$ (type-II polyphase).

Figure 89.10(a) is the polyphase representation of the structure in Fig. 89.9(a). Using the noble identities to move the decimators to the left of $\mathbf{E}(z^M)$ and the expanders to the right of $\mathbf{R}(z^M)$, Fig. 89.10(a) becomes the structure in Fig. 89.10(b). A few words on the implementation efficiency of this representation are needed here. As indicated in the figure, the input is blocked into a vector using a serial-parallel converter (implemented as cascade of delay chain and decimators), filtered by $\mathbf{R}(z)\mathbf{E}(z)$ and then recombined using a parallel-serial converter (implemented as a cascade of expanders and reversed-ordered delay chain). Comparing to the system in Fig. 89.9(a), the total number of nonzero coefficients in $\mathbf{E}(z)$ and $\mathbf{R}(z)$ are the same as that in $H_k(z)$ and $F_k(z)$, respectively. The main difference is the rate of operation. In other words, the filtering operations in the original filter bank [Fig. 89.9(a)] are done at the input rate, whereas the filtering operations in the polyphase representation [Fig. 89.10(b)] are done at $1/M$ the input rate.

Necessary and Sufficient Condition for Alias-Free Filter Bank [7], [29]

Defining $\mathbf{P}(z) = \mathbf{R}(z)\mathbf{E}(z)$, then the necessary and sufficient condition on $\mathbf{P}(z)$ such that the output signal $y(n)$ has no aliased component of $x(n)$, i.e., $T_k(z) = 0$ for $1 \le k \le M - 1$, is

© 2003 by CRC Press LLC

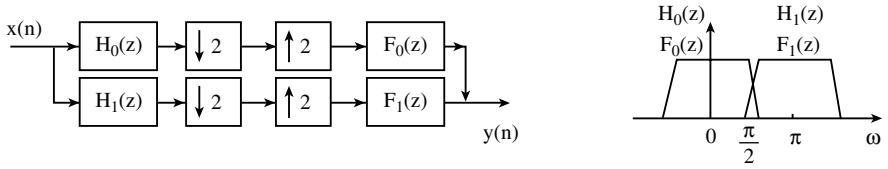

FIGURE 89.11 Two-channel filter bank.

$\mathbf{P}(z)$ = pseudo-circulant matrix

$$= \begin{pmatrix} P_0(z) & P_1(z) & \cdots & P_{M-2}(z) & P_{M-1}(z) \\ z^{-1}P_{M-1}(z) & P_0(z) & \cdots & P_{M-3}(z) & P_{M-2}(z) \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ z^{-1}P_1(z) & z^{-1}P_2(z) & \cdots & z^{-1}P_{M-1}(z) & P_0(z) \end{pmatrix} \tag{89.12}$$

In other words, as long as the product of the polyphase matrices $\mathbf{R}(z)$ and $\mathbf{E}(z)$ is a pseudo-circulant matrix, then the only distortions at the output are the amplitude and phase distortions [represented in $T_0(z)$]. Examples of alias-free (non-PR) filter banks are the two-channel quadrature mirror filter (QMF) bank (known as the Johnston filter bank), the two-channel allpass-based IIR filter bank, and the M-channel DFT filter bank. These will all be considered in the next three subsections.

Two-Channel QMF (Johnston) Filter Bank [20]

Figure 89.11 shows a two-channel filter bank, where $H_0(z)$ and $H_1(z)$ are analysis filters and $F_0(z)$ and $F_1(z)$ are synthesis filters, respectively. From (89.8), it can be verified that ($M = 2$)

$$Y(z) = T_0(z)X(z) + T_1(z)X(-z) \tag{89.13}$$

where $T_0(z)$ and $T_1(z)$ are the distortion and aliasing functions, respectively. $T_k(z)$ are

$$\begin{cases} T_0(z) = F_0(z)H_0(z) + F_1(z)H_1(z) \\ T_1(z) = F_0(z)H_0(-z) + F_1(z)H_1(-z) \end{cases} \tag{89.14}$$

For arbitrary choices of $H_k(z)$, the only choices of $F_k(z)$ such that aliasing is canceled are [1]–[4] (i.e., $T_1(z) = 0$): $F_1(z) = -H_0(-z)$ and $F_0(z) = H_1(-z)$. With the above choices of $F_k(z)$, the distortion function $T_0(z)$ becomes

$$T_0(z) = H_0(z)H_1(-z) - H_0(-z)H_1(z) \tag{89.15}$$

The objective in an alias-free filter bank is to find $H_k(z)$ such that the distortion function $T_0(z)$ approximates a delay. The Johnston filter bank assumes that

$$H_0(z) \text{ is an even-length linear-phase (symmetric) filter and } H_1(z) = H_0(-z) \tag{89.16}$$

Note that this is a two-channel DFT filter bank where $H_1(z)$ is a shifted version of $H_0(z)$. The analysis filter bank is

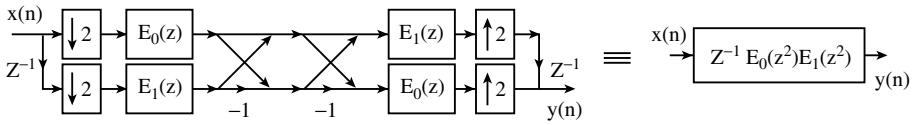

FIGURE 89.12 Johnson QMF bank (two-channel DFT filter bank).

$$\begin{aligned}\begin{pmatrix} H_0(z) \\ H_1(z) \end{pmatrix} &= \begin{pmatrix} E_0(z^2) & E_1(z^2) \\ E_0(z^2) & -E_1(z^2) \end{pmatrix} \begin{pmatrix} 1 \\ z^{-1} \end{pmatrix} \\ &= \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \begin{pmatrix} E_0(z^2) & 0 \\ 0 & E_1(z^2) \end{pmatrix} \begin{pmatrix} 1 \\ z^{-1} \end{pmatrix}\end{aligned} \tag{89.17}$$

where $E_k(z)$ are the polyphase components of the low-pass filter $H_0(z)$. The corresponding synthesis filters are

$$\begin{aligned}\begin{bmatrix} F_0(z) & F_1(z) \end{bmatrix} &= \begin{bmatrix} H_1(-z) & -H_0(-z) \end{bmatrix} \\ &= \begin{pmatrix} z^{-1} & 1 \end{pmatrix} \begin{pmatrix} E_1(z^2) & 0 \\ 0 & E_0(z^2) \end{pmatrix} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}\end{aligned} \tag{89.18}$$

and the overall distortion function $T_0(z)$ is $T_0(z) = z^{-1}E_0(z^2)E_1(z^2)$, which can be equalized using either IIR or FIR filters. Figure 89.12 shows the equivalent system for the two-channel Johnston filter bank. Several designs have been tabulated in [20].

Let N be the length of $H_0(z)$, then the number of coefficients in $E_k(z)$ are $N/2$. From Fig. 89.12, the total number of multiplications and additions in the analysis bank are N and N, respectively. Since the filtering is computed at the lower rate, then the effective complexity is $N/2$ multiplications and $N/2$ additions per unit time, respectively. The computation complexity of the synthesis bank is the same as that of the analysis bank.

Two-Channel Allpass-Based IIR Filter Bank [22], [23], [29]

It is clear from the above derivation that the DFT filter bank is not a PR system and the distortion function $T_0(z)$ is a product of the two polyphase components of $H_0(z)$, i.e., $E_0(z)$ and $E_1(z)$. If these polyphase components have unit magnitudes, then there will be no amplitude distortion at the output of the filter bank. In other words, if the polyphase components are allpass functions, then $|Y(e^{j\omega})| = |X(e^{j\omega})|$. For example, if both polyphase components are delays (which is a special case of allpass function), then $H_0(z)$ and $H_1(z)$ are sum and difference of delays (which is not very interesting). However, if both polyphase components are IIR allpass functions, i.e.,

$$E_0(z) = A_0(z) \qquad E_1(z) = A_1(z) \tag{89.19}$$

then $H_0(z)$ and $H_1(z)$ are sum and differences of two allpass filters $A_0(z)$ and $A_1(z)$, as depicted in Fig. 89.13, i.e.,

$$\begin{cases} H_0(z) = \dfrac{1}{2}\left[A_0(z^2) + z^{-1}A_1(z^2)\right] \\ H_1(z) = \dfrac{1}{2}\left[A_0(z^2) - z^{-1}A_1(z^2)\right] \end{cases} \tag{89.20}$$

© 2003 by CRC Press LLC

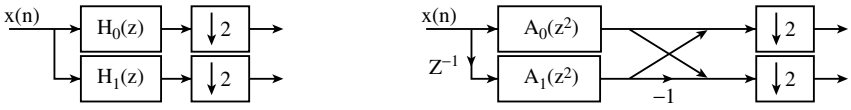

FIGURE 89.13 Two-channel allpass-based IIR filter bank.

With the above choices of $H_k(z)$, the only distortion at the output is phase distortion (being the sum of the phase responses of the allpass filters), which could be equalized using an allpass filter. Butterworth, Chebyshev, and elliptic filters (with appropriate frequency specifications) can be decomposed into sum and difference of two allpass filters [22], as in (89.20). Given the filter, the synthesis procedure to find $A_k(z)$ is given in [22].

Choice of $A_k(z)$. For any choice of $A_k(z)$, it is not clear that the resulting analysis filters $H_k(z)$ approximate ideal low-pass and high-pass responses. Thus, it is important to choose $A_k(z)$ carefully to obtain desirable frequency characteristics. Let $\phi_0(\omega)$ and $\phi_1(\omega)$ be the phase responses of $A_0(e^{j\omega})$ and $A_1(e^{j\omega})$, respectively, then

$$\left|H_0\left(e^{j\omega}\right)\right| = \frac{1}{2}\left|e^{j\phi_0(2\omega)} + e^{j\left(\phi_1(2\omega)-\omega\right)}\right| = \frac{1}{2}\left|1 + e^{j\left(\phi_1(2\omega)-\phi_0(2\omega)-\omega\right)}\right| \tag{89.21}$$

To obtain a good low-pass filter characteristic for $\mathbf{H_0}(z)$, (89.21) implies that the phases of the allpass functions should be in-phase in the passband region and out-of-phase in the stopband region. The choice of $\phi_0(2\omega)$ is irrelevant here and should be chosen such that the filters have approximately linear phase in their passband regions. Let $A_0(z) = z^{-K}$ (i.e., $\phi_0(\omega) = -K\omega$), then $A_1(z)$ should have the following phase response:

$$\phi_1(2\omega) - 2K\omega - \omega = \begin{cases} 0 & \text{in the passband region} \\ \pi & \text{in the stopband region} \end{cases} \tag{89.22}$$

and the filters are

$$\begin{cases} H_0(z) = \dfrac{1}{2}\left[z^{-2K} + z^{-1}A_1\left(z^2\right)\right] \\ H_1(z) = \dfrac{1}{2}\left[z^{-2K} - z^{-1}A_1\left(z^2\right)\right] \end{cases} \tag{89.23}$$

Methods for designing an allpass transfer function approximating a given phase response are elaborated in [23].

For a given K, the polyphase component $A_1(z)$ is a K-order allpass transfer function, which can be decomposed into a cascade of K first-order allpasses. Each first-order allpass transfer function is implemented by one multiplication and two additions. For the K allpass sections in the analysis bank, K multiplications and $2K$ additions are needed. The effective (computed at the lower rate) computation complexity for the analysis bank is $K/2$ multiplications and $K + 1$ additions, respectively (with the additional cost of a two-point DFT).

M-Channel DFT Filter Bank [21], [29]

The analysis and synthesis filters $H_k(z)$ and $F_k(z)$ are uniformly shifted versions of the low-pass filters $H_0(z)$ and $F_0(z)$, respectively, i.e.,

© 2003 by CRC Press LLC

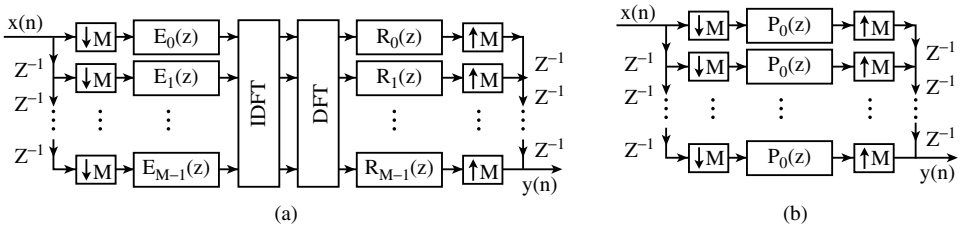

FIGURE 89.14 *M*-channel uniform DFT filter bank.

$$\begin{cases} H_0(z) = \sum_{k=0}^{M-1} z^{-k} E_k\left(z^M\right) & H_k(z) = H_0\left(zW^k\right) \quad W = e^{-j2\pi/M} \\ F_0(z) = \sum_{k=0}^{M-1} z^{-(M-1-k)} R_k\left(z^M\right) & F_k(z) = F_0\left(zW^k\right) \quad W = e^{-j2\pi/M} \end{cases} \tag{89.24}$$

Figure 89.14(a) shows the polyphase representation of the M-channel DFT filter bank. It is clear that PR cannot be achieved. By choosing $R_k(z) = \Pi_{l\neq k} E_1(z)$, then Fig. 89.14(a) simplifies to Fig. 89.14(b), which implies that the overall distortion function is

$$T_0(z) = z^{-(M-1)} P_0\left(z^M\right) \quad \text{where} \quad P_0(z) = \prod_{k=0}^{M-1} E_k(z) \tag{89.25}$$

Similarly, as in the two-channel DFT filter bank and the two-channel allpass-based IIR filter bank, the output $y(n)$ should be equalized to minimize the distortion function $T_0(z)$.

89.4 Perfect-Reconstruction Filter Bank

Necessary and Sufficient Condition. Equation (89.12) gives the necessary and sufficient condition for an alias-free filter bank. If there exists a transfer function $P_k(z) = z^{-m_0}$ and all other functions $P_l(z) = 0$, $l \neq k$, then the filter bank is a PR one, i.e., [7], [29]

$$\mathbf{P}(z) = \mathbf{R}(z)\mathbf{E}(z) = z^{-m_0} \begin{pmatrix} \mathbf{0} & \mathbf{I}_{M-r} \\ z^{-1}\mathbf{I}_r & \mathbf{0} \end{pmatrix} \tag{89.26}$$

The resulting overall delay is $r + M - 1 + m_0 M$, i.e., $T_0(z) = cz^{-(r+M-1+m_0M)}$.

Example. When $M = 2$, there are only two choices for $\mathbf{P}(z)$, i.e., $\mathbf{P}(z) = z^{-m_0}\mathbf{I}$ or

$$\mathbf{P}(z) = z^{-m_0} \begin{pmatrix} 0 & 1 \\ z^{-1} & 0 \end{pmatrix}$$

The corresponding filter banks are shown in Fig. 89.4.

The PR filter bank where the polyphase transfer matrices $\mathbf{R}(z)$ and $\mathbf{E}(z)$ satisfy (89.26) is called a biorthogonal filter bank. Example of biorthogonal filter bank is the two-channel linear-phase PR filter bank [4] (see the subsection) and the three-channel linear-phase PR filter bank [10].

© 2003 by CRC Press LLC

Paraunitary Filter Bank [6]–[9], [29]

The paraunitary filter bank is a special case of biorthogonal filter bank where $\mathbf{E}(z)$ and $\mathbf{R}(z)$ are related as

$$\mathbf{R}(z) = \mathbf{E}^{-1}(z) = \tilde{\mathbf{E}}(z) = \mathbf{E}^{T}\left(z^{-1}\right) \tag{89.27}$$

The synthesis filters $F_k(z)$ are related to analysis filter $H_k(z)$ (of length N) as

$$F_k(z) = z^{-(N-1)} H_k\left(z^{-1}\right) \qquad f_k(n) = h_k(N-1-n) \tag{89.28}$$

Factorization. Any causal degree-J FIR paraunitary $\mathbf{E}(z)$ can be expressed as [12], [61]

$$\mathbf{E}(z) = \mathbf{V}_J(z)\mathbf{V}_{J-1}(z)\cdots\mathbf{V}_1(z)\mathbf{U} \quad \text{where} \quad \begin{cases} \mathbf{V}_k(z) = \mathbf{I} - \mathbf{v}_k\mathbf{v}_k^{\dagger} + z^{-1}\mathbf{v}_k\mathbf{v}_k^{\dagger} \\ \mathbf{U}^{\dagger}\mathbf{U} = \mathbf{I} \end{cases} \tag{89.29}$$

Here, $\mathbf{v}_k$ is a unit-norm column vector. The constant unitary matrix $\mathbf{U}$ can be factorized as $\mathbf{U} = \mathbf{U}_1 \mathbf{U}_2 \ldots \mathbf{U}_{M-1}\mathbf{D}$, where $\mathbf{D}$ is a diagonal matrix with diagonal elements $D_{kk} = e^{j\theta_k}$ and $\mathbf{U}_k = \mathbf{I} - 2\mathbf{u}_k\,\mathbf{u}_k^{\dagger}$ for unit-norm column vector $\mathbf{u}_k$.

The above factorization is complete in the sense that it covers all paraunitary filter banks, i.e., given any paraunitary filter bank, there exists a set of vectors $\mathbf{v}_k$ and $\mathbf{u}_k$ that implement it. Synthesis procedure is discussed in [9], [29]. Alternative factorizations based on Givens rotation are discussed in [8].

Power Complementary. A set of filters $H_k(z)$ is said to be power-complementary if their frequency responses $H_k(e^{j\omega})$ satisfy the property

$$\sum_k \left|H_k\left(e^{j\omega}\right)\right|^2 = c$$

where c is a positive constant. The analysis (and synthesis) filters of a paraunitary filter bank satisfy the power complementary property.

Two-Channel Paraunitary Filter Bank [1]–[3]

Let

$$H_1(z) = -z^{-(N-1)} H_0\left(-z^{-1}\right) \qquad F_k(z) = z^{-(N-1)} H_k\left(z^{-1}\right) \tag{89.30}$$

where N is the filter's length (even N). Substituting the above relations into (89.14) yields $T_1(z) = 0$ and

$$\begin{aligned} T_0(z) &= \left[H_0(z)H_0\left(z^{-1}\right) + H_1(z)H_1\left(z^{-1}\right)\right] z^{-(N-1)} \\ &= \left[H_0(z)H_0\left(z^{-1}\right) + H_0(-z)H_0\left(-z^{-1}\right)\right] z^{-(N-1)} \end{aligned}$$

For PR system, $T_0(z)$ should be a delay, i.e., $z^{-(N-1),}$ which implies that

$$H_0(z)H_0\left(z^{-1}\right) + H_0(-z)H_0\left(-z^{-1}\right) = 1 \tag{89.31}$$

Let $G(z) = H_0(z)\,H_0(z^{-1})$, then (89.31) implies that $G(z)$ is a halfband filter and $H_0(z)$ is a spectral factor of a halfband filter [29], [40]. In summary, the two-channel paraunitary filter bank has the following properties:

© 2003 by CRC Press LLC

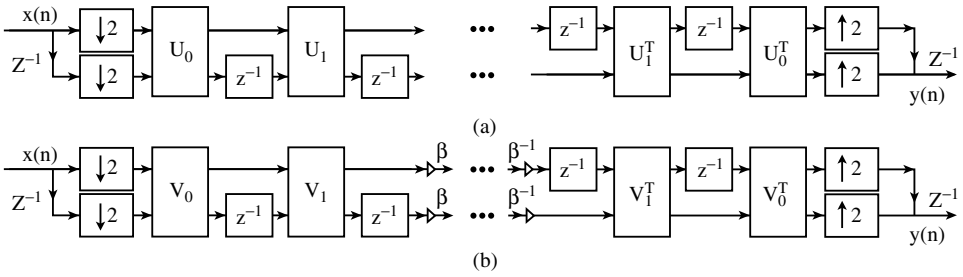

FIGURE 89.15 Factorization of two-channel paraunitary filter bank.

$$\begin{cases} H_0(z) \text{ is a spectral factor of a halfband filter} \\ H_1(z) = -z^{-(N-1)} H_0\left(-z^{-1}\right) \\ F_k(z) = z^{-(N-1)} H_k\left(z^{-1}\right) \end{cases} \tag{89.32}$$

A design procedure for a two-channel paraunitary filter bank [2] would be (a). Design an equiripple halfband filter $\hat{G}(z)$ using Remez algorithm of length $2N-1$ [37] (b). Measure the stopband attenuation (δ) and form a nonnegative function $G(z) = \hat{G}(z) + \delta z^{-(N-1)}$ (c). Find the spectral factorization $H_0(z)$ of $\hat{G}(z)$ and (d). $H_1(z)$ and $F_k(z)$ are computed using (89.32).

The above two-channel paraunitary filter bank can also be realized in a lattice structure as shown in Fig. 89.15(a), where

$$\mathbf{U}_k = \begin{pmatrix} \cos\theta_k & \sin\theta_k \\ -\sin\theta_k & \cos\theta_k \end{pmatrix}$$

and Fig. 89.15(b), where

$$\mathbf{V}_k = \begin{pmatrix} 1 & \alpha_k \\ -\alpha_k & 1 \end{pmatrix}$$

and

$$\beta = 1 \Big/ \sqrt{\prod_k 1 + \alpha_k^2}$$

The lattice structure is complete in the sense that for any choices of θ_k (or α_k), the resulting filter satisfies (89.32) (and is thus paraunitary) and given any paraunitary filter bank, then there exists a unique set of angle θ_k (or α_k) that implements it. Given $H_0(z)$, the procedure to synthesize θ_k (or α_k) is given in [3]. The orthogonal Daubechies wavelet [32] is a paraunitary filter bank and can be implemented using the lattice structure below. For example, the D_6 wavelet has lattice angles $\theta_0 = \pi/3$ and $\theta_1 = -\pi/12$.

We only consider the implementation complexity of the structure in Fig. 89.15(b) here. Let N be the length of $H_0(z)$, ($N = 2J$), then the number of lattice sections V_k in the analysis bank is J. Each lattice section requires 2 multiplications and 2 additions, which implies that the number of multiplications and additions in the analysis bank is $2J + 2$ (for the extra multiplications β) and $2J$, respectively. The effective computation complexity (at the input rate) is $J + 1$ multiplications and J additions.

© 2003 by CRC Press LLC

For a given design specification (stopband attenuation, transition band, etc.), [29, p. 311] compares the complexity between the Johnston's filter and the paraunitary filter bank.

Two-Channel Paraunitary Linear-Phase Filter Bank (FIR) [29]

$$\begin{cases} H_0(z) \text{ is an even-length} & \\ \quad \text{symmetric filter} & H_0(z) = z^{-(N-1)} H_0(z^{-1}) \\ H_1(z) \text{ is an even-length} & \\ \quad \text{antisymmetric filter} & H_1(z) = -z^{-(N-1)} H_1(z^{-1}) \\ F_0(z) = z^{-(N-1)} H_0(z^{-1}) = H_0(z) & F_1(z) = z^{-(N-1)} H_1(z^{-1}) = -H_1(z) \end{cases} \tag{89.33}$$

With the above choices of filters, aliasing is canceled and the distortion function becomes

$$T_0(z) = H_0^2(z) - H_1^2(z) = \left[H_0(z) + H_1(z)\right]\left[H_0(z) - H_1(z)\right] \tag{89.34}$$

which should be a delay (z^{-n_0}) for a PR filter bank. From (89.34), it is clear that both $[H_0(z) + H_1(z)]$ and $[H_0(z) - H_1(z)]$ should be delays, which implies that

$$\begin{cases} H_0(z) = \dfrac{1}{2}\left(z^{-n_1} + z^{-n_2}\right) \\ H_1(z) = \dfrac{1}{2}\left(z^{-n_1} - z^{-n_2}\right) \end{cases} \quad n_0 = n_1 + n_2 \tag{89.35}$$

In other words, only a trivial two-channel linear-phase paraunitary filter bank exists. In order to obtain a nontrivial two-channel paraunitary linear-phase filter bank, one has to sacrifice the paraunitary property (see the separate subsection).

Linear-Phase Filter Bank

Let $H_k(z)$ be the linear-phase analysis filters with centers c_k, and the filters' lengths are defined to be $N_k = 2c_k + 1$. For a given number of channels (M), N_k can be uniquely expressed as $N_k = m_k M + i_k$, where m_k and i_k are the modulo and the remainder parts of N_k with respect to M. The polyphase representation of $H_k(z)$ is $H_k(z) = \sum_{l=0}^{M-1} z^{-l} E_{k,l}(z^M)$ where $E_{k,l}(z)$ are type-I polyphase components of $H_k(z)$ [7]. $E_{k,l}(z)$ are related [10], [29] as

$$E_{k,l}\left(z^{-1}\right) = z^{m_k} J_k \times \begin{cases} E_{k,(i_k - l)}(z), & l \le i_k \\ z^{-1} E_{k,(M + i_k - l)}(z), & l > i_k \end{cases}$$

where

$$J_k = \begin{cases} +1 & h_k(n) \text{ is symmetric} \\ -1 & h_k(n) \text{ is antisymmetric} \end{cases}$$

For a special case where all i_k are equal to a constant, then the total number of linear-phase PR filter banks [10] is

© 2003 by CRC Press LLC

$$\text{total} = \psi\left(\Delta_M - \Theta_M\right) + M\Theta_M$$

where

$$\psi = \begin{cases} M/2 & M \text{ is even} \\ M & M = 4r+1 \\ 0 & \text{otherwise} \end{cases} \qquad \Delta_M = \begin{cases} M/2 & \text{even } M \\ (M+1)/2 & \text{odd } M \end{cases}$$

$$\Theta_M = \begin{cases} M/2 & \text{even } M \\ ((M-1)/2 & \text{odd } M \end{cases}$$

In the following subsections, the theory and analysis of the two-channel linear-phase biorthogonal filter bank and the M-channel linear-phase paraunitary filter bank are covered in detail.

Two-Channel Biorthogonal Linear-Phase Filter Bank [4], [5]

There are two types of biorthogonal filter banks [4]:

- Type A (SAOO) [4]: Both filters have odd orders (even length). $H_0(z)$ is symmetric and $H_1(z)$ is antisymmetric.
- Type B (SSEE) [4]: Both filters have even orders (odd length). Both filters have symmetric impulse responses.

Type A: (*SAOO*). Considering a pair of even-length (N) FIR transfer functions where the first function is symmetric and the other is antisymmetric (we only consider the case of equal length here, the general case is discussed in [4]), and defining

$$\begin{pmatrix} P(z) \\ Q(z) \end{pmatrix} = \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}\begin{pmatrix} H_0(z) \\ H_1(z) \end{pmatrix} \tag{89.36}$$

then it can be proved that $Q(z) = z^{-(N-1)}P(z^{-1}) = [q(n) = p(N-1-n)]$. Thus, as long as we can find a one-input/two-input system [as depicted in Fig. 89.16(a)] that gives us the transfer function pair $[P(z), \tilde{P}(z)]$, then the analysis filters (with the above symmetric properties) can be found, as depicted in Fig. 89.16(b).

The simplest choice for the black box that gives the pair $[P(z), \tilde{P}(z)]$ is $\Gamma\Lambda(z)$ where [see Fig. 89.16(b)]

$$\Gamma = \begin{pmatrix} 1 & \gamma \\ \gamma & 1 \end{pmatrix} \quad \Lambda(z) = \begin{pmatrix} 1 & 0 \\ 0 & z^{-1} \end{pmatrix} \tag{89.37}$$

which yields $P(z) = 1 + \gamma z^{-1}$, $H_0(z) = 0.5\,[(1+\gamma) + (1+\gamma)z^{-1}]$, and $H_1(z) = 0.5\,[(1-\gamma) - (1-\gamma)z^{-1}]$. The resulting analysis filters have length 2. In order to increase their lengths (and keep them even), the

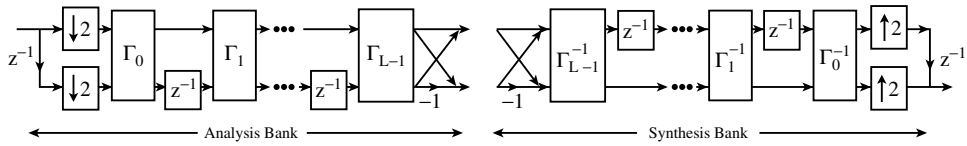

FIGURE 89.17 Lattice structure for the two-channel biorthogonal linear-phase filter bank (type A).

additional block must have only z^{-2} power (not z^{-1}). Figure 89.17 shows the general lattice structure for a biorthogonal linear-phase type A (SAOO) filter bank. Since Γ_k is nonsingular (except for the case where $\gamma_k = 1$, which is discussed in [4]), one can reconstruct the input by inverting the operations in the analysis bank (Fig. 89.17). The above lattice structure is the complete structure for a two-channel biorthogonal linear-phase filter bank (type A). In other words, given any type A pair of filters $[H_0(z), H_1(z)]$, its polyphase transfer matrix $\mathbf{E}(z)$ can be factorized as

$$\mathbf{E}(z) = \Gamma_{L-1}\Lambda(z)\Gamma_{L-2}\Lambda(z)\cdots\Lambda(z)\Gamma_0 \tag{89.38}$$

where Γ_k and $\Lambda(z)$ are shown in (89.37), respectively.

Let N ($N = 2J$) be the length of $H_0(z)$, then the number of lattice section Γ_k in the analysis bank is J. Each lattice section requires 2 multiplications and 2 additions, which implies that the number of multiplications and additions at the analysis bank is $2J$ and $2J$, respectively. The effective computation complexity (at the input rate) is J multiplications and J additions. An alternative implementation that uses one multiplication and three additions per lattice section is discussed in [29, p. 343].

***Type B*: (*SSEE*) [4].** Consider a pair of odd-length (even-order) symmetric FIR transfer functions. Let N_k be the lengths of $H_k(z)$, then their sum should satisfy the condition $N_1 = N_0 + 4\alpha + 2$, where α is any nonnegative number [4]. It can be shown that the polyphase transfer matrix $\mathbf{E}(z)$ can be factorized as [4]

$$\mathbf{E}(z) = \prod_{k=0}^{L-1} \mathbf{A}_{L-1-k}(z) \quad \text{where } \mathbf{A}_k(z) = \mathbf{B}_k(z)\begin{pmatrix} \alpha_k z^{-2K_k} & 0 \\ 0 & 1 \end{pmatrix} \tag{89.39}$$

The above lattice structure implementation in (89.39) is complete. In other words, given a pair of type B biorthogonal linear-phase filter banks, one can find the corresponding lattice sections $\mathbf{A}_k(z)$. The biorthogonal Daubechies wavelets [32] are a type B linear-phase filter bank and they can be implemented using the above lattice structure. The lattice structure offers efficient implementations (see [4]).

M-Channel Linear-Phase Paraunitary Filter Bank ($M > 2$) [11]

Although linear-phase and paraunitary properties cannot be simultaneously imposed in the case of two-channel, they can coexist for filter banks with more channels [11]. For instance, DCT (discrete-cosine-transform) and LOT (lapped orthogonal transform) are two examples where both the analysis and synthesis filters $H_k(z)$ and $F_k(z)$ are linear-phase FIR filters and the corresponding filter banks are paraunitary filter banks. Assuming that

$$\begin{cases} M \text{ is even} \quad L = NM \\ f_k(n) = h_k(N-1-n) \end{cases} \tag{89.40}$$

it is shown that $M/2$ filters (in analysis or synthesis) have symmetric impulse responses and the other $M/2$ filters have antisymmetric impulse responses. Under the assumptions on N, M, and on the filter symmetry, the polyphase transfer matrix $\mathbf{E}(z)$ of the LPPUFB (linear-phase paraunitary filter bank) of degree $K - 1$ can be decomposed as a product of orthogonal factors and delays [11], i.e.,

© 2003 by CRC Press LLC

$$\mathbf{E}(z) = \mathbf{S}\mathbf{Q}\mathbf{T}_{N-1}\Lambda(z)\mathbf{T}_{N-2}\Lambda(z)\cdots\Lambda(z)\mathbf{T}_0\mathbf{Q} \tag{89.41}$$

where

$$\mathbf{Q} = \begin{pmatrix} \mathbf{I}_{M/2} & \mathbf{0}_{M/2} \\ \mathbf{0}_{M/2} & \mathbf{J}_{M/2} \end{pmatrix} \quad \Lambda(z) = \begin{pmatrix} \mathbf{I}_{M/2} & \mathbf{0}_{M/2} \\ \mathbf{0}_{M/2} & z^{-1}\mathbf{I}_{M/2} \end{pmatrix}$$
$$\mathbf{S} = \frac{1}{\sqrt{2}} \begin{pmatrix} \mathbf{S}_0 & \mathbf{0}_{M/2} \\ \mathbf{0}_{M/2} & \mathbf{S}_1 \end{pmatrix} \begin{pmatrix} \mathbf{I}_{M/2} & \mathbf{J}_{M/2} \\ \mathbf{I}_{M/2} & -\mathbf{J}_{M/2} \end{pmatrix} \tag{89.42}$$

where $\mathbf{S}_0$ and $\mathbf{S}_1$ can be any $M/2 \times M/2$ orthogonal matrices. $\mathbf{T}_i$ are $M \times M$ orthogonal matrices

$$\mathbf{T}_i = \begin{pmatrix} \mathbf{I}_{M/2} & \mathbf{I}_{M/2} \\ \mathbf{I}_{M/2} & -\mathbf{I}_{M/2} \end{pmatrix} \begin{pmatrix} \mathbf{U}_i & \mathbf{0} \\ \mathbf{0} & \mathbf{V}_i \end{pmatrix} \begin{pmatrix} \mathbf{I}_{M/2} & \mathbf{I}_{M/2} \\ \mathbf{I}_{M/2} & -\mathbf{I}_{M/2} \end{pmatrix} \tag{89.43}$$

where $\mathbf{U}_i$ and $\mathbf{V}_i$ are arbitrary orthogonal matrices. The above factorization in (89.41) covers all LPPUFB for even number of channels. In other words, given any set of filters $H_k(z)$ that belong to LPPUFB, one can obtain the corresponding matrices $\mathbf{S}$, $\mathbf{Q}$, and $\mathbf{T}_k(z)$. The synthesis procedure is given in [11].

GenLOT (Generalized Lapped Orthogonal Transform) [12]

The basis functions (analysis filters) of the DCT and of the LOT are linear phase and orthonormal. They must belong to the class of LPPUFB, discussed in the previous subsection. In other words, the PTM (polyphase transfer matrix) of the DCT and LOT must be in the form of (89.41). It is shown in [14] that the PTM of the LOT can be represented as in Fig. 89.18. Since the factorization in (89.41) covers all M-channel linear-phase paraunitary filter banks, the PTM in Fig. 89.18 should have the form as in (89.41). It does not, however. Our objective below is to derive another lattice form for (89.41) in which both the DCT and the LOT are special cases.

We will abbreviate the notation for (89.41) as

$$\mathbf{E}(z) = \mathbf{S}\mathbf{Q}\mathbf{T}_{N-1}\left(\prod_{i=N-2}^{0} \Lambda(z)\mathbf{T}_i\right)\mathbf{Q} \tag{89.44}$$

Let

$$\mathbf{W} = \frac{1}{\sqrt{2}} \begin{bmatrix} \mathbf{I}_{M/2} & \mathbf{I}_{M/2} \\ \mathbf{I}_{M/2} & -\mathbf{I}_{M/2} \end{bmatrix} \text{and } \Phi_i = \begin{bmatrix} \mathbf{U}_i & \mathbf{0}_{M/2} \\ \mathbf{0}_{M/2} & \mathbf{V}_i \end{bmatrix} \tag{89.45}$$

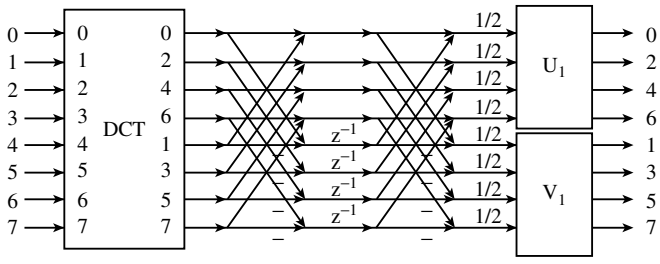

FIGURE 89.18 Polyphase transfer matrix of the lapped orthogonal transform.

© 2003 by CRC Press LLC

where $\mathbf{U}_i$ and $\mathbf{V}_i$ can be any $M/2 \times M/2$ orthogonal matrices, then $\mathbf{T}_i$ can be expressed as $\mathbf{T}_i = \mathbf{W}\boldsymbol{\Phi}_i\,\mathbf{W}$ and $\mathbf{SQT}_{N-1}$ can be simplified to

$$\mathbf{SQT}_{N-1} = \begin{bmatrix} \mathbf{S}_0\mathbf{U}_{N-1} & \mathbf{0}_{M/2} \\ \mathbf{0}_{M/2} & \mathbf{S}_1\mathbf{V}_{N-1} \end{bmatrix}\mathbf{W}$$

As $\mathbf{U}_{N-1}$ and $\mathbf{S}_0$ are generic orthogonal matrices, and the product $\mathbf{S}_0\mathbf{U}_{N-1}$ is also a generic orthogonal matrix, we can discard the term S_0 without any loss of generality. The same is valid for $\mathbf{S}_1$ with regard to $\mathbf{V}_{N-1}$. Therefore, we get $\mathbf{SQT}_{N-1} = \boldsymbol{\Phi}_{N-1}\,\mathbf{W}$ and (89.44) reduces to

$$\mathbf{E}(z) = \left(\prod_{i=N-1}^{1} \Phi_i \mathbf{W}\Lambda(z)\mathbf{W}\right)\mathbf{E}_0 \tag{89.46}$$

where $\mathbf{E}_0 = \boldsymbol{\Phi}_0\,\mathbf{WQ}$ is a general $M \times M$ orthogonal matrix with symmetric basis functions, i.e., the PTM of order of a LPPUFB. Since an order-n PTM leads to filters of length $(n + 1)\,M$, a LPPUFB with filter length $nM + M$ can be obtained from one with filter length nM by adding a stage to the PTM of the latter. For any $N > 1$, any PTM of a LPPUFB can be expressed as

$$\mathbf{E}(z) = \mathbf{K}_{N-1}(z)\mathbf{K}_{N-2}(z)\cdots\mathbf{K}_1(z)\mathbf{E}_0 \quad \text{where} \quad \mathbf{K}_i(z) = \Phi_i\mathbf{W}\Lambda(z)\mathbf{W} \tag{89.47}$$

The GenLOT is defined as a LPPUFB obeying (89.47) where $\mathbf{E}_0$ is chosen to be the DCT matrix, which we denote as $\mathbf{D}$ [Fig. 89.19(a)]. The output of the DCT is, then, separated into groups of even and odd indexed coefficients [Fig. 89.19(b)]. The GenLOT with $N - 1$ stages after the DCT has basis functions (filters) with length $L = NM$ and has its PTM defined as

$$\mathbf{E}(z) = \mathbf{K}_{N-1}(z)\mathbf{K}_{N-2}\cdots\mathbf{K}_1(z)\mathbf{D} \tag{89.48}$$

The implementation flow-graphs for the analysis and synthesis sections are shown in Fig. 89.19(b). In this figure, each branch carries $M/2$ samples.

The class of GenLOT's, defined in this way, allows us to view the DCT and LOT as special cases, respectively, for $N = 1$ and $N = 2$. The degrees of freedom reside on the matrices $\mathbf{U}_i$ and $\mathbf{V}_i$ that are only

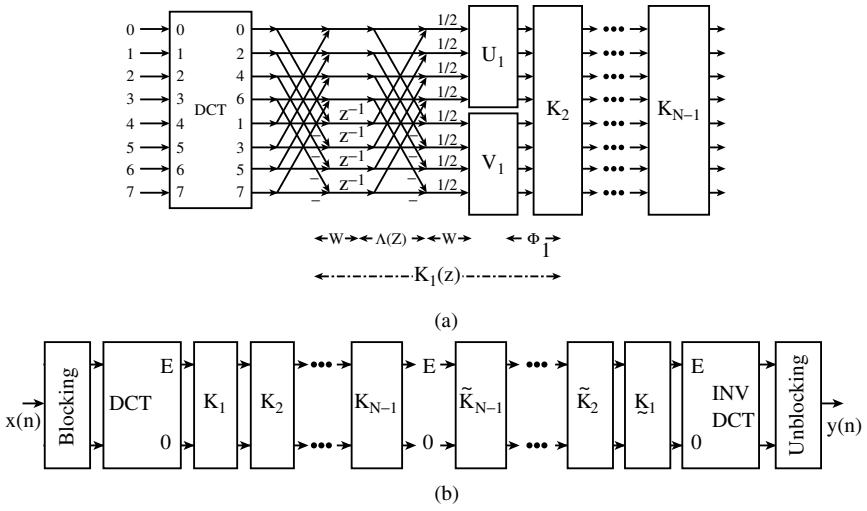

FIGURE 89.19 GenLOT–Generalized lapped orthogonal transform.

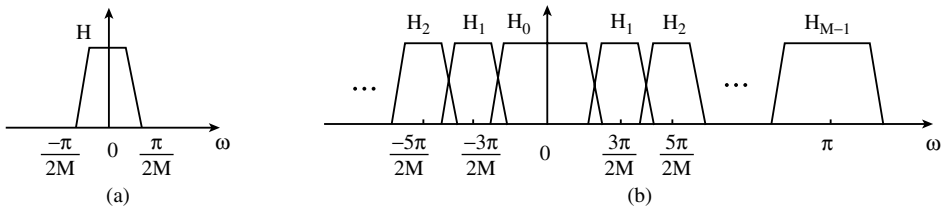

FIGURE 89.20 Ideal frequency response of the (a) prototype filter and (b) the analysis filters.

restricted to be real $M/2 \times M/2$ orthogonal matrices. Thus, each one can be parameterized into a set of $M(M-2)/8$ plane rotations, (or less, for constrained solutions). Similarly, to the lattice factorization in (89.41), the above factorization in (89.48) is a general factorization that covers all LPPUFB (even M).

Cosine-Modulated Filter Bank [13]–[16]

Let $H(z)$ and $F(z)$ be the prototype filters of the analysis and synthesis banks, respectively [as shown in Fig. 89.20(a)]. The cosine-modulated analysis and synthesis filters $H_k(z)$ and $F_k(z)$ are defined as

$$\begin{cases} H_k(z) = a_k b_k U_k(z) + a_k^* b_k^* U_k^*(z) \\ F_k(z) = a_k^* b_k V_k(z) + a_k b_k^* V_k^*(z) \end{cases} \quad \text{where} \begin{cases} U_k(z) = H\left(zW^{k+\frac{1}{2}}\right) \\ V_k(z) = F\left(zW^{k+\frac{1}{2}}\right) \end{cases} \tag{89.49}$$

$$\begin{cases} a_k = e^{j(-1)^k \frac{\pi}{4}} \\ b_k = W^{-\frac{1}{2}\left(k+\frac{1}{2}\right)} \end{cases}$$

and $W = e^{-jk\pi/M}$. The analysis and synthesis filters are cosine-modulated versions of the prototype filters, i.e.,

$$\begin{cases} h_k(n) = 2h(n)\cos\left[(2k+1)\dfrac{\pi}{2M}\left(n - \dfrac{N-1}{2}\right) + (-1)^k \dfrac{\pi}{4}\right] \\ f_k(n) = 2f(n)\cos\left[(2k+1)\dfrac{\pi}{2M}\left(n - \dfrac{N-1}{2}\right) - (-1)^k \dfrac{\pi}{4}\right] \end{cases} \tag{89.50}$$

Clearly from the above equations, the only parameters to be found are $h(n)$ and $f(n)$, $0 \le n \le N-1$. In the subsections below, we will elaborate on the pseudo-QMF bank and the paraunitary cosine-modulated filter bank.

Pseudo-QMF Bank [17]–[19]

$$\begin{cases} F(z) = H(z), H_k(z) \text{ and } F_k(z) \text{ are as in (89.47)} \\ H(z) \text{ is an even-length symmetric filter} \\ H(z) \text{ is a spectral factor of an } M\text{th band filter;} \end{cases} \tag{89.51}$$

The above choices of $H_k(z)$ and $F_k(z)$ ensure that the aliasing from an adjacent band is canceled (i.e., $T_1(z) \approx T_{M-1}(z) \approx 0$). The aliasing levels from $T_2(z)$ to $T_{M-2}(z)$ are comparable to the stopband attenuation

© 2003 by CRC Press LLC

of $H(e^{jw})$. The distortion function $T_0(z)$ is a delay. In summary, as long as one can design a low-pass filter with high stopband attenuation and satisfies (89.51), then the only reconstruction error in the pseudo-QMF bank is the aliasing components in $T_k(z)$, $2 \le k \le M-2$.

Paraunitary Cosine-Modulated Filter Bank [13]

Let $H(z) = \sum_{l=0}^{2M-1} z^{-l} G_l(z^{2M})$ be the linear-phase prototype filters, where $G_l(z)$ is the type-I polyphase components of $H(z)$. $\mathbf{E}(z)$ can be expressed in terms of $G_l(z)$ and $\hat{\mathbf{C}}$ as [13].

$$\mathbf{E}(z) = \hat{\mathbf{C}} \begin{pmatrix} \mathbf{g}_0(-z^2) \\ z^{-1}\mathbf{g}_1(-z^2) \end{pmatrix} \tag{89.52}$$

where

$$\begin{cases} \mathbf{g}_0(z) = \mathrm{diag}\left[G_0(z)\ G_1(z)\ \cdots\ G_{M-1}(z)\right] \\ \mathbf{g}_1(z) = \mathrm{diag}\left[G_M(z)\ G_{M+1}(z)\ \cdots\ G_{2M-1}(z)\right] \\ \left[\hat{\mathbf{C}}\right]_{k,l} = 2\cos\left((2k+1)\dfrac{\pi}{2M}\left(1-\dfrac{N-1}{2}\right)+(-1)^k\dfrac{\pi}{4}\right) \end{cases} \tag{89.53}$$

Using the above $\mathbf{E}(z)$, one obtains the expression for $\mathbf{P}(z) \triangleq \tilde{\mathbf{E}}\mathbf{E}(z)$ as follows:

$$\mathbf{P}(z) = \left(\tilde{\mathbf{g}}_0(-z^2)\ \ z\tilde{\mathbf{g}}_1(-z^2)\right)\hat{\mathbf{C}}^T\hat{\mathbf{C}} \begin{pmatrix} \mathbf{g}_0(-z^2) \\ z^{-1}\mathbf{g}_1(-z^2) \end{pmatrix} \tag{89.54}$$

Substitute the appropriate expression for $\hat{\mathbf{C}}^T\hat{\mathbf{C}}$ and simplifying, (89.54) becomes (for length = $2m$M)

$$\frac{1}{2M}\mathbf{P}(z) = \tilde{\mathbf{g}}_0(z)\mathbf{g}_0(z) + \tilde{\mathbf{g}}_1(z)\mathbf{g}_1(z) \tag{89.55}$$

The above equations are the necessary and sufficient conditions on the polyphase filters $G_l(z)$ for a paraunitary cosine-modulated filter bank. Writing (89.52) in terms of the polyphase filters $G_l(z)$, we have

$$\tilde{G}_l(z)G_l(z) + \tilde{G}_{M+l}(z)G_{M+l}(z) = \frac{1}{2M}(-z)^{-s} \tag{89.56}$$

In summary, as long as the polyphase components $G_l(z)$ of the linear-phase prototype filter $H(z)$ satisfy the conditions in (89.56), then the cosine-modulated filter bank is paraunitary.

Lattice Structure **[13],[29].** The above condition (89.56) is the same as the condition in the paraunitary two-channel filter bank. Thus, the cosine-modulated filter bank can be implemented as a parallel bank of two-channel paraunitary filter banks, as depicted in Fig. 89.21.

The theory for the paraunitary cosine-modulated filter bank where the lengths of the analysis filters are arbitrary is discussed in [16]. It turns out that the same PR conditions on the polyphase components as in (89.56) hold for the arbitrary-length case [16]. The above paraunitary cosine-modulated filter bank is general and covers all paraunitary cosine-modulated filter banks. The implementation is efficient because of the lattice structures associated with the pair $[G_k(z), G_{k+M}(z)]$ and the matrix $\hat{\mathbf{C}}$. See [13],[29] for the details.

Biorthogonal cosine-modulated filter banks allow additional properties such as allpass polyphase components and variable overall delay [15]. By trading-off between the filter attenuation and the overall system delay, it is possible to obtain a PR cosine-modulated filter bank where the overall delay is a variable.

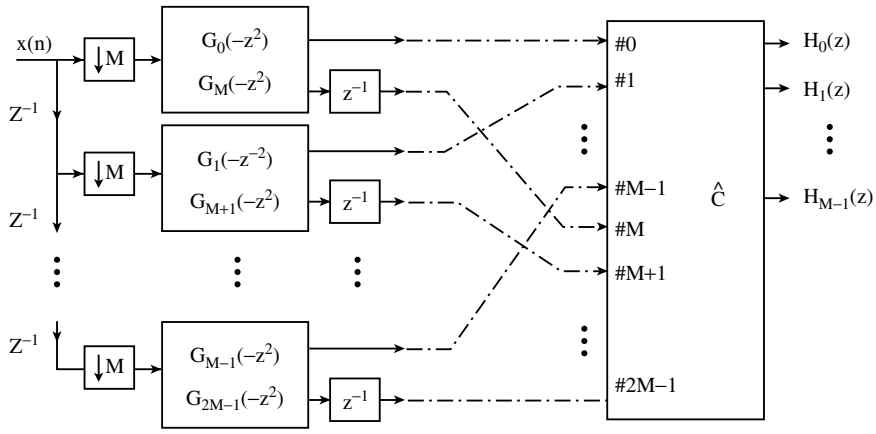

FIGURE 89.21 Lattice structure implementation of paraunitary cosine-modulated filter bank.

89.5 Design of Filter Bank

The problem of designing a PR filter bank can be formulated as finding **h** such that it

$$\text{Minimize } \Phi \text{ subject to PR conditions} \tag{89.57}$$

where Φ is the objective function. The specific form of Φ depends on the application of the filter bank. Some popular objective functions are the passband and stopband attenuation and/or coding gain, etc. Since all of the above PR filter banks are characterized by the appropriate set of lattice coefficients, therefore, the PR conditions are satisfied automatically as long as the search space is constrained to the lattice coefficient space only. The design problem reduces to finding the lattice coefficient such that the objective function is minimized.

For any set of lattice coefficients, the corresponding filters can be computed. The filters are a nonlinear function with respect to the lattice coefficients. Consequently, the objective function (which is normally a function of the filter coefficients) is also a nonlinear function with respect to the lattice coefficients. Thus, designing filter banks with small objective function is a problem because of the nonlinear relation between the lattice coefficients and the objective function. Instead of dealing with the lattice coefficients, the QCLS (quadratic constrained least squares) approach uses the filter coefficients as design parameters. Both the objective function and the PR conditions are formulated in quadratic forms $\mathbf{h}^T\mathbf{P}\mathbf{h}$ and $\mathbf{h}^T\mathbf{Q}_k\mathbf{h} = c_k$, respectively. The design problem becomes

$$\text{Minimize } \mathbf{h}^T\mathbf{P}\mathbf{h} \text{ subject to } \mathbf{h}^T\mathbf{Q}_k\mathbf{h} = c_k \tag{89.58}$$

The advantage here is that the derivatives and the Hessian of both the objective function and the PR conditions can be computed exactly, which helps the minimization algorithm.

Lattice-Structure Approach

Most of the PR filter banks such as the

- two-channel paraunitary filter bank,
- two-channel biorthogonal linear-phase filter bank,
- *M*-channel linear-phase paraunitary filter bank,
- GenLOT,
- paraunitary cosine-modulated filter bank,

can be implemented based on lattice structure (see the separate subsections). For any set of lattice coefficients, the properties associated with the filter bands (such as paraunitary, linear-phase, cosine-modulation,

© 2003 by CRC Press LLC

etc.) are structurally imposed. Consequently, the only question to be addressed in the design is to find the appropriate set of lattice coefficients such that the resulting filters have desirable frequency responses. The design problem can be formulated as

$$\min \Phi$$

where the parameter space is the lattice coefficients k_i and Φ is the objective function. The objective function could take many different forms depending on the applications. Examples are stopband attenuation, coding gain (the optimization becomes maximization problem in this case), interference energy, etc. Design examples of lattice-based design method can be found in [3], [4], [7]–[13].

Consider the lattice structure for the two-channel paraunitary filter bank in Fig. 89.15. The analysis filters $H_k(z)$ are nonlinear functions with respect to the lattice coefficients (in blocks $\mathbf{U}_k$ and $\mathbf{V}_k$). In other words, a small deviation in the lattice coefficients at the first few stages affects the frequency responses of $H_k(z)$ greatly. On the other hand, the effect on $H_k(z)$ by a small deviation in the lattice coefficients at the last few stages is minimal. Since the relations between the lattice coefficients and the filters are nonlinear, designing filter banks with high attenuation is a challenging task. Alternative methods on designing filter banks where the parameters are the filter coefficients are presented below.

Quadratic-Constrained Least-Squares (QCLS) Approach

For a paraunitary filter bank, the PR condition in (89.10) becomes

$$\begin{cases} T_0(z) = z^{-n_o} \\ T_k(z) = 0 \quad 1 \le k \le M-1 \end{cases} \qquad T_k(z) = \frac{1}{M} \sum_{l=0}^{M-1} z^{-(N-1)} H_l\left(z^{-1}\right) H_l\left(zW^k\right) \tag{89.59}$$

where the parameters to be found are the coefficients of $H_k(z)$. Let $\mathbf{h}$ be a vector consisting of all the filter coefficients $h_k(n)$, $0 \le k \le M-1$, and $0 \le n \le N-1$, i.e.,

$$\mathbf{h} = \left[h_0(0) \quad \cdots \quad h_0(N-1) \quad \cdots \quad h_{M-1}(0) \quad \cdots \quad h_{M-1}(N-1)\right]^T \tag{89.60}$$

then (89.59) can be written in the following form:

$$\begin{cases} \mathbf{h}^T \mathbf{Q}_k \mathbf{h} = 0 \\ \mathbf{h}^T \mathbf{S}_k \mathbf{h} - 1 \end{cases} \tag{89.61}$$

where $\mathbf{Q}_k$ and $\mathbf{S}_k$ depend on the filter bank parameters. Furthermore, it is possible to express the objective function as a quadratic form in $\mathbf{h}$ [38], i.e.,

$$\Phi = \mathbf{h}^T \mathbf{P} \mathbf{h} \tag{89.62}$$

where $\mathbf{P}$ is a real, symmetric and positive-definite matrix. Combining (89.61) and (89.62), the optimized filter $H_k(z)$ is precisely $\mathbf{h}_{\text{opt}}$ such that

$$\mathbf{h}_{\text{opt}} = \min \mathbf{h}^T \mathbf{P} \mathbf{h} \text{ subject to } \begin{cases} \mathbf{h}^T \mathbf{Q}_k \mathbf{h} = 0 \\ \mathbf{h}^T \mathbf{S}_k \mathbf{h} = 1 \end{cases} \tag{89.63}$$

In summary, we would like to formulate the design problem into a least-squares optimization problem with quadratic constraints as in (89.63). Since $\mathbf{Q}_k$ is normally not positive definite, it is difficult to solve the above minimization problem. However, there are optimization procedures that approximately solve (89.63) by linearizing the quadratic constraints [35]. Using these procedures will yield an approximate solution (i.e., the constraints are not satisfied exactly). However, the errors are very small and can be ignored in most practical cases, as we will demonstrate in the examples below.

© 2003 by CRC Press LLC

In the following subsections, we will express the appropriate PR conditions in quadratic form as in (89.63) for the two-channel PR linear-phase filter bank, the NPR pseudo-QMF bank, PR cosine-modulated filter bank, and the M-channel orthonormal filter bank. The forms of $\mathbf{Q}_k$ and $\mathbf{S}_K$ will be derived in detail.

Two-Channel Linear-Phase Biorthogonal (SAOO) Filter Bank

In this subsection, the PR condition for the two-channel linear-phase (SAOO) biorthogonal filter bank is formulated as a QCLS problem. Let $H_0(z) = \sum_{n=0}^{2m-1} h_0(n)z^{-n}$ and $H_1(z) = \sum_{n=0}^{2m-1} h_1(n)z^{-n}$ be the symmetric and antisymmetric linear-phase filters, respectively. Because of the symmetries in both $h_0(n)$ and $h_1(n)$, the only parameters in this filter bank are $h_0(n)$ and $h_1(n)$ for $0 \le n \le (m-1)$. In order to cancel aliasing at the output, the synthesis filters must be $F_0(z) = -H_1(-z)$ and $F_1(z) = H_0(-z)$. Using the above choices for $F_1(z)$, the overall distortion function $T(z)$ for a PR system (which should be a delay) is

$$T(z) \triangleq \sum_{n=0}^{4m-2} t(n)z^{-n} = -H_0(z)H_1(-z) + H_0(-z)H_1(z) = z^{-n_0} \tag{89.64}$$

where n_0 is a positive integer. One can verify that $T(z)$ is a symmetric transfer function and consequently, $n_0 = 2m-1$. Thus, $t(n)$ must satisfy the following conditions for a PR system

$$t(n) = \begin{cases} 0 & 0 \le n \le 2m-2 \\ & \\ 1 & n = 2m-1 \end{cases} \tag{89.65}$$

Substituting $(-z)$ for z in (89.64), one obtains $T(z) = -T(-z) = z^{-1}\hat{T}(z^2)$, where $\hat{T}(z)$ is an arbitrary polynomial. In other words, $t(n) = 0$ for even n. Consequently, the $2m$ conditions in (89.65) reduce to the following m conditions:

$$t(2k+1) = \begin{cases} 0 & 0 \le k \le m-2 \\ & \\ 1 & k = m-1 \end{cases} \tag{89.66}$$

Let

$$\begin{cases} \mathbf{h} = \begin{bmatrix} h_0(0) & \dots & h_0(m-1) & h_1(0) & \dots & h_1(m-1) \end{bmatrix}^T \\ \mathbf{e}(z) = \begin{pmatrix} 1 & z^{-1} & \dots & z^{-(m-1)} \end{pmatrix}^T \end{cases} \tag{89.67}$$

It is our objective to express the above m conditions in (89.66) in terms of the unknown variable **h.** The polynomials $H_0(z)$, $H_1(z)$, $H_0(-z)$, and $H_1(-z)$ can be written in the following forms:

$$\begin{cases} H_0(z) = \mathbf{h}^T \begin{pmatrix} \mathbf{e}(z) + z^{-m}\mathbf{J}\mathbf{e}(z) \\ \mathbf{0} \end{pmatrix} \\ \\ H_0(-z) = \mathbf{h}^T \begin{pmatrix} \mathbf{U}\mathbf{e}(z) + (-1)^m z^{-m}\mathbf{J}\mathbf{U}\mathbf{e}(z) \\ \mathbf{0} \end{pmatrix} \\ \\ H_1(z) = \mathbf{h}^T \begin{pmatrix} \mathbf{0} \\ \mathbf{e}(z) - z^{-m}\mathbf{J}\mathbf{e}(z) \end{pmatrix} \\ \\ H_1(-z) = \mathbf{h}^T \begin{pmatrix} \mathbf{0} \\ \mathbf{U}\mathbf{e}(z) - (-1)^m z^{-m}\mathbf{J}\mathbf{U}\mathbf{e}(z) \end{pmatrix} \end{cases} \tag{89.68}$$

© 2003 by CRC Press LLC

where **J** is the exchange matrix and **U** is a diagonal matrix with elements $U_{k,k} = (-1)^k$ Substituting the above relations into (89.64), $T(z)$ is simplified to

$$T(z) = \mathbf{h}^T \begin{pmatrix} \mathbf{0} & \Gamma(z) \\ \mathbf{0} & \mathbf{0} \end{pmatrix} \mathbf{h} \tag{89.69}$$

where

$$\begin{aligned} \Gamma(z) = &\left[\mathbf{U}\mathbf{e}(z)\mathbf{e}^T(z) - \mathbf{e}(z)\mathbf{e}^T(z)\mathbf{U}\right] + z^{-m}\Big[(-1)^m\left(\mathbf{J}\mathbf{U}\mathbf{e}(z)\mathbf{e}^T(z) + \mathbf{e}(z)\mathbf{e}^T(z)\mathbf{U}\mathbf{J}\right) \\ &-\left(\mathbf{U}\mathbf{e}(z)\mathbf{e}^T(z)\mathbf{J} + \mathbf{J}\mathbf{e}(z)\mathbf{e}^T(z)\mathbf{U}\right)\Big] \\ &+z^{-2m}(-1)^m\left[\mathbf{J}\mathbf{e}(z)\mathbf{e}^T(z)\mathbf{U}\mathbf{J} - \mathbf{J}\mathbf{U}\mathbf{e}(z)\mathbf{e}^T(z)\mathbf{J}\right] \end{aligned} \tag{89.70}$$

The only matrix in $\Gamma(z)$ that is a function of z is $\mathbf{e}(z)\mathbf{e}^T(z)$. Substituting

$$\mathbf{e}(z)\mathbf{e}^T(z) = \sum_{n=0}^{2m-2} z^{-n}\mathbf{D}_n \quad \text{where} \quad \left[\mathbf{D}_n\right]_{i,j} = \begin{cases} 1 & i+j=n \\ 0 & \text{otherwise} \end{cases}$$

in $\Gamma(z)$, then the right-hand side of (89.69) is a polynomial of the form

$$\sum_{k=0}^{4m-2} z^{-k}\mathbf{h}^T \begin{pmatrix} \mathbf{0} & \Gamma_n \\ \mathbf{0} & \mathbf{0} \end{pmatrix} \mathbf{h}$$

where Γ_k are constant matrices depending on $\mathbf{D}_k$, **J,** and **U**. Comparing term-by-term in (89.69), (89.66) becomes

$$\begin{cases} \mathbf{h}^T\mathbf{Q}_{2k+1}\mathbf{h} = 0 & 0 \le k \le m-2 \\ \mathbf{h}^T\mathbf{Q}_{2m-1}\mathbf{h} = 1 \end{cases} \tag{89.71}$$

where

$$\mathbf{Q}_n = \begin{pmatrix} \mathbf{0} & \Gamma_n \\ \mathbf{0} & \mathbf{0} \end{pmatrix}$$

and

$$\Gamma_n = \begin{cases} \mathbf{U}\mathbf{D}_n - \mathbf{D}_n\mathbf{U} & 0 \le n \le m-1 \\ \mathbf{U}\mathbf{D}_n - \mathbf{D}_n\mathbf{U} + (-1)^m\left(\mathbf{J}\mathbf{U}\mathbf{D}_{n-m} + \mathbf{D}_{n-m}\mathbf{U}\mathbf{J}\right) & \\ \quad -\left(\mathbf{U}\mathbf{D}_{n-m}\mathbf{J} + \mathbf{J}\mathbf{D}_{n-m}\mathbf{U}\right) & m \le n \le 2m-2 \\ (-1)^m\left(\mathbf{J}\mathbf{U}\mathbf{D}_{m-1} + \mathbf{D}_{M-1}\mathbf{U}\mathbf{J}\right) & \\ \quad -\left(\mathbf{U}\mathbf{D}_{m-1}\mathbf{J} + \mathbf{J}\mathbf{D}_{m-1}\mathbf{U}\right) & n = 2m-1 \end{cases} \tag{89.72}$$

In summary, the PR condition in (89.64) is rewritten as m quadratic constraints on **h** as in (89.71).

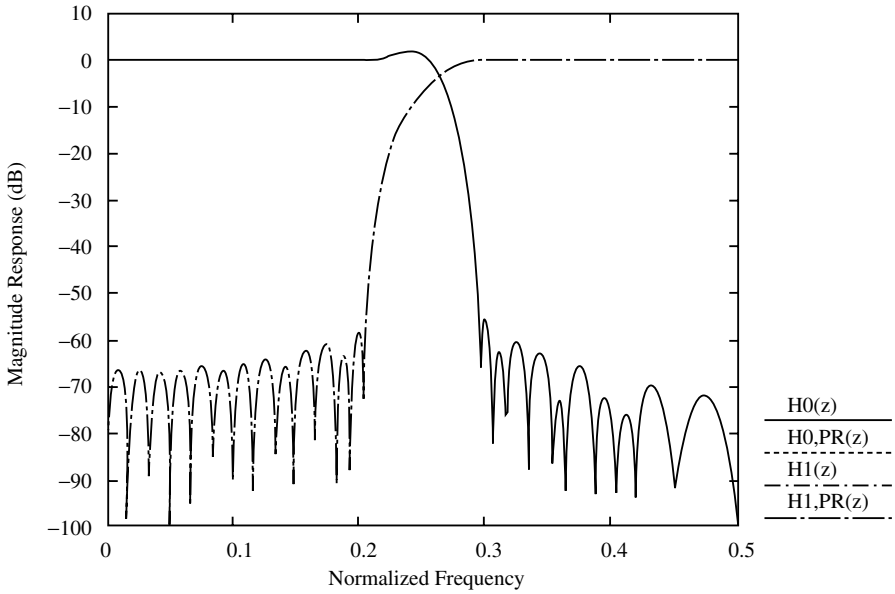

FIGURE 89.22 Magnitude response plots for the two-channel linear-phase filter bank.

Design Procedure.

- Given m and the passband and stopband edges of $H_k(z)$, compute $\mathbf{P}$ using the eigenfilter technique [38]. Since the polyphase matrices are not lossless, the frequency error Φ must include both passband and stopband errors in $H_k(z)$.
- Compute $\mathbf{Q}_{2k+1}$ from (89.72).
- Design a low-pass and a high-pass linear-phase filter with the same specifications as in $H_0(z)$ and $H_1(z)$, using any filter design method. Use their coefficients as an initialized value for $\mathbf{h}$ in the quadratic-constrained minimization problem as in (89.63). Use any nonlinear optimization algorithm (such as IMSL [36]) to solve the above minimization problem.

Example. Let $m = 31$ and the passband and stopband edges of $H_0(z)$ and $H_1(z)$ be 0.414π and 0.586π, respectively. The magnitude responses of $H_k(z)$ are plotted in Fig. 89.22. The stopband attenuations for $H_0(z)$ and $H_1(z)$ are –57.4 dB and –57.9 dB, respectively, which are about 14.9 dB and 15.4 dB better than those designed using the lattice approach [4]. The above filter bank is only an approximate PR filter bank since the quadratic constraints are approximately satisfied (the error is about 1×10^{-15}). To obtain a PR filter bank, we synthesize the lattice coefficients using the procedure in [4]. With these lattice coefficients, the corresponding PR analysis filters $H_{0,\mathrm{PR}}(z)$ and $H_{1,\mathrm{PR}}(z)$ are computed and their magnitude responses, together with those of $H_k(z)$, are plotted in Fig. 89.22. We observe practically no difference between the PR analysis filters $H_{k,\mathrm{PR}}(z)$ and the analysis filters $H_k(z)$ designed using the proposed method.

M-Channel Near-Perfect-Reconstruction (NPR) Pseudo-QMF Bank

The pseudo-QMF banks belong to the family of modulated filter banks. Pseudo-QMF theory is well known and is widely used. The analysis and synthesis filters are cosine-modulated versions of a prototype filter. Since the desired analysis and synthesis filters have narrow transition bands and high stopband attenuation, the overlap between nonadjacent filters is negligible. Moreover, the significant aliasing terms from the overlap of the adjacent filters are canceled by the filter designs. The prototype filter $H(z)$ is found by minimizing an objective function consisting of the stopband attenuation and the overall distortion. Although it is possible to obtain a pseudo-QMF bank with high attenuation, the overall distortion level might be high (on the order of –40 dB). In summary, the overall distortion of the pseudo-QMF bank is not sufficiently small for applications where a –100 dB error level is required.

© 2003 by CRC Press LLC

The NPR pseudo-QMF bank is a special case of the pseudo-QMF bank where the prototype filter $H(z)$ is a *linear-phase spectral factor of a 2Mth band filter.* The analysis and synthesis filters $h_k(n)$ and $f_k(n)$ are cosine-modulated versions of the prototype filter $h(n)$. With the above properties, the output of an NPR filter bank does not have any amplitude or phase distortions. The only reconstruction error is the aliasing error, which is comparable to the stopband attenuation. Even though $H(z)$ is a spectral factor of a 2Mth band filter, no spectral factorization is needed in the new approach. In other words, the 2Mth band constraints are imposed approximately. This approach yields NPR solutions where there is some aliasing at the reconstructed output (the level is comparable to the stopband attenuation). In order to obtain total aliasing cancellation (and thus, PR), not only the prototype filter $h(n)$ should be a spectral factor of a 2Mth band filter, but each polyphase component (in an M-phase decomposition) of $h(n)$ should be a spectral factor of a halfband filter.

***QCLS Formulation* (*Even Length*) [19].** Let $H(z) = \sum_{n=0}^{N-1} h(n)z^{-n}$ be the real-coefficient, linear-phase, even-length prototype filter of length N, where $N = 2\ (mM + m_1)$ and $0 \le m_1 \le M - 1$. Assume that $H(z)$ is a linear-phase spectral factor of a 2Mth band filter $G(z)$, i.e., $G(z) = z^{-(N-1)}H(z)\ \tilde{H}(z) = H^2(z)$ in lieu of linear-phase property of $H(z)$. The analysis and synthesis filters $h_k(n)$ and $f_k(n)$ are cosine-modulated versions of $h(n)$. Defining $\mathbf{h}$ and $\mathbf{e}(z)$ as

$$\begin{cases} \mathbf{h} = \begin{bmatrix} h(0) & h(1) & \cdots & h(mM + m_1 - 1) \end{bmatrix}^T \\ \mathbf{e}(z) = \begin{bmatrix} 1 & z^{-1} & \cdots & z^{-1(mM+m_1-1)} \end{bmatrix}^T \end{cases} \tag{89.73}$$

then the prototype filter $H(z)$ can be represented as

$$H(z) = \mathbf{h}^T \begin{pmatrix} \mathbf{I} & \mathbf{J} \end{pmatrix} \begin{pmatrix} \mathbf{e}(z) \\ z^{(mM+m_1)}\mathbf{e}(z) \end{pmatrix}$$

where the dimensions of both $\mathbf{I}$ and $\mathbf{J}$ are $(mM + m_1) \times (mM + m_1)$. Using the above notation, the 2Mth band filter $G(z)$ is

$$\begin{aligned} G(z) &= \sum_{n=0}^{4mM+4m_1-2} g(n)z^{-n} \\ &= H^2(z) = \mathbf{h}^T \begin{pmatrix} \mathbf{I} & \mathbf{J} \end{pmatrix} \begin{pmatrix} \mathbf{e}(z) \\ z^{-(mM+m_1)}\mathbf{e}(z) \end{pmatrix} \begin{bmatrix} \mathbf{e}^T(z) & z^{-(mM+m_1)}\mathbf{e}^T(z) \end{bmatrix} \begin{pmatrix} \mathbf{I} \\ \mathbf{J} \end{pmatrix} \mathbf{h} \\ &= \mathbf{h}^T \Big[\mathbf{V}(z) + z^{-(mM+m_1)}(\mathbf{J}\mathbf{V}(z) + \mathbf{V}(z)\mathbf{J}) + z^{-2(mM+m_1)}\mathbf{J}\mathbf{V}(z)\mathbf{J} \Big] \mathbf{h} \end{aligned} \tag{89.74}$$

where

$$\mathbf{V}(z) = \mathbf{e}(z)\mathbf{e}^T(z) = \begin{pmatrix} 1 \\ z^{-1} \\ \vdots \\ z^{-(mM+m_1-1)} \end{pmatrix} (1\ z^{-1} \cdots z^{-(mM+m_1-1)}) = \sum_{n=0}^{2mM+2m_1-2} z^{-n}\mathbf{D}_n \tag{89.75}$$

© 2003 by CRC Press LLC

Here, $\mathbf{D}_n$ is defined as

$$\left[\mathbf{D}_n\right]_{i,j} = \begin{cases} 1 & i+j=n \\ 0 & \text{otherwise} \end{cases}$$

Substituting (89.75) into (89.74) and simplifying, we have

$$G(z) = \sum_{n=0}^{4mM+4m_1-2} \mathrm{g}(n) z^{-n} = \mathbf{h}^T \left(\sum_{n=0}^{4mM+4m_1-2} z^{-n} \mathbf{S}_n \right) \mathbf{h} \tag{89.76}$$

where $\mathbf{S}_n$ depends on $\mathbf{D}_n$ and $\mathbf{J}$ as follows:

$$\mathbf{S}_n = \begin{cases} \mathbf{D}_n & 0 \le n \le mM + m_1 - 1 \\ \mathbf{D}_n + \mathbf{J}\mathbf{D}_{n-mM-m_1} & \\ \quad + \mathbf{D}_{n-mM-m_1}\mathbf{J} & mM + m_1 \le n \le 2\left(mM + m_1 - 1\right) \\ \mathbf{J}\mathbf{D}_{mM+m_1-1} + \mathbf{D}_{mM+m_1-1}\mathbf{J} & n = 2\left(mM + m_1\right) - 1 \\ \mathbf{J}\mathbf{D}_{n-mM-m_1} + \mathbf{D}_{n-mM+m_1}\mathbf{J} & \\ \quad + \mathbf{J}\mathbf{D}_{n-2mM-2m_1}\mathbf{J} & 2\left(mM + m_1\right) \le n \le 3\left(mM + m_1\right) - 2 \\ \mathbf{J}\mathbf{D}_{n-2mM-2m_1}\mathbf{J} & 3\left(mM + m_1\right) - 1 \le n \le 4\left(mM + m_1\right) - 2 \end{cases} \tag{89.77}$$

The objective is to find $\mathbf{h}$ such that $G(z)$ is a $2M$th band filter, i.e.,

$$g_n = \begin{cases} 0 & n = 2\left(mM + m_1\right) - 1 - 2lM \quad \begin{cases} 1 \le l \le m-1 & m_1 = 0 \\ 1 \le l \le m & m_1 \ne 0 \end{cases} \\ \dfrac{1}{2M} & n = 2\left(mM + m_1\right) - 1 \end{cases} \tag{89.78}$$

Equating the terms with the same power of z^{-1} in (89.76) and using (89.77) and (89.78), the following m constraints on $\mathbf{h}$ are obtained:

$$\begin{cases} \mathbf{h}^T \mathbf{D}_n \mathbf{h} = 0 & \begin{cases} \left\lfloor \dfrac{(m+1)}{2} \right\rfloor \le l \le (m-1) & m_1 = 0 \\ \left\lfloor \dfrac{(m+1)}{2} \right\rfloor \le l \le m & m_1 \ne 0 \end{cases} \\ \mathbf{h}^T \left(\mathbf{D}_n + \mathbf{J}\mathbf{D}_{n-mM-m_1} + \mathbf{D}_{n-mM-m_1}\mathbf{J} \right) \mathbf{h} = 0 & 1 \le l \le \left\lfloor \dfrac{(m+1)}{2} \right\rfloor - 1 \\ \mathbf{h}^T \left(\mathbf{J}\mathbf{D}_{mM+n_1-1} + \mathbf{D}_{mM+m_1-1}\mathbf{J} \right) \mathbf{h} = \dfrac{1}{2M} & \end{cases} \tag{89.79}$$

© 2003 by CRC Press LLC

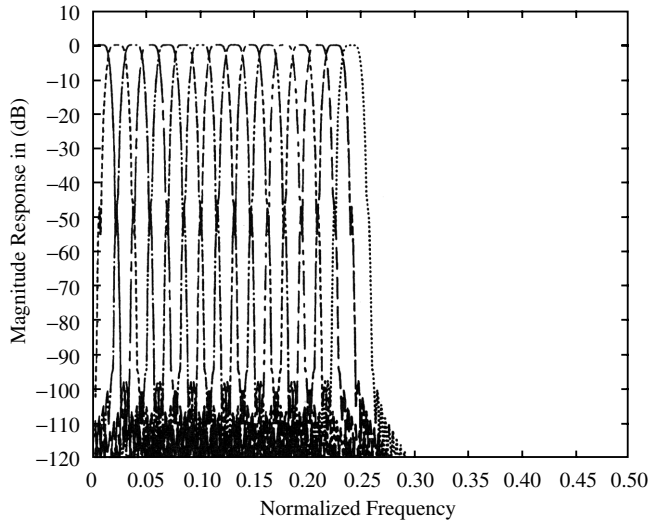

FIGURE 89.23 Magnitude response plots for the NPR pseudo-QMF bank.

for $n = 2M(m - l) + 2m_1 - 1$. In summary, as long as **h** satisfies the m conditions in (89.79), the resulting pseudo-QMF band has no amplitude or phase distortions. The only reconstruction error is aliasing which can be minimized by finding solutions with high stopband attenuation. The optimized filter $H(z)$ of the NPR pseudo-QMF band is the solution of

$$\mathbf{h}_{\text{opt}} = \text{Min}\,\mathbf{h}^T\mathbf{P}\mathbf{h} \quad \text{subject to} \quad (89.79) \tag{89.80}$$

Example. In this example, a 32-channel pseudo-QMF bank is designed using the above method. Let $m = 8$, $m_1 = 0$, $M = 32$ ($N = 512$). The magnitude responses of the optimized analysis filters $H_k(z)$ are plotted in Fig. 89.23. The stopband attenuation and the aliasing level are about 96 dB and –96 dB, respectively. The amplitude distortion in this example is about 1×10^{-12}.

M-Channel Paraunitary Cosine-Modulated Filter Bank

Recently, the paraunitary cosine-modulated filter bank has emerged as an optimal filter bank with respect to implementation cost and design ease. The impulse responses of the analysis filters $h_k(n)$ and $f_k(n)$ are cosine-modulated versions of the prototype filter $h(n)$, i.e.,

$$\begin{cases} h_k(n) = 2h(n)\cos\left((2k+1)\dfrac{\pi}{2M}\left(n-\dfrac{N-1}{2}\right)+(-1)^k\dfrac{\pi}{4}\right) \\ f_k(n) = 2h(n)\cos\left((2k+1)\dfrac{\pi}{2M}\left(n-\dfrac{N-1}{2}\right)-(-1)^k\dfrac{\pi}{4}\right) \end{cases} \tag{89.81}$$

where n and k are in the range of $0 \le n \le N-1$ and $0 \le k \le M-1$, respectively. Here, the lengths of $H_k(z)$ and $F_k(z)$ are assumed to be multiples of $2M$, i.e., $N = 2mM$. The PR condition is shown in (89.56) for the case of even M. It is our objective to rewrite these PR conditions in quadratic form (89.61). Here we only consider the even M case since the odd M case is very similar. In terms of the variables $h(n)$, the polyphase filter $G_k(z)$ is

$$G_k(z) = \mathbf{h}^T\mathbf{V}_k\mathbf{e}(z) \quad \text{and} \quad G_k(z-1) = z^{m-1}\mathbf{h}^T\mathbf{V}_k\mathbf{J}\mathbf{e}(z) \tag{89.82}$$

© 2003 by CRC Press LLC

where

$$\begin{cases} \mathbf{h} = \left[\mathrm{h}(0) \quad h(1) \quad \cdots \quad h(mM-1)\right]^T \\ \mathbf{e}(z) = \left(1 \quad z^{-1} \quad \cdots \quad z^{-(m-1)}\right)^T \end{cases}$$

$$\left[\mathbf{V}_k\right]_{i,j} = \begin{cases} 1 & \begin{cases} i = k + 2jm & k + 2jM < mM \\ i = 2M(m-j) - 1 - k & k + 2jM \geq mM \end{cases} \\ 0 & \text{otherwise} \end{cases} \tag{89.83}$$

Note that the dimensions of **h,** $\mathbf{e}(z)$ and $\mathbf{V}_k$ are $(mM \times 1)$, $(m \times 1)$, and $(mM \times m)$, respectively. Equation (89.56) is simplified to

$$\mathbf{h}^T\left[\mathbf{V}_k \mathbf{J} \mathbf{e}(z) \mathbf{e}^T(z) \mathbf{V}_k^T + \mathbf{V}_{M+k} \mathbf{J} \mathbf{e}(z) \mathbf{e}^T(z) \mathbf{V}_{M+k}^T\right]\mathbf{h} = \frac{1}{2M} z^{-(m-1)} \tag{89.84}$$

Substituting

$$\mathbf{e}(z)\mathbf{e}^T(z) = \sum_{n=0}^{2m-2} z^{-n} \mathbf{D}_n \quad \text{where} \quad \left[\mathbf{D}_n\right]_{i,j} = \begin{cases} 1 & i + j = n \\ 0 & \text{otherwise} \end{cases} \tag{89.85}$$

into (89.84) and simplifying, one obtains the following conditions on **h**:

$$\mathbf{h}^T\left[\mathbf{V}_k \mathbf{J} \mathbf{D}_n \mathbf{V}_k^T + \mathbf{V}_{M+k} \mathbf{J} \mathbf{D}_n \mathbf{V}_{M+k}^T\right]\mathbf{h} = \begin{cases} 0 & 0 \leq n \leq m-2 \\ \dfrac{1}{2M} & n = m-1 \end{cases} \tag{89.86}$$

for k in the range $0 \leq k \leq M/2 - 1$. Note that the index n only goes to $m - 1$ since (89.56) is symmetric. In summary, the $M/2$ PR conditions in (89.56) are rewritten as $mM/2$ quadratic constraints in **h** as in (89.86).

Design Procedure.

- Given M, m, and the stopband edge of $H(z)$, compute **P** using the eigenfilter technique [38] (only the stopband of $|H(\mathbf{e}^{j\omega})|$ is needed because of the power-complementary property).
- For each k in the range $0 \leq k \leq M/2 - 1$, compute the m conditions using (89.86). The total number of conditions is $mM/2$.
- Design a low-pass filter with the same specifications as in $H(z)$ and use its coefficients as an initialized value for **h** in the quadratic-constrained minimization problem (89.63). Use any nonlinear minimization algorithm (such as IMSL [36]) to solve the above minimization problem.

Example. Let $M = 16$ and $m = 8$; thus the filter length is $N = 256$. The magnitude responses of the optimized analysis filters $H_k(z)$ are shown in Fig. 89.24. The stopband attenuation of the optimized analysis filters is about –82 dB, which is much higher than those designed using conventional approaches. Keep in mind that the above filter bank is only an approximate PR filter bank since the involved quadratic constraints are approximately satisfied (the error is about 1×10^{-9}). This error is very small and can be considered to be negligible for all practical purposes.

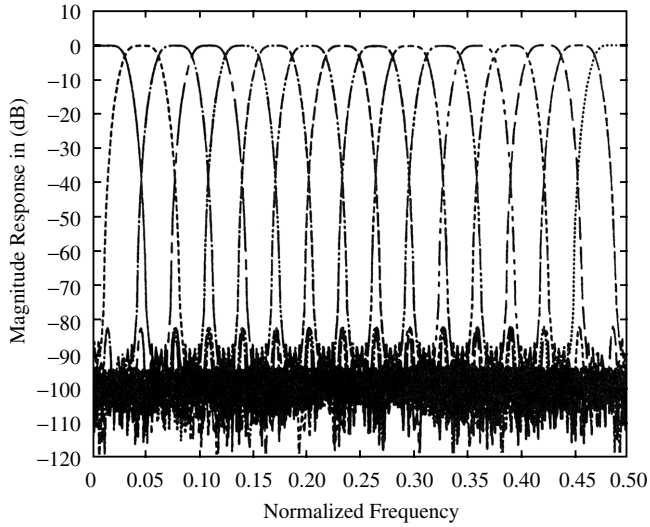

FIGURE 89.24 Magnitude response plots for the cosine-modulated filter bank.

M-Channel Linear-Phase Paraunitary Filter Bank

Let $H_k(z)$ be the analysis linear-phase filters (of lengths N) of an M-channel paraunitary linear-phase filter bank. The synthesis filters $F_k(z)$ are $F_k(z) = z^{-(Nk-1)}H_k(z^{-1}) = J_kH_k(z)$, where

$$J_k = \begin{cases} 1 & H_k(z) \text{ is symmetric} \\ -1 & H_k(z) \text{ is antisymmetric} \end{cases}$$

It is shown that there are

$$\begin{cases} M/2 & \text{symmetric and } M/2 \text{ antisymetric filters} \quad \text{even } M \\ (M+1)/2 & \text{symmetric and } (M-1)/2 \text{ antisymmetric filters} \quad \text{odd } M \end{cases}$$

Moreover, in a linear-phase orthonormal filter bank with high attenuation, the even-indexed and the odd-indexed analysis filters $H_k(z)$ should be symmetric and antisymmetric, respectively. The reconstructed output $\hat{X}(z)$ is

$$\hat{X}(z) = \frac{1}{M}\sum_{l=0}^{M-1} T_l(z)X(zW^l) \quad \text{where} \quad T_l(z) = \sum_{k=0}^{M-1} J_kH_k(z)H_k(zW^l) \tag{89.87}$$

Since the filter bank is a perfect-reconstruction one, then

$$\begin{cases} T_0(z) = z^{-(N-1)} \\ T_l(z) = 0, & l \neq 0 \end{cases}$$

We will formulate the above PR conditions in quadratic form (QCLS) as in (89.63). Instead of analyzing the complex-coefficient $T_l(z)$, we will work with the real-coefficient function $T_l(zW^{-1/2})$ for simplicity, i.e.,

© 2003 by CRC Press LLC

$$T_l\left(zW^{-l/2}\right)=\sum_{k=0}^{M-1}J_kH_k\left(zW^{-l/2}\right)H_k\left(zW^{l/2}\right) \tag{89.88}$$

Here, only the even N case is considered, since the odd N case can be derived similarly. Let $\mathbf{h}_k$ be the vector of the first $N/2$ elements of $h_k(n)$ and $\mathbf{e}$ is the vector of the delay chain, i.e.,

$$\begin{cases}\mathbf{h}_k=\left[h_k(0) \quad h_k(1) \quad \cdots \quad h_k(L-1)\right]^T\\ \mathbf{e}=\left(1 \quad z^{-1} \quad \cdots \quad z^{-(N-1)}\right)^T\end{cases} \tag{89.89}$$

where $L = N/2$, then the function $H_k(zW^{-l/2})$ is $H_k(zW^{-l/2})=\mathbf{h}_k^T\mathbf{C}\Lambda_l\mathbf{e}$ where

$$\mathbf{C}=\begin{cases}\left(\mathbf{I} \quad \mathbf{J}\right) & H_k(z) \text{ is symmetric}\\ \left(\mathbf{I} \quad -\mathbf{J}\right) & H_k(z) \text{ is antisymmetric}\end{cases}$$

and Λ_1 is a diagonal matrix of element $[\Lambda_1]_{m,m} = \mathrm{W}^{-.ml/2}$. Moreover,

$$H_k\left(zW^{-l/2}\right)H_k\left(zW^{l/2}\right)=\mathbf{h}_k^TJ_k\mathbf{C}\mathbf{\Lambda}_l\mathbf{e}\mathbf{e}^T\Lambda_l^{-1}\mathbf{C}^T\mathbf{h}_k=\mathbf{h}_k^T\sum_{\alpha=0}^{2N-1}z^{-\alpha}\mathbf{Q}_{l,k}(\alpha)\mathbf{h}_k \tag{89.90}$$

where

$$\begin{cases}\mathbf{Q}_{1,k}(\alpha)=J_k\mathbf{C}\Lambda_l\mathbf{D}(\alpha)\Lambda_l^{-1}\mathbf{C}^T\\ \left[\mathbf{D}(\alpha)\right]_{m.n}=\begin{cases}1 & m+n=\alpha\\ 0 & \text{otherwise}\end{cases}\end{cases} \tag{89.91}$$

Consequently, $T_1(zW^{-l/2})$ is

$$T_l\left(zW^{-l/2}\right)=\sum_{\alpha=0}^{2N-1}z^{-\alpha}\sum_{k=0}^{M-1}\mathbf{h}_k^T\mathbf{Q}_{l,k}(\alpha)\mathbf{h}_k=\mathbf{h}^T\sum_{\alpha=0}^{2N-1}z^{-\alpha}\mathbf{Q}_1(\alpha)\mathbf{h} \tag{89.92}$$

where

$$\begin{cases}\mathbf{h}=\left(\mathbf{h}_0^T \quad \mathbf{h}_1^T \quad \cdots \quad \mathbf{h}_{M-1}^T\right)^T\\ \mathbf{Q}_1(\alpha)=\mathrm{diag}\left[\mathbf{Q}_{l,0}(\alpha) \quad \mathbf{Q}_{l,1}(\alpha) \quad \cdots \quad \mathbf{Q}_{l,M-1}(\alpha)\right]\end{cases} \tag{89.93}$$

Thus, the PR conditions become (note that only the first N coefficients of $T_1(zW^{-l/2})$ are considered since it is an even-order linear-phase function)

$$\mathbf{h}^T\mathbf{Q}_1(\alpha)\mathbf{h}=\begin{cases}\text{constant} & l=0, \quad \alpha=N-1\\ 0 & \text{otherwise}\end{cases} \tag{89.94}$$

for $0 \le l \le M/2$ and $0 \le \alpha \le N - 1$. The number of conditions here is $(M/2 + 1)N$, which can be large for filter banks with many channels and large lengths. The number of conditions can be reduced (approximately by half) by imposing relations on the analysis filters, such as the pairwise-mirror-image property.

© 2003 by CRC Press LLC

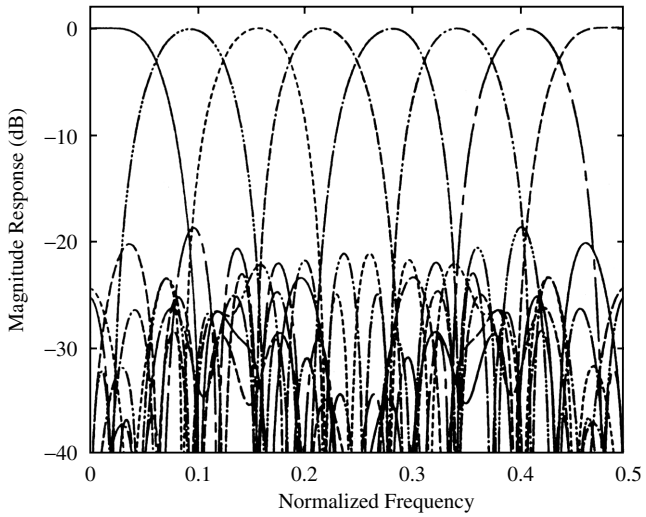

FIGURE 89.25 Magnitude response plots for the paraunitary linear-phase filter bank.

In other words, the filters are related as $H_{M-1-k}(z) = H_k(-z)$. The design problem is reduced to finding the vector $\mathbf{h}_{opt}$ such that

$$\mathbf{h}_{opt} = \text{Min}\,\mathbf{h}^T\mathbf{P}\mathbf{h} \quad \text{subject to} \quad (89.94) \tag{89.95}$$

The objective function $\mathbf{h}^T\mathbf{P}\mathbf{h}$ consists of all the stopband errors of $H_k(e^{j\omega})$. The design procedure is as follows.

Design Procedure.

- Given M, N, and the cutoff frequencies of $H_k(z)$, compute $\mathbf{P}$ (note that only the stopbands of $|H(e^{j\omega})|$ are included in P because of the power-complementary property).
- Compute the matrices $\mathbf{Q}_1(\alpha)$ for $0 \le l \le M/2$ and $0 \le \alpha \le N-1$.
- Design the initialize filters $H_k(z)$ and use their coefficients for initialization.
- Find $\mathbf{h}_{opt}$ by solving the minimization problem in (89.95).

Example. Let $M = 8$, $N = 40$, and the filters $H_k(z)$ satisfy the pairwise-mirror-image property. We design the paraunitary linear-phase filter band using the above quadratic-constrained formulation. The magnitude response plots of the analysis filters are plotted in Fig. 89.25.

90.1 Introduction

Digital implementations of filters are preferred over analog realizations for many reasons. Improvements in VLSI technology have enabled digital filters to be used in an increasing number of application domains.

There are a variety of methods that can be used to implement digital filters. In this discussion, we focus on the use of traditional VLSI digital logic families such as CMOS, rather than more exotic approaches. The vast majority of implementations encountered in practice make use of traditional technologies because the performance and cost characteristics of these approaches are so favorable.

Digital filter implementations can be classified into several categories based on the architectural approach used; these are general purpose, special purpose, and programmable logic implementations. The choice of a particular approach should be based upon the flexibility and performance required by a particular application. General purpose architectures possess a great deal of flexibility, but are somewhat limited in performance, being best suited for relatively low sampling frequencies, usually under 10 MHz. Special purpose architectures are capable of much higher performance, with sampling frequencies as high as 1 GHz, but are often only configurable for one application domain. Programmable logic implementations lie somewhere between these extremes, providing both flexibility and reasonably high performance, with sampling rates as high as 200 MHz.

Digital filtering implementations have been strongly influenced by evolution of VLSI technology. The regular computational structures encountered in filters are well suited for VLSI implementation. This regularity often translates into efficient parallelism and pipelining. Further, the small set of computational structures required in digital filtering makes automatic synthesis of special purpose and programmable logic designs feasible. The design automation of digital filter implementation is relatively simple compared to the general design synthesis problem. For this reason, digital filters are often the test case for evaluating new device and computer-aided design technologies.

90.2 General Purpose Processors

General-purpose digital signal processors are by far the most commonly used method for digital filter implementation, particularly at audio bandwidths. These systems possess architectures well suited to digital filtering, as well as other digital signal processing algorithms.

Historical Perspective

General-purpose digital signal processors trace their lineage back to the microprocessors of the early 1980s. The generic microprocessors of that period were ill suited for the implementation of DSP algorithms, due to the lack of hardware support for numerical algorithms of significant complexity in those architectures. The primary requirement for digital signal processing implementation was identified to be hardware support for multiplication, due to the large number of multiply-accumulate operations in digital signal processing algorithms and their large contribution to computational delays. The earliest widely available single chip general purpose DSP implementation was from AT&T, which evolved into the AT&T DSP20 family. Products such as the Texas Instruments TMS32010 and NEC 7720 soon followed. The early DSP chips exhibited several shortcomings, such as difficult programming paradigms, awkward architectures for many applications, and limited numerical precision. Many of these difficulties were imposed by the limits of the VLSI technology of the time, and some by inexperience in this particular application area. Despite these shortcomings, however, the early processors were well suited to the implementation of digital filter algorithms, because digital filtering was identified as one of the target areas for these architectures. This match between architecture and algorithms continues to be exhibited in current general-purpose DSP chips.

Current Processors

There are a variety of general-purpose digital signal processors currently commercially available. We will look at several of the most common architectural families in detail, although this discussion will not be comprehensive by any means. The processors are best classified in two categories, fixed point processors and floating point processors. In both cases, these architectures are commonly (although not exclusively) based on a single arithmetic unit shared among all computations, which leads to constraints on the sampling rates that may be attained.

Fixed-point processors exhibit extremely high performance in terms of maximum throughput as compared to their floating-point counterparts. In addition, fixed-point processors are typically inexpensive as compared to floating-point options, due to the smaller integrated circuit die area occupied by fixed-point processing blocks. A major difficulty encountered in implementing filters on fixed-point processors is that overflow and underflow need to be prevented by careful attention to scaling, and round-off effects may be significant.

Floating point processors, on the other hand, are significantly easier to program, particularly in the case of complex algorithms, at the cost of lower performance and larger die area. Given the regular structure of most digital filtering algorithms and computer-aided design support for filters based on limited precision arithmetic, fixed point implementations may be the more cost effective option for this type of algorithm. Because of the prevalence of both types of general-purpose processor, examples of each will be examined in detail.

Two widely used floating-point processor families will be studied, although there are many contenders in this field. These families are the Texas Instruments family of floating-point DSPs, in particular the TI TMS320C3x [TI, 1992] family, and the Analog Devices ADSP-21020 family [Schweber, 1993]. More recent examples of the TI family are the TMS320C67x DSP chips [TI, 2000], and more recent Analog Devices parts are the ADSP-2116x SHARC chips [Analog Devices, 2001].

The architecture of the TI TMS320C30 is illustrated in Fig. 90.1. The floating-point word size used by this processor is 32 bits. The most prominent feature of this chip is the floating-point arithmetic unit, which contains a floating-point multiplier and adder. This unit is highly pipelined to support high

© 2003 by CRC Press LLC

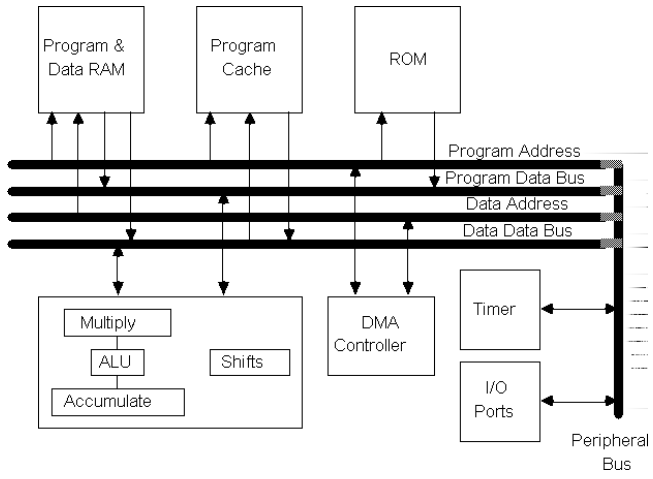

FIGURE 90.1 The Texas Instruments TMS320C30 architecture.

throughput, at the cost of latency; when data is input to the multiplier, for example, the results will not appear on the output from that unit until several clock cycles later. Other features include a separate integer unit for control calculations, and significant amounts (2k words) of SRAM for data and on-chip instruction memory. On-chip ROM (4k words) is also optionally provided in order to eliminate the need for an external boot ROM in some applications. This chip also includes a 64-word instruction cache to allow its use with lower speed memories. The modified Harvard architecture, that is, the separate data and instruction buses, provides for concurrent instruction and data word transfers within one cycle time. The TMS320C30 offers instruction cycle times as low as 60 ns. A code segment that implements portions of an FIR filter on this device is as follows:

```
        RPTS    RC
        MPYF3   *AR0++(1),*AR1++(1)%,R0
||      ADDF3   R0,R2,R2
        ADDF    R0,R2,R0
```

where the `MPYF3` instruction performs a pipelined multiply operation in parallel with data and coefficient pointer increments. The `ADDF3` instruction is performed in parallel with the `MPYF3` instruction, as denoted by the "||" symbol. Because these operations are in parallel, only one instruction cycle per tap is required. An FIR filter tap is benchmarked at 60 ns on this chip. Similarly, a typical biquad IIR filter code segment is

```
        MPYF3   *AR0,*AR1,R0
        MPYF3   *++AR0(1),*AR1--(1)%,R1
        MPYF3   *++AR0(1),*AR1,R0
||      ADDF3   R0,R2,R2
        MPYF3   *++AR0(1),*AR1--(1)%,R0
||      ADDF3   R0,R2,R2
        MPYF3   *++AR0(1),R2,R2
||      STF     R2,*AR1++(1)%
        ADDF    R0,R2
        ADDF    R1,R2,R0
```

where the `MPYF3` and `ADDF3` instructions implement the primary filter arithmetic and memory pointer modification operations in parallel, as in the previous example. The biquad IIR benchmark on this

© 2003 by CRC Press LLC

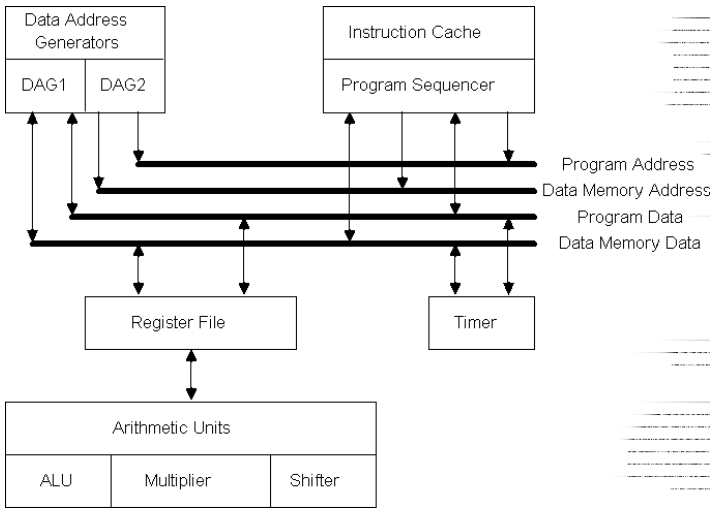

FIGURE 90.2 The Analog Devices ADSP-21020 architecture.

processor is 300 ns. More recent members of the TI floating point family such as the TMS320C6701 support two parallel FIR filter taps at 6 ns and two IIR biquad sections at 222 ns.

Another floating-point chip worthy of note is the Analog Devices ADSP-21020 series. The architecture of the ADSP-21020 chip is shown in Fig. 90.2. This chip can be seen to share a number of features with the TMS320C3x family, that is, a 32-bit by 32-bit floating-point multiply-accumulate unit (not pipelined), modified Harvard architecture, and 16 words of on-chip memory. In this case, the scratchpad memory is organized into register files, much like a general purpose RISC architecture register set. The memory capacity of this device is significantly smaller than that of its competitors. As in the case of the TMS320C3x, on the other hand, an instruction cache (32 words) is also provided. The cycle time for the ADSP-21020 is 40 ns. An N tap FIR filter code segment illustrates the operation of this device:

```
        i0=coef;
        f9=0.0;
        f1=0; f4=dm(i0,m0); f5=pm(i8,m8);
        lcntr = N, DO bottom until lce;
bottom:     f1=f1+f9; f9=f4*f5; f4=dm(i0,m0); f5=pm(i8,m8);
        f1=f1+f9;
```

where the "*" and "+" instructions perform the multiply-accumulate operations, and the dm( ) and pm( ) instructions perform the memory address update operations in parallel. An FIR filter tap thus executes in one instruction per tap on the ADSP-21020, or in 40 ns. An IIR filter biquad section requires 200 ns on this chip. More recent members of this family such as the ADSP-21161N support FIR filter taps at 5 ns and IIR biquad sections at 100 ns. Note that while the assembly language for the Analog Devices chip is significantly different from that of the Texas Instruments chip, the architectural similarities are striking.

Two families of fixed-point digital signal processors will also be examined and compared. These are the Texas Instruments TMS320C5x family [TI, 1993], and the Motorola DSP56000 series of devices [Motorola, 1989]. More recent examples of the TI family are the TMS320C62x DSP chips [TI, 2002], and more recent Motorola parts are the DSP56300 series of chips [Motorola, 2002].

The Texas Instruments TMS320C5x series devices are high performance digital signal processors derived from the original TI DSP chip, the TMS32010, and its successor, the TMS320C2x. The architecture of the TMS320C50 is shown in Fig. 90.3. This chip is based on the Harvard architecture, that is, separate data and instruction buses. This additional bandwidth between processing elements supports rapid

© 2003 by CRC Press LLC

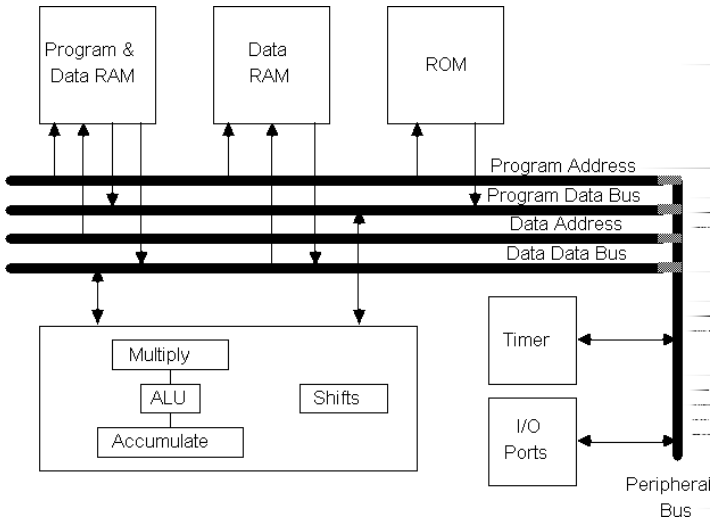

FIGURE 90.3 The Texas Instruments TMS320C50 architecture.

concurrent transfers of data and instructions. This chip uses a 16-bit by 16-bit fixed-point multiplier and a 32-bit accumulator, and up to 10k words on-chip scratchpad RAM. This architecture supports instruction rates of 50 ns. An FIR filter code segment is shown below, where the primary filter tap operations are performed by the `MACD` instruction,

```
RPTK    N
MACD    *-,COEFFP
```

This exhibits a general similarity with that for the TI floating-point chips, in particular a single instruction cycle per tap, although in this case a single instruction is executed as opposed to two parallel instructions on the TMS320C3x. The memory addressing scheme is also significantly different. An FIR filter on the TMS320C5x could thus be implemented in 25 ns per tap. An Nth-order IIR filter code segment is show below, where the `MACD` and `AC` instructions perform the primary multiplication operations,

```
ZPR
LACC    *,15,AR1
RPT     #(N-2)
AC      COEFFB,*-
APAC
SACH    *,1
ADRK    N-1
RPTZ    #(N-1)
MACD    COEFFA,*-
LTA     *,AR2
SACH    *,1
```

A single IIR biquad section could be performed in 250 ns on this chip. More recent members of the TI family such as the TMS320C6203C support two parallel FIR filter taps at 3.33 ns speeds and IIR biquad sections at 66.6 ns.

The Motorola 56001 series is a fixed-point architecture with 24-bit word size, as opposed to the smaller word sizes in most fixed point DSP chips. The architecture of the 56001 is depicted in Fig. 90.4. This chip shares many of the same features as other DSP chips, that is, Harvard architecture, on-chip scratch-pad memory (512 words), and hardware multiply-accumulate support, in this case 24-bit by 24-bit

© 2003 by CRC Press LLC

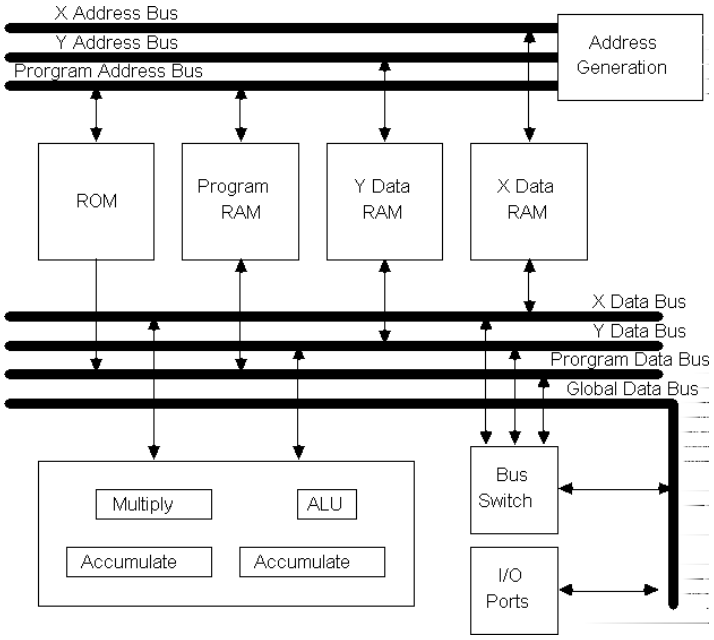

FIGURE 90.4 The Motorola 56001 architecture.

operators that form a 56-bit result. The instruction cycle time of the Motorola 56001 is 97.5 ns. An FIR filter implemented on the 56001 might use the code segment shown below:

```
MOVE    #AADDR, R0
MOVE    #BADDR+n, R4
NOP
CLR                     A           X:(R0)+,X0    Y:(R4)-,Y0
REP                     #N
MAC                     X0,Y0,A     X:(R0)+,X0    Y:(R4)-,Y0
RND                     A
```

where the `MAC` instruction retrieves data from the appropriate registers, loads it into the multiplier, and leaves the result in the accumulator. The 56001 could perform FIR filtering at a rate of one instruction per tap, or 97.5 ns per tap. An IIR filter code segment uses the `MAC` instruction, as well as several others to set up the registers for the arithmetic unit, as shown below.

```
OR      #$08,MR
RND     A           X:(R0)-,X0      Y:(R4)+,Y0
MAC     -Y0,X0,A    X:(R0)-,X1      Y:(R4)+,Y0
MAC     -Y0,X1,A    X1,X:(R0)+      Y:(R4)+,Y0
MAC     Y0,X0,A     A,X:(R0)        Y:(R4),Y0
MAC     Y0,X1,A                     1
MOVE        A,X:OUTPUT
```

The 56001 could compute a second-order IIR biquad in seven instruction cycles, or 682.5 ns. More recent members of this family such as the DSP56L307 support FIR filter taps at an asymptotic speed of 6.25 ns and IIR biquad sections at 56.25 ns.

From these examples, it can be seen that general-purpose DSP processors possess many common features which make them well suited for digital filtering. The hardware multiply-accumulate unit,

© 2003 by CRC Press LLC

Harvard architecture, and on-chip memory are consistent characteristics of these devices. The major shortcoming of such architectures for digital filtering is the necessity to multiplex a single arithmetic unit (or very small number of ALUs), which implies that sampling rates above 1/NT are not possible, where N is the number of atomic operations (e.g., FIR filter taps) and T is the time to complete those operations.

Future Directions

Several trends have become apparent as VLSI technology has improved. One trend of note is the increasing use of parallelism, both on-chip and between chips. The support for multiprocessor communications in the TI TMS320C80 provides an avenue for direct parallel implementation of algorithms. Architectures based upon multiple fixed point DSP processors on a single chip have also been fielded.

Another trend has been the development of better programming interfaces for the general purpose chips. In particular, high level language compilers have improved to the point where they provide for reasonably good performance for complex algorithms, although still not superior to that obtained by manual assembly language programming.

Another trend that is worthy of note is the development of low power DSP implementations. These devices are targeted at the wireless personal communications system (PCS) marketplace, where minimum power usage is critical. The developments in this area have been particularly striking, given the strong dependence of power consumption on clock frequency, which is usually high in DSP implementations. Through a combination of careful circuit design, power supply voltage reductions, and architectural innovations, extremely low power implementations have been realized.

A final trend is related to the progress of general-purpose processors relative to digital signal processing chips. The evolution of general purpose DSP implementations may have come full circle, as general purpose processors such as the Intel Pentium family and DEC Alpha family possess on-chip floating-point multiplication units, as well as memory bandwidths equaling or exceeding that of the DSP chips. These features are reflected in the performance of these chips on standard benchmarks [Stewart, 1992], in which the DEC Alpha outperforms the fastest DSP engines. Similar results were obtained from the Pentium upon the implementation of the MMX capabilities; even older Pentium chipsets outperform most floating-point and fixed-point DSP chips [BDTI, 2000].

90.3 Special Purpose Implementations

The tremendous growth in the capabilities of VLSI technology and the corresponding decrease in the fabrication costs have lead to the wide availability advent of application-specific integrated circuits (ASICs). These devices are tailored to a particular application or domain of applications in order to provide the highest possible performance at low per-unit costs.

Although it is difficult to generalize, special purpose implementations share some common features. The first is the high degree of parallelism in these designs. For example, a typical special purpose FIR filter implementation will contain tens or hundreds of multiply-accumulate units, each of which executes a filter tap operation at the same time. This is in contrast to most general-purpose architectures, in which a single multiply-accumulate unit is shared. Another common feature is extensive pipelining between arithmetic operators; this leads to high sampling rates and high throughput, at some cost in latency. Finally, these implementations are often lacking in flexibility, being designed for specific application domains. The number of filter taps may be fixed, or the filter coefficients themselves may be fixed. In almost all instances, these implementations are based on fixed-point arithmetic.

Because the implementation cost of multiplication operations is so large compared to other operations, significant research effort has been expended on developing fast and efficient multiplier architectures, as well as digital filter design techniques that can be used to reduce the number of multiplications. A large number of multiplier architectures have been developed, ranging from bit-serial structures to bit and word level pipelined array designs [Ma, 1990]. The most appropriate architecture is a function of the application requirements, as various area vs. speed options are available. The other major research

© 2003 by CRC Press LLC

direction is the minimization of multiplication operations. In this case, multiplications are eliminated by conscientious structuring of the realization, as in linear phase filters, circumvented by use of alternate number systems such as the residue number system (RNS), or simplified to a limited number of shift-and-add operations. The later option has been used successfully in a large number of both FIR and IIR realizations, some of which will be discussed below.

Historically, bit-serial implementations of digital filters have been of some interest to researchers and practitioners in the early days of VLSI because of the relatively high cost of silicon area devoted to both devices and routing [Denyer and Renshaw, 1985]. Even in primitive technologies, bit-serial implementations could exploit the natural parallelism in digital filtering algorithms.

As clock rates have risen and silicon area has become more economical, parallel implementations have become the most effective way of implementing high performance digital filters. The concept of the systolic array has strongly influenced the implementation of both FIR and IIR filters [Kung, 1988]. Systolic arrays are characterized by spatial and temporal locality; that is, algorithms and processing elements should be structured to minimize interconnection distances between nodes and to provide at least a single delay element between nodes. Interconnection distances need to be kept to a minimum to reduce delays associated with signal routing, which is becoming the dominant limiting factor in VLSI systems. Imposing pipeline delays between nodes minimizes computational delay paths and leads to high throughput.

These characteristic features of special purpose digital filter designs will be illustrated by examples of FIR and IIR filter implementations. It should be noted that it is increasingly difficult to identify ASICs that only perform digital filtering; as VLSI capabilities increase, this functionality is more typically embedded with other functions in very application-focused devices.

FIR Filter Examples

FIR filters may be implemented in a number of ways, depending on application requirements. The primary factors that must be considered are the filter length, sampling rate, and area, which determine the amount of parallelism that can be applied. Once the degree of parallelism and pipelining are determined, the appropriate general filter structure can be determined.

A typical high-performance FIR filter implementation [Khoo, 1993] provided sampling rates of 180 MHz for 32 linear phase taps. This chip used canonical signed digit (CSD) coefficients. This representation is based on a number system in which the digits take the values (-1,0,1). A filter tap can be implemented with a small number of these digits, and hence that tap requires a small number of shift-and-add operations. Each coefficient is implemented based on two bit shift-and-add units, as depicted in Fig. 90.5. Delay elements are bypassed during configuration to allow realization of coefficients with additional bits. This chip also makes use of extensive pipelining, carry-save addition, and advanced single-phase clocking techniques to provide high throughput.

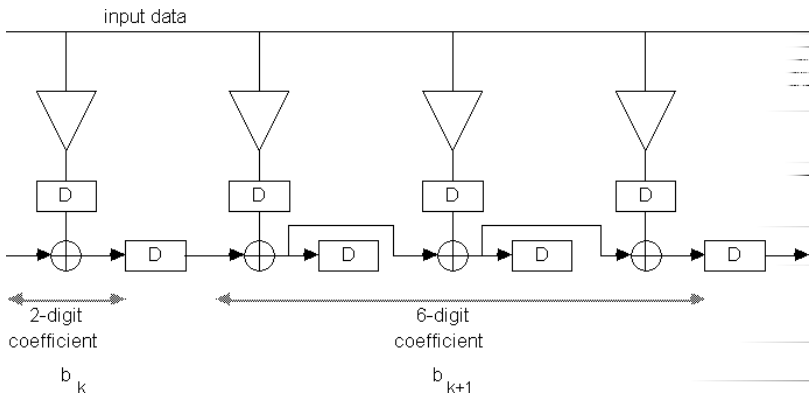

FIGURE 90.5 Custom FIR filter architecture for 180 MHz sampling rates.

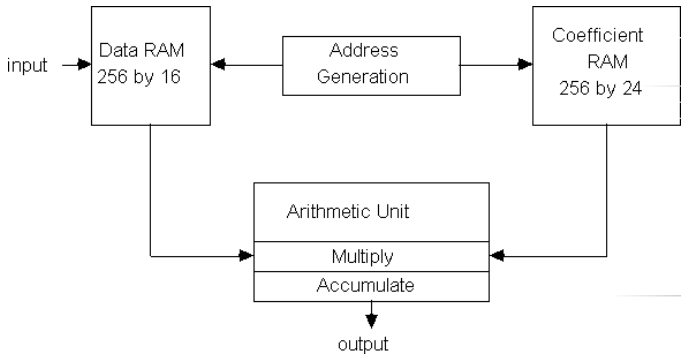

FIGURE 90.6 The Motorola 56200 architecture.

TABLE 90.1 FIR Filter ASIC Comparison

Design	Taps	Area (mm^2)	Rate (MHz)	Technology (μm)	Score
Khoo 1993	32	20.1	180.0	1.2	495.2
Laskowski 1992	43	40.95	150.0	1.2	139.3
Yoshino 1990	64	48.65	100.0	0.8	33.68
Ruetz 1989	64	225	22.0	1.5	21.12
Yassa 1987	16	17.65	30.0 (est.)	1.25	53.12
Hartley 1989	4	25.8 (est.)	37.0	1.25	11.20
Hatamian 1990	40	22	100.0	0.9	132.5

In part due to the highly structured nature of FIR filtering algorithms, automatic design tools have been used to successfully implement high performance FIR filters similar to that just presented. These methods often integrate the filter and architectural design into a unified process which can effectively utilize silicon area to provide the desired performance.

At the other extreme of performance is the Motorola 56200 FIR filter chip [Motorola, 1989]. This chip, although quite old, represents an approach to the custom implementation of long (several hundred taps) FIR filters. In this case, a single processing element is multiplexed among all of the filter taps, similar in concept to the approach used in general purpose DSP processors. Due to the regularity of the filter structure, extensive pipelining in the arithmetic unit can be used to support a large number of taps at audio rates. This chip can be used to realize a 256-tap FIR filter at sampling rates up to 19 kHz, with higher performance for shorter filters. Longer filters can be implemented using cascaded processors.

A comparison of implementations [Hartley, 1989; Hatamian, 1990; Khoo, 1993; Laskowski, 1992; Ruetz, 1989; Yassa, 1987; Yoshino, 1990] illustrates the range of design and performance options. This is illustrated in Table 90.1, where the "score" is calculated according to the sampling rate multiplied by the number of taps per unit area, with normalization for the particular technology used. This simplistic comparison does not consider differences in word length or coefficient codings, but it does provide some insight into the results of the various design approaches. A significant number of other digital FIR filtering chips exists, both research prototypes and commercial products; this exposition outlines only some of the architectural options.

IIR Filter Examples

Custom IIR filter implementations are also most commonly based on parallel architectures, although there are somewhat fewer custom realizations of IIR filters than FIR filters. A significant difficulty in the implementation of high performance IIR filters is the need for feedback in the computation of an IIR filter section. This limits the throughput that can be attained to at least one multiply-accumulate cycle in a straightforward realization. Another difficulty is the numerical stability of IIR filters with short coefficients, which makes aggressive quantization of coefficients less promising.

© 2003 by CRC Press LLC

In order to address the difficulties with throughput limitation due to feedback, structures based on systolic concepts have been developed. Although the feedback problem imposes a severe constraint on the implementation, use of bit and word level systolic structures that pipeline data most significant digit first can minimize the impact of this restriction [Woods, 1990]. Using these techniques, and a signed binary number representation (SBNR) similar to a CSD code, first-order sections with sampling rates of 15 MHz are demonstrated in a 1.5-μm standard cell process in an area of 21.8 mm^2. This particular design uses fairly large coefficient and data words, however, at 12 and 11 bits, respectively.

The numerical stability problem has been addressed through a variety of techniques. One of these is based on minimizing limited precision effects by manipulation of traditional canonical filter structures and clever partitioning of arithmetic operations. A more recent and general approach is based on modeling the digital implementations of filters after their analog counterparts; these classes of filters are known as wave digital filters (WDFs) [Fettweis 1986]. WDFs exhibit good passband ripple and stopband attenuation, with high tolerance to limited wordlength effects. Because of the later property, efficient implementations based on short word sizes are feasible. A WDF design for a second-order section in custom 1.5 μm CMOS based on a restricted coefficient set akin to CSD supports 10 MHz sampling rates in an area of 12.9 mm^2 [Wicks, 1993].

Future Trends

The future trends in digital filter implementation appear to be a fairly straightforward function of the increasing capability of VLSI devices. In particular, more taps and filter sections per chip and higher sampling rates are becoming achievable. Related to these trends are higher degrees of on-chip parallelism. Further, programmability is more reasonable as density and speed margins increase, although there is still a high cost in area and performance. Finally, special purpose implementations show extraordinary promise in the area of low power systems, where custom circuit design techniques and application-specific architectural features can be combined to best advantage.

90.4 Programmable Logic Implementations

The rapid evolution of VLSI technology has enabled the development of several high density programmable logic architectures. There are several novel features that make these devices of interest beyond their traditional field of state machine implementation. In particular, the density of the largest of these devices is over 8,000,000 gates [Xilinx, 2001], which encompasses the level of complexity found in the majority of ASICs (although some ASICs are significantly more complex). This level of complexity is sufficient to support many designs that would traditionally need to be implemented as ASICs. The speed of programmable logic devices (PLDs) and field programmable gate arrays (FPGAs) is quite reasonable, with toggle rates on the order of 600 MHz [Xilinx, 2002]. While this is not as great as custom implementations, it does allow many applications to be realized in this new technology.

One of the most significant features of FPGA implementations is the capability for in-system reprogrammability in many FPGA families. Unlike traditional field programmable parts based on anti-fuse technology and which can only be programmed once, many of the new architectures are based on memory technology. This means that entirely new computational architectures can be implemented simply by reprogramming the logic functions and interconnection routing on the chip. Ongoing research efforts have been directed toward using FPGAs as generalized coprocessors for supercomputing and signal processing applications.

The implications of programmable device technology for filter implementation are significant. These devices provide an enormous amount of flexibility, which can be used in the implementation of a variety of novel architectures on a single chip. This is particularly useful for rapid prototyping of digital filtering algorithms, where several high-performance designs can be evaluated in a target environment on the same hardware platform. Further, complex adaptive systems based on this technology and which use a variety of signal processing and digital filter techniques are becoming increasingly popular in a variety of applications.

© 2003 by CRC Press LLC

Because many of the programmable logic architectures are based on SRAM technology, the density of these devices can be expected to grow in parallel with the RAM growth curve, that is, at approximately 60% per year. Further, since these devices may be used for a large variety of applications, they have become high-volume commodity parts, and hence prices are relatively low compared to more specialized and low volume DSP chips. This implies that new digital signal processing systems that were not previously technically and economically feasible to implement in this technology are now feasible.

One of the extra costs of this approach, as opposed to the full custom strategy, is the need for support chips. Several chips are typically needed, including memory to store the programmable device configuration, as well as logic to control the downloading of the program. These issues are generally outweighed by the flexibility provided by programmable solutions.

Next we will examine the implementation of several FIR and IIR digital filtering architectures based on FPGAs.

FIR Filter Implementations

Several approaches to the FPGA implementation of FIR filters can be taken. Due to the flexibility of these parts, switching from one architecture to the next only requires reprogramming the device, subject to constraints on I/O pin locations. Two fundamental strategies for realizing FIR filters will be illustrated here, one which is suited to relatively short filters (or longer filters cascaded across several chips) operating at high rates, and another which is suited for longer filters at lower rates.

A high performance FIR filter example [Evans, 1993], illustrated in Fig. 90.7, was based on the observation that because the entire device is reprogrammable, architectures in which filter coefficient multiplications are implemented as "hardwired" shifts can be easily reconfigured depending on the desired filter response. In this example, each of the coefficients was represented in a canonical signed digit (CSD) code with a limited number of nontrivial (e.g., nonzero) bits, which allowed each tap to be implemented as a small number of shift and add operations. A filter tap could be implemented in two columns of logic blocks on a Xilinx 3100-series FPGA [Xilinx, 1993], where the two columns of full adders and associated delays implement a tap based on CSD coefficients with two nontrivial bits. With this architecture, up to 11 taps could be implemented on a single Xilinx XC3195 FPGA at sampling rates of above 40 MHz. Longer filters could be implemented by a cascade of FPGA devices.

An FIR filter architecture for longer filters was based upon implementation of several traditional multiply-accumulate (MAC) units on one chip, as shown in Fig. 90.8. Each of these MAC units could then be shared among a large number of filter tap computations, much as the single MAC unit in the Motorola 56200 was multiplexed. Since four multipliers could be implemented in the Xilinx 4000-series, the inherent parallelism of FIR filters can be exploited to support sampling rates of up to 1.25 MHz for 32 taps in that technology.

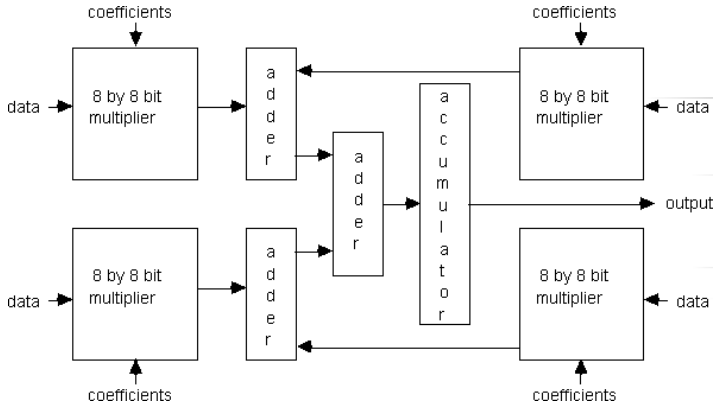

FIGURE 90.8 FIR architecture on FPGAs for large number of taps.

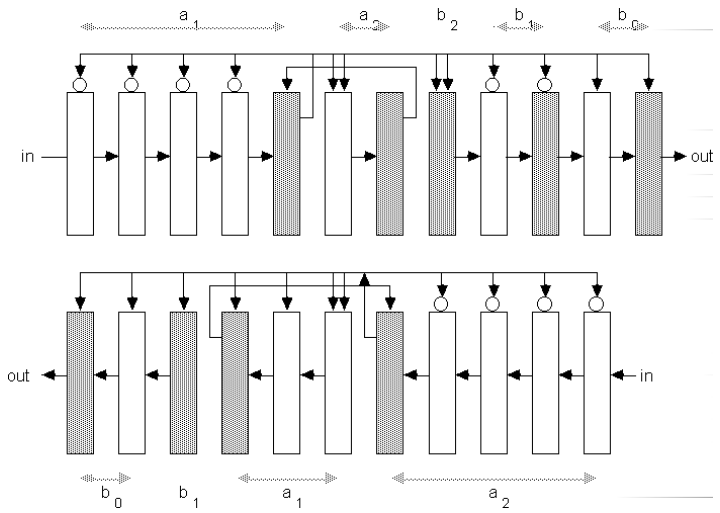

FIGURE 90.9 High performance IIR architecture on FPGAs.

IIR Filter Implementations

As in the case of FIR filters, IIR filters can be implemented using a "hardwired" architecture suited to high performance, or a more traditional approach based on general multiply-accumulate units. In the case of IIR filters, however, the hardwired implementation is significantly more desirable than the alternate approach due to the difficulty in rescheduling multiplexed processing elements in a system with feedback.

An architecture that is reconfigured to implement different filters will generally provide both high performance and good area efficiency. An example of such a system is shown in Fig. 90.9, in which two IIR biquad sections were implemented on a single FPGA using a traditional canonical filter structure [Chou, 1993]. Each of the columns realized a shift-and-add for one nontrivial bit of a coefficient, where the shaded blocks also contained delay registers. This implementation yielded sampling rates of better than 10 MHz for typical coefficients.

A more traditional approach to the realization of IIR filters using MAC units is also possible, but may be less efficient. The general architecture is similar to that of the FIR filter in Fig. 90.8, with slight modifications to the routing between arithmetic units and support for scaling necessary in an IIR biquad section.

Future Trends

Because of the rapid advances in FPGA technology, higher-performance digital filtering may in fact be possible with programmable logic rather than with typical custom ASIC approaches [Moeller, 1999]. In addition, there are a wide variety of DSP core functions being offered by FPGA manufacturers [Xilinx, 2000], which will further accelerate this revolution in digital signal processing implementation.

91.1 Introduction

In this chapter, methods of designing two-dimensional (2-D) finite-extent impulse response (FIR) discrete-time filters are described. Two-dimensional FIR filters offer the advantages of phase linearity and guaranteed stability, which makes them attractive in applications. Over the years an extensive array of techniques for designing 2-D FIR filters has been accumulated [14, 30, 23]. These techniques can be conveniently classified into the two categories of general and specialized designs. Techniques in the category of general design are intended for approximation of *arbitrary* desired frequency responses usually with no structural constraints on the filter. These techniques include approaches such as windowing of the ideal impulse response [22] or the use of suitable optimality criteria possibly implemented with iterative algorithms. On the other hand, techniques in the category of special design are applicable to restricted classes of filters, either due to the nature of the response being approximated or due to imposition of structural constraints on the filter used in the design. The specialized designs are a consequence of the observation that commonly used filters have characteristic underlying features that can be exploited to simplify the problem of design and implementation. The stopbands and passbands of filters encountered in practice are often defined by straight line, circular or elliptical boundaries. Specialized design methodologies have been developed for handling these cases and they are typically based on techniques such as the transformation of one-dimensional (1-D) filters or the rotation and translation of separable filter responses. If the desired response possesses symmetries, then the symmetries imply relationships among the filter coefficients which are exploited in both the design and the implementation of the filters. In some design problems it may be advantageous to impose structural constraints in the form of parallel and cascade connections.

© 2003 by CRC Press LLC

The material in this chapter is organized as follows. A preliminary discussion of characteristics of 2-D FIR filters and issues relevant to the design methods appears in Section 91.2. Following this, methods of general and special FIR filter design are described in Sections 91.3 and 91.4, respectively. Several examples of design illustrating the procedure are also presented. Issues in 2-D FIR filter implementation are briefly discussed in Section 91.5. Finally, additional topics are outlined in Section 91.6, and a list of sources for further information is provided.

91.2 Preliminary Design Considerations

In any 2-D filter design there is a choice between FIR and IIR filters, and their relative merits are briefly examined next. Two-dimensional FIR filters offer certain advantages over 2-D IIR filters as a result of which FIR filters have found widespread use in applications such as image and video processing. One key attribute of an FIR filter is that it can be designed with strictly linear passband phase, and it can be implemented with small delays without the need to reverse the signal array during processing. A 2-D FIR filter impulse response has only a finite number of nonzero samples which guarantees stability. On the other hand, stability is difficult to test in the case of 2-D IIR filters due to the absence of a 2-D counterpart of the fundamental theorem of algebra, and a 2-D polynomial is almost never factorizable. If a 2-D FIR filter is implemented nonrecursively with finite precision, then it does not exhibit limit cycle oscillations. Arithmetic quantization noise and coefficient quantization effects in FIR filter implementation are usually very low. A key disadvantage of FIR filters is that they typically have higher computational complexity than IIR filters for meeting the same specifications, especially in cases where the specifications are stringent.

The term 2-D FIR filter refers to a linear shift-invariant system whose input–output relation is represented by a convolution [14]

$$y(n_1,n_2)=\sum_{(k_1,k_2)\in}\sum_{I}h(k_1,k_2)x(n_1-k_1,n_2-k_2), \tag{91.1}$$

where $x(n_1, n_2)$ and $y(n_1, n_2)$ are the input and the output sequences, respectively, $h(n_1, n_2)$ is the impulse response sequence, and I is the support of the impulse response sequence. FIR filters have compact support, meaning that only a finite number of coefficients are nonzero. This makes the impulse response sequence of FIR filters absolutely summable, thereby ensuring filter stability. Usually the filter support, I, is chosen to be a rectangular region centered at the origin, e.g., $I = \{(n_1,n_2):-N_1 \le n_1 \le N_1,-N_2 \le n_2 \le N_2\}$. However, there are some important cases where it is more advantageous to select a non-rectangular region as the filter support [32].

Once the extent of the impulse response support is determined, the sequence $h(n_1, n_2)$ should be chosen in order to meet given filter specifications under suitable approximation criteria. These aspects are elaborated on in the next subsection. This is followed by a discussion of phase linearity and filter response symmetry considerations and then some guidelines on using the design methods are provided.

Filter Specifications and Approximation Criteria

The problem of designing a 2-D FIR filter consists of determining the impulse response sequence, $h(n_1, n_2)$, or its system function, $H(z_1, z_2)$, in order to satisfy given requirements on the filter response. The filter requirements are usually specified in the frequency domain, and only this case is considered here. The frequency response,[1] $H(\omega_1, \omega_2)$, corresponding to the impulse response $h(n_1, n_2)$, with a support, I, is expressed as

$$H(\omega_1,\omega_2)=\sum_{(n_1,n_2)}\sum_{\in I}h(n_1,n_2)e^{-j(\omega_1 n_1+\omega_2 n_2)}. \tag{91.2}$$

[1]Here $\omega_1 = 2\pi f_1$ and $\omega_2 = 2\pi f_2$ are the horizontal and vertical angular frequencies, respectively.

© 2003 by CRC Press LLC

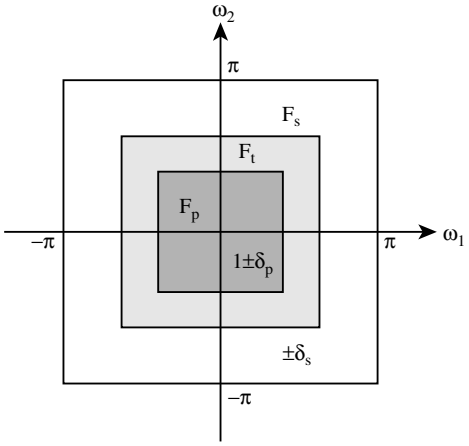

FIGURE 91.1 Frequency response specifications for a 2-D lowpass filter ($|H(\omega_1, \omega_2) - 1| \leq \delta_p$ for $(\omega_1, \omega_2) \in F_p$ and $|H(\omega_1, \omega_2)| \leq \delta_s$ for $(\omega_1, \omega_2) \in F_s$).

Note that $H(\omega_1, \omega_2) = H(\omega_1 + 2\pi, \omega_2) = H(\omega_1, \omega_2 + 2\pi)$ for all (ω_1, ω_2). In other words, $H(\omega_1, \omega_2)$ is a periodic function with a period 2π in both ω_1 and ω_2. This implies that by defining $H(\omega_1, \omega_2)$ in the region $\{-\pi < \omega_1 \leq \pi, -\pi < \omega_2 \leq \pi\}$, the frequency response of the filter for all (ω_1, ω_2) is determined.

For 2-D FIR filters the specifications are usually given in terms of the magnitude response, $|H(\omega_1, \omega_2)|$. Attention in this chapter is confined to the case of a two-level magnitude design, where the desired magnitude levels are either 1.0 (in the passband) or 0.0 (in the stopband). Some of the procedures can be easily modified to accommodate multilevel magnitude specifications, as, for instance, in a case that requires the magnitude to increase linearly with distance from the origin in the frequency domain.

Consider the design of a 2-D FIR lowpass filter whose specifications are shown in Fig. 91.1. The magnitude of the lowpass filter ideally takes the value 1.0 in the passband region, F_p, which is centered around the origin, $(\omega_1, \omega_2) = (0, 0)$, and 0.0 in the stopband region, F_s. As a magnitude discontinuity is not possible with a finite filter support, I, it is necessary to interpose a transition region, F_t, between F_p and F_s. Also, magnitude bounds $|H(\omega_1, \omega_2) - 1| \leq \delta_p$ in the passband and $|H(\omega_1, \omega_2)| \leq \delta_s$ in the stopband are specified, where the parameters δ_p and δ_s are positive real numbers, typically much less than 1.0. The frequency response $H(\omega_1, \omega_2)$ is assumed to be real. Consequently, the lowpass filter is specified in the frequency domain by the regions, F_p, F_s, and the tolerance parameters, δ_p and δ_s. A variety of stopband and passband shapes can be specified in a similar manner.

In order to meet given specifications, an adequate filter order (the number of non-zero impulse response samples) needs to be determined. If the specifications are stringent, with tight tolerance parameters and small transition regions, then the filter support region, I, must be large. In other words, there is a trade-off between the filter support region, I, and the frequency domain specifications. In the general case the filter order is not known *a priori*, and may be determined either through an iterative process or using estimation rules if available. If the filter order is given, then in order to determine an optimum solution to the design problem, an appropriate optimality criterion is needed. Commonly used criteria in 2-D filter design are minimization of the L_p norm, p finite, of the approximation error, or the L_∞ norm. If desired, a maximal flatness requirement at desired frequencies can be imposed [24]. It should be noted that if the specifications are given in terms of the tolerance bounds on magnitude, as described above, then the use of L_∞ criterion is appropriate. However, the use of other criteria such as a weighted L_2 norm can serve to arrive at an almost minimax solution [2].

Zero-Phase FIR Filters and Symmetry Considerations

Phase linearity is important in many filtering applications. As in the 1-D case, a number of conditions for phase linearity can be obtained depending on the nature of symmetry. But the discussion here is limited to the case of "zero phase" design, with a purely real frequency response. A salient feature of 2-D FIR filters is that realizable FIR filters, which have purely real frequency responses, are easily designed.

© 2003 by CRC Press LLC

The term "zero phase" is somewhat misleading in the sense that the frequency response may be negative at some frequencies. The term should be understood in the sense of "zero phase in passband" because the passband frequency response is within a small deviation of the value 1.0. The frequency response may assume negative values in the stopband region where phase linearity is immaterial. In frequency domain, the zero-phase or real frequency response condition corresponds to

$$H(\omega_1,\omega_2) = H^*(\omega_1,\omega_2), \tag{91.3}$$

where $H^*(\omega_1,\omega_2)$ denotes the complex conjugate of $H(\omega_1,\omega_2)$. The condition (91.3) is equivalent to

$$h(n_1,n_2) = h^*(-n_1,-n_2) \tag{91.4}$$

in the spatial-domain. Making a common practical assumption that $h(n_1, n_2)$ is real, the above condition reduces to

$$h(n_1,n_2) = h(-n_1,-n_2), \tag{91.5}$$

implying a region of support with the above symmetry about the origin.

Henceforth, only the design of zero-phase FIR filters is considered. With $h(n_1, n_2)$ real, and satisfying (91.5), the frequency response, $H(\omega_1, \omega_2)$, is expressed as

$$\begin{aligned} H(\omega_1,\omega_2) &= h(0,0) + \sum_{(n_1,n_2)\in I_1} h(n_1,n_2)e^{-j(\omega_1 n_1+\omega_2 n_2)} + \sum_{(n_1,n_2)\in I_2} h(n_1,n_2)e^{-j(\omega_1 n_1+\omega_2 n_2)} \\ &= h(0,0) + \sum_{(n_1,n_2)\in I_1} 2h(n_1,n_2)\cos(\omega_1 n_1 + \omega_2 n_2), \end{aligned} \tag{91.6}$$

where I_1 and I_2 are disjoint regions such that $I_1 \cup I_2 \cup \{(0,0)\} = I$, and if $(n_1,n_2)\in I_1$, then $(-n_1,-n_2)\in I_2$.

In order to understand the importance of phase linearity in image processing, consider an example that illustrates the effect of nonlinear-phase filters on images. In Fig. 91.2(a), an image that is corrupted by white Gaussian noise is shown. This image is filtered with a nonlinear-phase low-pass filter and the resultant image is shown in Fig. 91.2(b). It is observed that edges and textured regions are severely distorted in Fig. 91.2(b). This is due to the fact that the spatial alignment of frequency components that define an edge in the original is altered by the phase non-linearity. The same image is also filtered with a zero-phase lowpass filter, $H(\omega_1,\omega_2)$, which has the same magnitude characteristics as the nonlinear-phase filter. The resulting image is shown in Fig. 91.2(c). It is seen that the edges are perceptually preserved in Fig. 91.2(c), although blurred due to the lowpass nature of the filter. In this example, a separable zero-phase lowpass filter, $H(\omega_1,\omega_2) = H_1(\omega_1)\,H_1(\omega_2)$, is used, where $H_1(\omega)$ is a 1-D Lagrange filter with a cut-off $\pi/2$. In spatial domain $h(n_1, n_2) = h_1(n_1)\ h_1(n_2)$ where $h_1(n) = \{\ldots, 0, -1/32, 0, 9/32, 1/2, 9/32, 0, -1/32, 0, \ldots,\}$ is the impulse response of the 7th order symmetric (zero-phase) 1-D Lagrange filter. The nonlinear-phase filter is a cascade of the above zero-phase filter with an allpass filter.

In some filter design problems, symmetries in frequency domain specifications can be exploited by imposing restrictions on the filter coefficients and the shape of the support region for the impulse response. A variety of symmetries that can be exploited is extensively studied in [32, 44, 45]. For example, a condition often encountered in practice is the symmetry with respect to each of the two frequency axes. In this case, the frequency response of a zero-phase filter satisfies

$$H(\omega_1,\omega_2) = H(-\omega_1,\omega_2) = H(\omega_1,-\omega_2). \tag{91.7}$$

This yields an impulse response that is symmetric with respect to the n_1 and n_2 axes, i.e.,

$$h(n_1,n_2) = h(-n_1,n_2) = h(n_1,-n_2). \tag{91.8}$$

© 2003 by CRC Press LLC

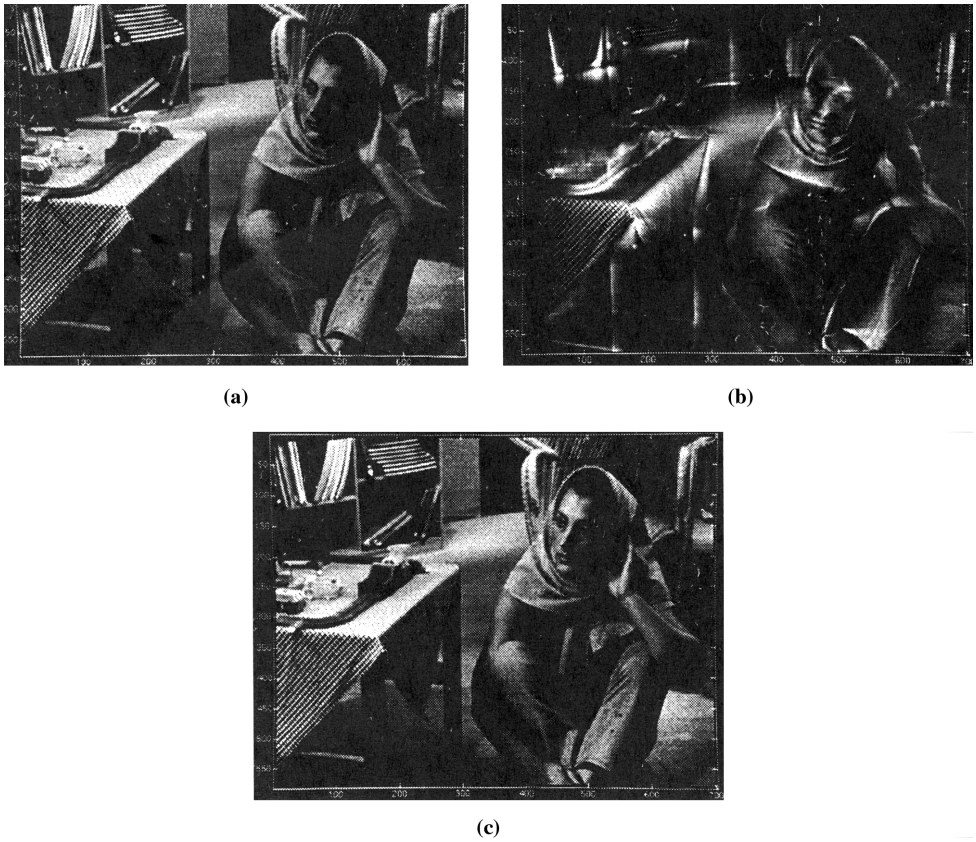

FIGURE 91.2 (a) Original image of 696 × 576 pixels; (b) nonlinear phase lowpass filtered image; (c) zero-phase lowpass filtered image.

By imposing symmetry conditions, one reduces the number of independently varying filter coefficients that must be determined in the design. This can be exploited in reducing both the computational complexity of the filter design and the number of arithmetic operations required in the implementation.

Guidelines On the Use of the Design Techniques

The design techniques described in this chapter are classified into the two categories of general and specialized designs. The user should use the techniques of general design in cases requiring approximation of arbitrary desired frequency responses, usually with no structural constraints on the filter. The specialized designs are recommended in cases where filters exhibit certain underlying features that can be exploited to simplify the problem of design and implementation.

In the category of general design, four methods are described. Of these, the windowing procedure is quick and simple. It is useful in situations where implementation efficiency is not critical, especially in single-use applications. The second procedure is based on linear programming, and is suitable for design problems where equiripple solutions are desired to meet frequency domain specifications. The remaining two procedures may also be used for meeting frequency domain specifications, and lead to nearly equiripple solution. The third procedure provides solutions for L_p approximations. The fourth procedure is an iterative procedure that is easy to implement, and is convenient in situations where additional constraints are to be placed on the filter.

In the category of specialized design described here, the solutions are derived from 1-D filters. These often lead to computationally efficient implementation, and are recommended in situations where low

© 2003 by CRC Press LLC

implementation complexity is critical, and the filter characteristics possess features that can be exploited in the design. An important practical class of filters is one where specifications can be decomposed into a set of separable filter designs requiring essentially the design of suitable 1-D filters. Here the separable design procedure should be used. Another class of filters is one where the passbands and stopbands are characterized by circular, elliptical, or special straight-line boundaries. In this case a frequency transformation method, called the McClellan transformation procedure, is convenient to use. The desired 2-D filter constant-magnitude contours are defined by a proper choice of parameters in a transformation of variables applied to a 1-D zero-phase filter. Finally, in some cases filter specifications are characterized by ideal frequency responses in which passbands and stopbands are separated by straight-line boundaries that are not suitable for applying the McClellan transformation procedure. In this case the design may be carried out by nonrectangular transformations and sampling grid conversions. The importance of this design method stems from the implementation efficiency that results from a generalized notion of separable processing.

91.3 General Design Methods for Arbitrary Specifications

Some general methods of meeting arbitrary specifications are now described. These are typically based on extending techniques of 1-D design. However, there are important differences. The Parks-McClellan procedure for minimax approximation based on the alternation theorem does not find a direct extension. This is because the set of cosine functions used in the 2-D approximation does not satisfy the Haar condition on the domain of interest [25], and the Chebyshev approximation does not have a unique solution. However, techniques that employ exchange algorithms have been developed for the 2-D case [25, 36, 20].

Here we consider four procedures in some detail. The first technique is based on windowing. It is a simple, but is not optimum for Chebyshev approximation. The second technique is based on frequency sampling, and this can be used to arrive at equiripple solutions using linear programming. Finally, two techniques for arriving iteratively at a nearly equiripple solution are described. The first of these is based on L_p approximations using nonlinear optimization. The second is based on the use of alternating projections in the sample and the frequency domains.

Design of 2-D FIR Filters by Windowing

This design method is basically an extension of the window-based 1-D FIR filter design to the case of 2-D filters. An ideal impulse response sequence, which is usually an infinite-extent sequence, is suitably windowed to make the support finite. One-dimensional FIR filter design by windowing and classes of 1-D windows are described in detail in Section 91.2.

Let $h_{id}(n_1, n_2)$ and $H_{id}(\omega_1, \omega_2)$ be the impulse and frequency responses of the ideal filter, respectively. The impulse response of the required 2-D filter, $h(n_1, n_2)$, is obtained as a product of the ideal impulse response sequence and a suitable 2-D window sequence which has a finite extent support, I, that is,

$$h(n_1, n_2) = \begin{cases} h_{id}(n_1, n_2) w(n_1, n_2) & (n_1, n_2) \in I, \\ 0, & \text{otherwise} \end{cases} \tag{91.9}$$

where $w(n_1, n_2)$ is the window sequence. The resultant frequency response, $H(\omega_1, \omega_2)$, is a smoothed version of the ideal frequency response as $H(\omega_1, \omega_2)$ is related to the $H_{id}(\omega_1, \omega_2)$ via the periodic convolution, that is,

$$H(\omega_1, \omega_2) = \frac{1}{4\pi^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} H_{id}(\Omega_1, \Omega_2) W(\omega_1 - \Omega_1, \omega_2 - \Omega_2) d\Omega_1 d\Omega_2, \tag{91.10}$$

© 2003 by CRC Press LLC

where $W(\omega_1,\omega_2)$ is the frequency response of the window sequence, $w(n_1, n_2)$.

As in the 1-D case, a 2-D window sequence, $w(n_1, n_2)$, should satisfy three requirements:

1. It must have a finite-extent support, I.
2. Its discrete-space Fourier transform should in some sense approximate the 2-D impulse function, $\delta(\omega_1,\omega_2)$.
3. It should be real, with a zero-phase discrete-space Fourier transform.

Usually 2-D windows are derived from 1-D windows. Three methods of constructing windows are briefly examined. One method is to obtain a separable window from two 1-D windows, that is,

$$w_r(n_1,n_2) = w_1(n_1)w_2(n_2), \tag{91.11}$$

where $w_1(n)$ and $w_2(n)$ are the 1-D windows. Thus, the support of the resultant 2-D window, $w_r(n_1, n_2)$, is a rectangular region. The frequency response of the 2-D window is also separable, i.e., $W_r(\omega_1,\omega_2) = W_1(\omega_1)\, W_2(\omega_2)$.

The second method of constructing a window, due to Huang [22], consists of sampling the surface generated by rotating a 1-D continuous-time window, $w(t)$, as follows:

$$w_c(n_1,n_2) = w\left(\sqrt{n_1^2 + n_2^2}\right), \tag{91.12}$$

where $w(t) = 0$, $t \geq N$. The impulse response support is $I = \{n_1, n_2: \sqrt{n_1^2 + n_2^2} < N\}$. Note that the 2-D Fourier transform of the $w_c(n_1, n_2)$ is not equal to the circularly rotated version of the Fourier transform of $w(t)$.

Finally, in the third method, proposed by Yu and Mitra [53], the window is constructed by using a 1-D to 2-D transformation belonging to a class called the McClellan transformations [33]. These transformations are discussed in greater detail in Section 91.4. Here we consider a special case of the transform that produces approximately circular contours in the 2-D frequency domain. Briefly, the discrete-space frequency transform of the 2-D window sequence obtained with a McClellan transformation applied to a 1-D window is given by

$$\begin{aligned} T(\omega_1,\omega_2) &= \sum_{n=-N}^{N} w(n)e^{-j\omega n}\Big|_{\cos(\omega)=0.5\cos(\omega_1)+0.5\cos(\omega_2)+0.5\cos(\omega_1)\cos(\omega_2)-0.5} \\ &= w(0) + \sum_{n=1}^{N} w(n)\cos(n\omega)\Big|_{\cos(\omega)=0.5\cos(\omega_1)+0.5\cos(\omega_2)+0.5\cos(\omega_1)\cos(\omega_2)-0.5} \\ &= \sum_{n=0}^{N} b(n)\cos^n(\omega)\Big|_{\cos(\omega)=0.5\cos(\omega_1)+0.5\cos(\omega_2)+0.5\cos(\omega_1)\cos(\omega_2)-0.5} \end{aligned} \tag{91.13}$$

where $w(n)$ is an arbitrary symmetric 1-D window of duration $2N + 1$ centered at the origin, and the coefficients, $b(n)$, are obtained from $w(n)$ via Chebyshev polynomials [33]. After some algebraic manipulations it can be shown that

$$T(\omega_1,\omega_2) = \sum_{n_1=-N}^{N}\sum_{n_2=-N}^{N} w_t(n_1,n_2)e^{-j(n_1\omega_1+n_2\omega_2)}, \tag{91.14}$$

where $w_t(n_1, n_2)$ is a zero-phase 2-D window of size $(2N+1)\times(2N+1)$ obtained by using the McClellan transformation.

© 2003 by CRC Press LLC

The construction of 2-D windows using the above three methods is now examined. In the case of windows obtained by the separable and the McClellan transformation approaches, the 1-D prototype is a Hamming window,

$$w_h(n) = \begin{cases} 0.54 + 0.46\cos(\pi n/N), & |n| < N, \\ 0, & \text{otherwise.} \end{cases} \tag{91.15}$$

In the second case $w_c(n_1, n_2) = 0.54 + 0.46\cos(\pi\sqrt{n_1^2 + n_2^2}/N)$. By selecting $w_1(n) = w_2(n) = w_h(n)$ in (91.11) we get a 2-D window, $w_r(n_1, n_2)$, of support $I = \{|n_1| < N, |n_2| < N\}$ which is a square-shaped symmetric region centered at the origin. For $N = 6$ the region of support, I contains $11 \times 11 = 121$ points. Figure 91.3(a) shows the frequency response of this window. A second window is designed by using (91.12), i.e., $w_c(n_1, n_2) = w_h(\sqrt{n_1^2 + n_2^2})$. For $N = 6$ the frequency response of this filter is shown in Fig. 91.3(b). The region of support is almost circular and it contains 113 points. From these examples, it is seen that the 2-D windows may not behave as well as 1-D windows. Speake and Mersereau [46] compared these two methods and observed that the main-lobe width and the highest attenuation level of the side-lobes of the 2-D windows differ from their 1-D prototypes.

Let us construct a 2-D window by the McClellan transformation with a 1-D Hamming window of order 13 ($N = 6$) as the prototype. The frequency response of the 2-D window, $w_t(n_1, n_2)$, is shown in Fig. 91.3(c). The frequency response of this window is almost circularly symmetric and it preserves the features of its 1-D prototype.

Consider the design of a circularly symmetric low-pass filter. The ideal frequency response for $(\omega_1, \omega_2) \in [-\pi, \pi] \times [-\pi, \pi]$ is given by

$$H_{id}(\omega_1, \omega_2) = \begin{cases} 1, & \sqrt{\omega_1^2 + \omega_2^2} \le \omega_c, \\ 0, & \text{otherwise.} \end{cases} \tag{91.16}$$

whose impulse response is given by

$$h_{id}(n_1, n_2) = \frac{\omega_c J_1\left(\omega_c\sqrt{n_1^2 + n_2^2}\right)}{2\pi\sqrt{n_1^2 + n_2^2}}, \tag{91.17}$$

where $J_1(.)$ is the first-order Bessel function of the first kind, and ω_c is the cutoff frequency. The frequency response of the 2-D FIR filter obtained with a rectangular window of size $2 \times 5 + 1$ by $2 \times 5 + 1$ is shown in Fig. 91.4(a). Note the Gibbs-phenomenon type ripples at the passband edges. In Fig. 91.4(b) the separable window of Fig. 91.3(a), derived from a Hamming window, is used to design the 2-D filter. Note that this 2-D filter has smaller ripples at the passband edges.

In windowing methods, it is often assumed that $H_{id}(\omega_1, \omega_2)$ is given. However, if the specifications are given as described in Section 91.2, then a proper $H_{id}(\omega_1, \omega_2)$ should be constructed. The ideal magnitudes are either 1.0 (in passband) or 0.0 (in stopband). However, there is a need to define a *cutoff* boundary, which lies within the transition band. This can be accomplished by using a suitable notion of "midway" cutoff between the transition boundaries. In practical cases where transition boundaries are given in terms of straight-line segments or smooth curves such as circles and ellipses, the construction of "midway" cutoff boundary is relatively straightforward. The ideal impulse response, $h_{id}(n_1, n_2)$, is computed from the desired frequency response, $H_{id}(\omega_1, \omega_2)$, either analytically (if possible), or by using the discrete Fourier transform (DFT). In the latter case the desired response, $H_{id}(\omega_1, \omega_2)$, is first sampled on a rectangular grid in the Fourier domain, then an inverse DFT computation is carried out via a 2-D fast Fourier transform (FFT) algorithm to obtain an approximation to the sequence $h_{id}(n_1, n_2)$. The resulting sequence is an aliased version of the ideal impulse response. Therefore, a sufficiently dense grid should be used in order to reduce the effects of aliasing.

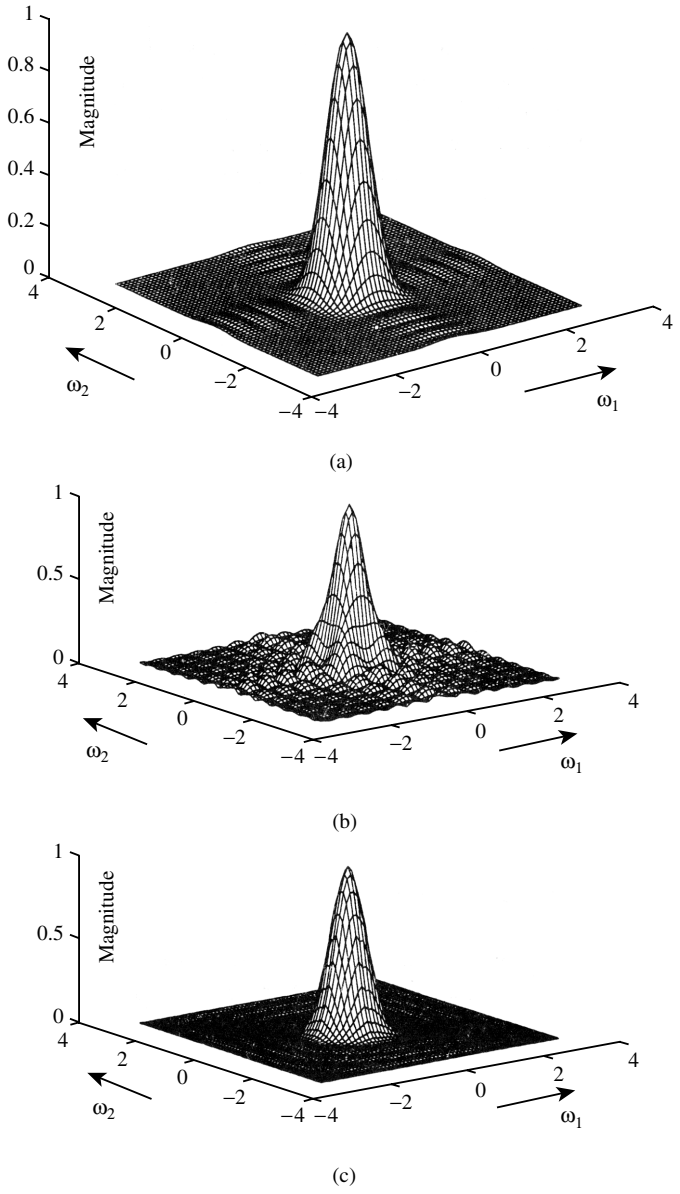

FIGURE 91.3 Frequency responses of the (a) separable, (b) Huang, and (c) McClellan 2-D windows generated from a Hamming window of order 13 ($N = 6$).

In practice, several trials may be needed to design the final filter satisfying bounds both in the passbands and stopbands. The filter support is adjusted to obtain the smallest order to meet given requirements.

Filter design with windowing is a simple approach that is suitable for applications where a quick and non-optimal design is needed. Additional information on windowing can be found in [26, 46].

Frequency Sampling and Linear Programming Based Method

This method is based on the application of the sampling theorem in the frequency domain. Consider the design of a 2-D filter with impulse response support of $N_1 \times N_2$ samples. The frequency response of the filter can be obtained from a conveniently chosen set of its samples on a $N_1 \times N_2$ grid. For example,

© 2003 by CRC Press LLC

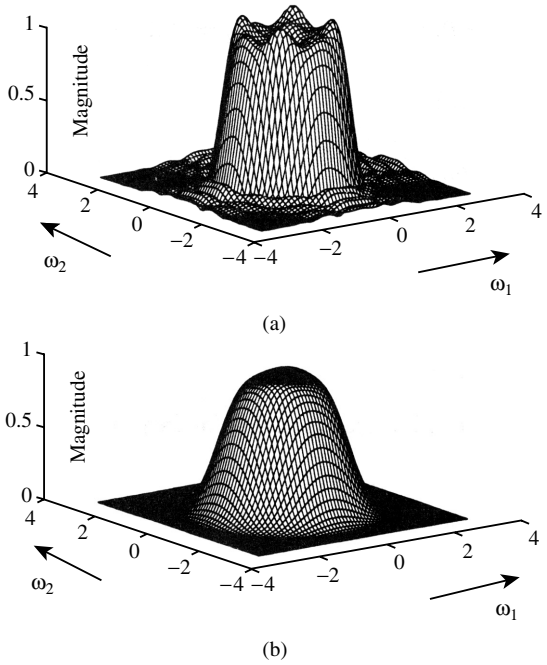

FIGURE 91.4 Frequency responses of the 2-D filters designed with (a) a rectangular window and (b) a separable window of Fig. 91.3(a).

the DFT of the impulse response can be used to interpolate the response for the entire region $[0,2\pi] \times [0,2\pi]$. The filter design then becomes a problem of choosing an appropriate set of DFT coefficients [21].

One choice of DFT coefficients consists of the ideal frequency response values, assuming a suitable cutoff. However, the resultant filters usually exhibit large magnitude deviations away from the DFT sample locations in the filter passbands and stopbands. The approximation error can be reduced by allowing the DFT values in the transition band to vary, and choosing them to minimize the deviation of the magnitude from the desired values. Another option is to allow all the DFT values to vary, and pick the optimal set of values for minimum error. The use of DFT-based interpolation allows for a computationally efficient implementation. The implementation cost of the method basically consists of a 2-D array product and inverse discrete Fourier transform (IDFT) computation, with appropriate addition.

Let us consider the set $S \subset Z^2$ that defines the equi-spaced frequency locations $\left(\frac{2k_1\pi}{N_1}, \frac{2k_2\pi}{N_2}\right)$:

$$S = \{k_1 = 0,1,...,N_1 - 1, k_2 = 0,1,...,N_2 - 1\}. \tag{91.18}$$

The DFT values can be expressed as

$$H_{DFT}[k_1,k_2] = H(\omega_1,\omega_2)\Big|_{(\omega_1,\omega_2)=\left(\frac{2k_1\pi}{N_1},\frac{2k_2\pi}{N_2}\right)}, \quad (k_1,k_2) \in S. \tag{91.19}$$

The filter coefficients, $h(n_1, n_2)$, are found by using an IDFT computation

$$h(n_1,n_2) = \frac{1}{N_1N_2}\sum_{k_1=0}^{N_1-1}\sum_{k_2=0}^{N_2-1} H_{DFT}[k_1,k_2]\, e^{j\left(\frac{2\pi}{N_1}k_1n_1 + \frac{2\pi}{N_2}k_2n_2\right)}, \quad (n_1,n_2) \in S. \tag{91.20}$$

© 2003 by CRC Press LLC

If Eq. (91.20) is substituted in the the expression for frequency response

$$H(\omega_1,\omega_2)=\sum_{n_1=0}^{N_1-1}\sum_{n_2=0}^{N_2-1}h(n_1,n_2)e^{-j(\omega_1 n_1+\omega_2 n_2)}, \tag{91.21}$$

we arrive at the interpolation formula

$$H(\omega_1,\omega_2)=\sum_{k_1=0}^{N_1-1}\sum_{k_2=0}^{N_2-1}H_{DFT}[k_1,k_2]A_{k_1k_2}(\omega_1,\omega_2), \tag{91.22}$$

where

$$A_{k_1k_2}(\omega_1,\omega_2)=\frac{1}{N_1N_2}\left(\frac{1-e^{-jN_1\omega_1}}{1-e^{-j(\omega_1-2\pi k_1/N_1)}}\right)\left(\frac{1-e^{-jN_2\omega_2}}{1-e^{-j(\omega_2-2\pi k_1k_2/N_2)}}\right). \tag{91.23}$$

Equation (91.22) serves as the basis of the frequency sampling design. As mentioned before, if the H_{DFT} are chosen directly according to the ideal response, then the magnitude deviations are usually large. To reduce the ripples, one option is to express the set S as the disjoint union of two sets S_t and S_c, where S_t contains indices corresponding to the transition band F_t, and S_c contains indices corresponding to the "care"-bands, i.e., the union of the passbands and stopbands, $F_p \cup F_s$. The expression for frequency response in Eq. (91.22) can be split into two summations, one over S_t and the other over S_c

$$H(\omega_1,\omega_2)=\sum_{S_t}H_{DFT}[k_1,k_2]A_{k_1k_2}(\omega_1,\omega_2)+\sum_{S_c}H_{DFT}[k_1,k_2]A_{k_1k_2}(\omega_1,\omega_2), \tag{91.24}$$

where the first term on the right-hand side is optimized. The design equations can be put in the form:

$$1-\alpha\delta\le H(\omega_1,\omega_2)\le 1+\alpha\delta,\ (\omega_1,\omega_2)\in F_p \tag{91.25}$$

and

$$-\delta\le H(\omega_1,\omega_2)\le \delta,\ (\omega_1,\omega_2)\in F_s \tag{91.26}$$

where δ is the peak approximation error in the stopband and $\alpha\delta$ is the peak approximation error in the passband, where α is any positive constant defining the relative weights of the deviations. The problem is readily cast as a linear programming problem with a sufficiently dense grid of points.

For equiripple design, all the DFT values H_{DFT} over S_t and S_c are allowed to vary. Following is an example of this design.

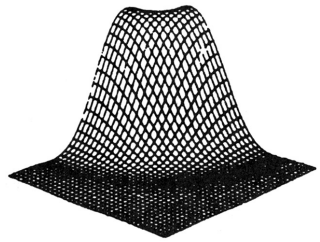
***Example*:** The magnitude response for the approximation of a circularly symmetric response is shown in Fig. 91.5. Here the passband is the interior of the circle $R_1 = \pi/3$ and the stopband is the exterior of the circle $R_2 = 2\pi/3$. With $N_1 = N_2 = 9$, the passband ripple is 0.08dB and the minimum stopband attenuation is 32.5dB.

FIR Filters Optimal in L_p Norm

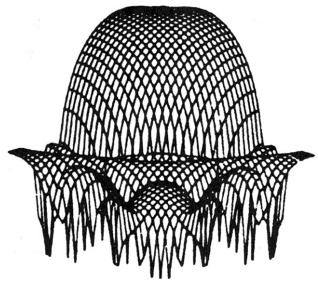
A criterion different from the minimax criterion is briefly examined. Let us define the error at the frequency pair (ω_1, ω_2) as follows:

$$E(\omega_1,\omega_2)=H(\omega_1,\omega_2)-H_{id}(\omega_1,\omega_2). \tag{91.27}$$

© 2003 by CRC Press LLC



$R_1 = 1.5\pi/4.5$
$R_2 = 3\pi/4.5$
$N_1 = N_2 = 9$
AMPLITUDE RESPONSE



LOG MAGNITUDE RESPONSE
IN-BAND RIPPLE = 0.08
PEAK ATTENUATION = 32.5dB

FIGURE 91.5 Frequency response of the circularly symmetric filter obtained by using the frequency sampling method. (Adaped from [23] with permission from IEEE.)

One design approach is to minimize the L_p norm of the error

$$\varepsilon_p = \left(\frac{1}{4\pi^2} \int_{-\pi}^{\pi} \int_{-\pi}^{\pi} \left| E(\omega_1, \omega_2) \right|^p d\omega_1 d\omega_2 \right)^{\frac{1}{p}}. \tag{91.28}$$

Filter coefficients are selected by a suitable algorithm. For $p = 2$ Parseval's relation implies that

$$\varepsilon_2^2 = \sum_{n_1=-\infty}^{\infty} \sum_{n_2=-\infty}^{\infty} \left[h(n_1, n_2) - h_{id}(n_1, n_2) \right]^2. \tag{91.29}$$

By minimizing (91.29) with respect to the filter coefficients, $h(n_1, n_2)$, which are nonzero only in a finite-extent region, I, one gets

$$h(n_1, n_2) = \begin{cases} h_{id}(n_1, n_2) & (n_1, n_2) \in I, \\ 0, & \text{otherwise.} \end{cases} \tag{91.30}$$

which is the filter designed by using a straightforward rectangular window. Due to the Gibbs phenomenon it may have large variations at the edges of passband and stopband regions. A suitable weighting function can be used to reduce the ripple [2], and an approximately equiripple solution can be obtained.

For the general case of $p \neq 2$ [32], the minimization of (91.28) is a nonlinear optimization problem. The integral in (91.28) is discretized and minimized by using an iterative nonlinear optimization technique. The solution for $p = 2$ is easy to obtain using linear equations. This serves as an excellent initial estimate for the coefficients in the case of larger values of p. As p increases, the solution becomes approximately equiripple. The error term, $E(\omega_1, \omega_2)$, in (91.28) is nonuniformly weighted in passbands and stopbands, with larger weight given close to band-edges where deviations are typically larger.

© 2003 by CRC Press LLC

Iterative Method for Approximate Minimax Design

We now consider a simple procedure based on alternating projections in the sample and frequency domains, which leads to an approximately equiripple response. In this method the zero-phase FIR filter design problem is formulated to alternately satisfy the frequency domain constraints on the magnitude response bounds and spatial domain constraints on the impulse response support [11, 12]. The algorithm is iterative and each iteration requires two 2-D FFT computations.

As pointed out in Section 91.2, 2-D FIR filter specifications are given as requirements on the magnitude response of the filter. It is desirable that the frequency response, $H(\omega_1, \omega_2)$, of the zero-phase FIR filter be within prescribed upper and lower bounds in its passbands and stopbands. Let us specify bounds on the frequency response $H(\omega_1, \omega_2)$ of the minimax FIR filter, $h(n_1, n_2)$, as follows

$$H_{id}(\omega_1,\omega_2) - E_d(\omega_1,\omega_2) \le H(\omega_1,\omega_2) \le H_{id}(\omega_1,\omega_2) + E_d(\omega_1,\omega_2) \quad \omega_1,\omega_2 \in R, \tag{91.31}$$

where $H_{id}(\omega_1, \omega_2)$ is the ideal filter response, $E_d(\omega_1, \omega_2)$ is a positive function of (ω_1, ω_2) which may take different values in different passbands and stopbands, and R is a region defined in (91.28) consisting of passbands and stopbands of the filter (note that $H(\omega_1, \omega_2)$ is real for a zero-phase filter). Usually, $E_d(\omega_1, \omega_2)$ is chosen constant in a passband or a stopband. Inequality (91.31) is the frequency domain constraint of the iterative filter design method.

In spatial domain the filter must have a finite-extent support, I, which is symmetric region around the origin. The spatial domain constraint requires that the filter coefficients must be equal to zero outside the region, I.

The iterative method begins with an arbitrary finite-extent, real sequence $h_0(n_1, n_2)$ that is symmetric ($h_0(n_1, n_2) = h_0(-n_1, n_2)$). Each iteration consists of making successive imposition of spatial and frequency domain constraints onto the current iterate. The kth iteration consists of the following steps:

- Compute the Fourier transform of the kth iterate $h_k(n_1, n_2)$ on a suitable grid of frequencies by using a 2-D FFT algorithm.
- Impose the frequency domain constraint as follows:

$$G_k(\omega_1,\omega_2) = \begin{cases} H_{id}(\omega_1,\omega_2) + E_d(\omega_1,\omega_2) & \text{if } H_k(\omega_1,\omega_2) > H_{id}(\omega_1,\omega_2) + E_d(\omega_1,\omega_2), \\ H_{id}(\omega_1,\omega_2) - E_d(\omega_1,\omega_2) & \text{if } H_k(\omega_1,\omega_2) < H_{id}(\omega_1,\omega_2) - E_d(\omega_1,\omega_2), \\ H_k(\omega_1,\omega_2) & \text{otherwise.} \end{cases} \tag{91.32}$$

- Compute the inverse Fourier transform of $G_k(\omega_1, \omega_2)$.
- Zero out $g_k(n_1, n_2)$ outside the region I to obtain h_{k+1}.

The flow diagram of this method is shown in Fig. 91.6. It can be proven that the algorithm converges for all symmetric input sequences. This method requires the specification of the bounds or equivalently, $E_d(\omega_1, \omega_2)$, and the filter support, I. In 2-D filter design, filter order estimates for prescribed frequency domain specifications are not available. Therefore, successive reduction of bounds is used. If the specifications are too tight, then the algorithm does not converge. In such cases one can either progressively enlarge the filter support region, or relax the bounds on the ideal frequency response.

The size of the 2-D FFT must be chosen sufficiently large. The passband and stopband edges are very important for the convergence of the algorithm. These edges must be represented accurately on the frequency grid of the FFT algorithm.

The shape of the filter support is very important in any 2-D filter design method. The support should be chosen to exploit the symmetries in the desired frequency response. For example, diamond-shaped supports show a clear advantage over the commonly assumed rectangular regions in designing diamond filters or 90° fan filters [4, 6].

$$h_k(n) = \begin{cases} \hat{h}_k(n) & \text{if } n \in I \\ 0 & \text{if } n \notin I \end{cases}$$

FIGURE 91.6 Flow diagram of the iterative filter design algorithm.

Since there are efficient FFT routines, 2-D FIR filters with large orders can be designed by using this procedure.

Example 1: Let us consider the design of a circularly symmetric lowpass filter. Maximum allowable deviation is $\delta_p = \delta_s = 0.05$ in both passband and the stopband. The passband and stopband cut-off boundaries have radii of $0.43\,\pi$ and $0.63\,\pi$, respectively. This means that the functions $E_d(\omega_1, \omega_2) = 0.05$ in the passband and the stopband. In the transition band the frequency response is conveniently bounded by the lower bound of the stopband and the upper bound of the passband. The filter support is a square shaped 17×17 region. The frequency response of this filter is shown in Fig. 91.7.

Example 2: Let us now consider an example in which we observe the importance of filter support. We design a fan filter whose specifications are shown in Fig. 91.8. Maximum allowable deviation is $\delta_p = \delta_s = 0.1$ in both passband and the stopband. If one uses a 7×7 square-shaped support which has 49 points, then it cannot meet the design specifications. However, a diamond shaped support,

$$I_d = \{-5 \le n_1 + n_2 \le 5\} \cap \{-5 \le n_1 - n_2 \le 5\}, \tag{91.33}$$

together with the restriction that

$$I_{de} = I_d \cap \{n_1 + n_2 = \text{odd or } n_1 = n_2 = 0\} \tag{91.34}$$

produces a filter satisfying the bounds. The filter support region, I_{de}, contains 37 points. The resultant frequency response is shown in Fig. 91.8.

91.4 Special Design Procedure for Restricted Classes

Many cases of practical importance typically require filters belonging to restricted classes. The stopbands and passbands of these filters are often defined by straight-line, circular or elliptical boundaries. In these cases, specialized procedures lead to efficient design and low-cost implementation. The filters in these cases are derived from 1-D prototypes.

Separable 2-D FIR Filter Design

The design of 2-D FIR filters composed of 1-D building blocks is briefly discussed. In cases where the specifications are given in terms of multiple passbands in the shapes of rectangles with sides parallel to the frequency axes, the design problem can be decomposed into multiple designs. The resulting filter is a parallel connection of component filters that are themselves separable filters. The separable structure was encountered earlier in the construction of 2-D windows from 1-D windows in Section 91.3. The

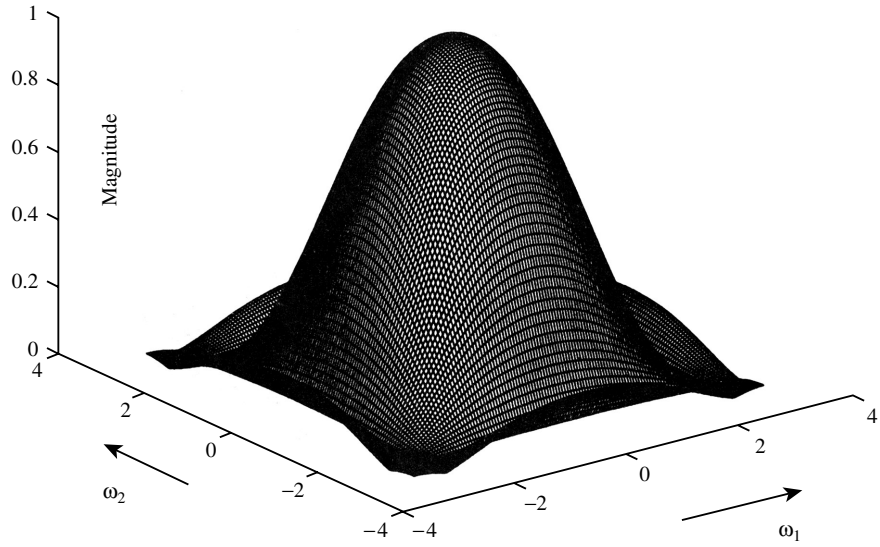

FIGURE 91.9 Frequency response of the separable lowpass filter $H(\omega_1, \omega_2) = H_1(\omega_1)H_1(\omega_2)$ where $H_1(\omega)$ is a 7th order Lagrange filter.

design approach is essentially the same. We will confine the discussion to cascade structures, which is a simple and very important practical case.

The frequency response of the 2-D separable FIR filter is expressed as

$$H(\omega_1, \omega_2) = H_1(\omega_1)H_2(\omega_2), \tag{91.35}$$

where $H_1(\omega)$ and $H_2(\omega)$ are frequency responses of two 1-D zero-phase FIR filters of durations N_1 and N_2. The corresponding 2-D filter is also a zero-phase FIR filter with $N \times M$ coefficients, and its impulse response is given by

$$h(n_1, n_2) = h_1(n_1)h_2(n_2), \tag{91.36}$$

where $h_1(n)$ and the $h_2(n)$ are the impulse responses of the 1-D FIR filters.

If the ideal frequency response can be expressed in a separable cascade form as in (91.35), then the design problem is reduced to the case of appropriate 1-D filter designs. A simple but important example is the design of a 2-D low-pass filter with a symmetric square-shaped passband, $PB = \{(\omega_1, \omega_2): |\omega_1| < \omega_c, |\omega_2| < \omega_c\}$. Such a lowpass filter can be designed from a single 1-D FIR filter with a cut-off frequency of ω_c by using (91.36). A lowpass filter constructed this way is used in Fig. 91.2(c). The frequency response of this 2-D filter whose 1-D prototypes are 7th order Lagrange filters is shown in Fig. 91.9.

This design method is also used in designing 2-D filter banks which are utilized in subband coding of images and video signals [49, 51, 52]). The design of 2-D filter banks is discussed in Section 91.6.

Frequency Transformation Method

In this method a 2-D zero-phase FIR filter is designed from a 1-D zero-phase filter by a clever substitution of variables. The design procedure was first proposed by McClellan [33] and the frequency transformation is usually called the McClellan transformation [14, 37, 35, 38].

Let $H_1(\omega)$ be the frequency response of a 1-D zero-phase filter with $2N+1$ coefficients. The key idea of this method is to find a suitable transformation $\omega = G(\omega_1, \omega_2)$ such that the 2-D frequency response, $H(\omega_1, \omega_2)$, which is given by

© 2003 by CRC Press LLC

$$H(\omega_1, \omega_2) = H_1(\omega)\big|_{\omega = G(\omega_1, \omega_2)} \tag{91.37}$$

approximates the desired frequency response, $H_{id}(\omega_1, \omega_2)$.

Since the 1-D filter is a zero-phase filter, its frequency response is real, and it can be written as follows:

$$H_1(\omega) = h_1(0) + \sum_{n=1}^{N} 2h_1(n)\cos(\omega n), \tag{91.38}$$

where the term $\cos(\omega n)$ can be expressed as a function of $\cos(\omega)$ by using the nth order Chebyshev polynomial, T_n,[2] i.e.,

$$\cos(\omega n) = T_n(\cos(\omega)). \tag{91.39}$$

Using (91.39), the 1-D frequency response can be written as

$$H_1(\omega) = \sum_{n=0}^{N} 2b(n)(\cos(\omega))^n, \tag{91.40}$$

where the coefficients, $b(n)$, are related to the filter coefficients, $h(n)$.

In this design method the key step is to substitute a transformation function, $F(\omega_1, \omega_2)$, for $\cos(\omega)$ in (91.40). In other words, the 2-D frequency response, $H(\omega_1, \omega_2)$, is obtained as follows:

$$\begin{aligned} H(\omega_1, \omega_2) &= H_1(\omega)\big|_{\cos(\omega) = F(\omega_1, \omega_2)} \\ &= \sum_{n=0}^{N} 2b(n)(F(\omega_1, \omega_2))^n. \end{aligned} \tag{91.41}$$

The function, $F(\omega_1, \omega_2)$, is called the McClellan transformation.

The frequency response, $H(\omega_1, \omega_2)$, of the 2-D FIR filter is determined by two free functions, the 1-D prototype frequency response, $H_1(\omega)$, and the transformation, $F(\omega_1, \omega_2)$. In order to have $H(\omega_1, \omega_2)$ be the frequency response of an FIR filter, the transformation, $F(\omega_1, \omega_2)$, must itself be the frequency response of a 2-D FIR filter. McClellan proposed $F(\omega_1, \omega_2)$ to be the frequency response of a 3×3 zero-phase filter in [33]. In this case the transformation, $F(\omega_1, \omega_2)$, can be written as follows:

$$F(\omega_1, \omega_2) = A + B\cos(\omega_1) + C\cos(\omega_2) + D\cos(\omega_1 - \omega_2) + E\cos(\omega_1 + \omega_2), \tag{91.42}$$

where the real parameters, A, B, C, D, and E, are related to the coefficients of the 3×3 zero-phase FIR filter. For $A = -\frac{1}{2}$, $B = C = \frac{1}{2}$, $D = E = \frac{1}{4}$, the contour plot of the transformation, $F(\omega_1, \omega_2)$, is shown in Fig. 91.10. Note that in this case the contours are approximately circularly symmetric around the origin. It can be seen that the deviation from the circularity, expressed as a fraction of the radius, decreases with the radius. In other words, the distortion from a circular response is larger for large radii. It is observed from Fig. 91.10 that, with the above choice of parameters, A, B, C, D, and E, the transformation is bounded ($|F(\omega_1, \omega_2)| \le 1$), which implies that $H(\omega_1, \omega_2)$ can take only the values that are taken by the 1-D prototype filter, $H_1(\omega)$. Since $|\cos(\omega)| \le 1$, the transformation, $F(\omega_1, \omega_2)$, which replaces $\cos(\omega)$ in (19.41) must also take values between 1 and –1. If a particular transformation does not obey these bounds, then it can be scaled such that the scaled transformation satisfies the bounds.

[2]Chebyshev polynomials are recursively defined as follows: $T_0(x) = 1$, $T_1(x) = x$, and $T_n(x) = 2xT_{n-1}(x) - T_{n-2}(x)$.

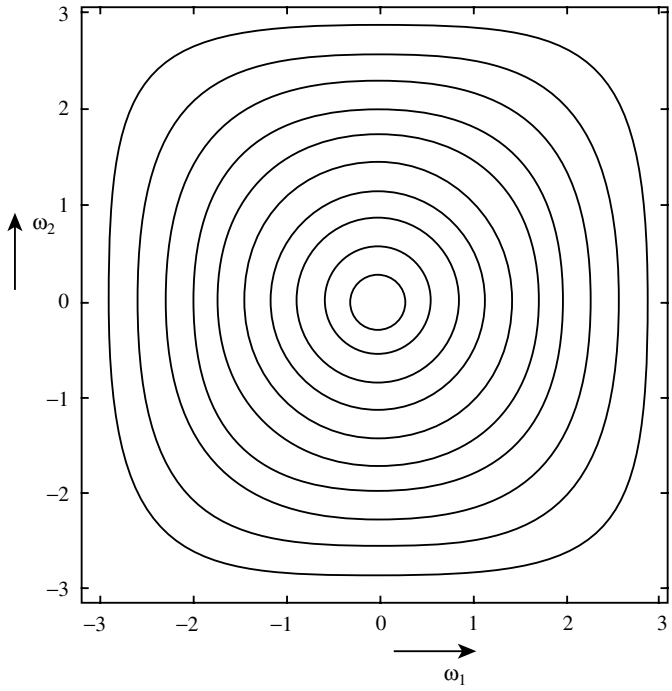

FIGURE 91.10 Contour plot of the McClellan transformation, $F(\omega_1, \omega_2) = 0.5\cos(\omega_1) + 0.5\cos(\omega_2) + 0.5\cos(\omega_1)\cos(\omega_2) - 0.5$.

If the transformation, $F(\omega_1, \omega_2)$, is real (it is real in (19.42)) then the 2-D filter, $H(\omega_1, \omega_2)$, will also be real or, in other words, it will be a zero-phase filter. Furthermore, it can be shown that the 2-D filter, $H(\omega_1, \omega_2)$, is an FIR filter with a support containing $(2M_1N + 1) \times (2M_2N + 1)$ coefficients, if the transformation, $F(\omega_1, \omega_2)$, is an FIR filter with $(2M_1 + 1) \times (2M_2 + 1)$ coefficients, and the order of the 1-D prototype filter is $2N + 1$. In (19.42) $M_1 = M_2 = 1$. As it can be intuitively guessed, one can design a 2-D approximately circularly symmetric low-pass (highpass) [bandpass] filter with the above McClellan transformation by choosing the 1-D prototype filter, $H_1(\omega)$, a low-pass (highpass) [bandpass] filter.

We will present some examples to demonstrate the effectiveness of the McClellan transformation.

Example 1: 2-D Window Design by Transformations [53]: In this example we design 2-D windows by using the McClellan transformation. Actually, we briefly mentioned this technique in Section 91.3. The 1-D prototype filter is chosen as an arbitrary 1-D symmetric window centered at the origin. Let $w(n)$ be the 1-D window of size $2N + 1$, and $W(\omega) = \sum_{n=-N}^{N} w(n)\exp(-j\omega n)$ be its frequency response. The transformation, $F(\omega_1, \omega_2)$, is chosen as in (91.42) with the parameters $A = -\frac{1}{2}$, $B = C = \frac{1}{2}$, $D = E = \frac{1}{4}$, of Fig. 91.10. This transformation, $F(\omega_1, \omega_2)$, can be shown to be equal to

$$F(\omega_1, \omega_2) = 0.5\cos(\omega_1) + 0.5\cos(\omega_2) + 0.5\cos(\omega_1)\cos(\omega_2) - 0.5. \tag{91.43}$$

The frequency response of the McClellan window, $H_t(\omega_1, \omega_2)$, is given by

$$H_t(\omega_1, \omega_2) = W(\omega)\Big|_{\cos(\omega)=F(\omega_1,\omega_2)}. \tag{91.44}$$

The resultant 2-D zero-phase window, $w_t(n_1, n_2)$, is centered at the origin and of size $(2N + 1) \times (2N + 1)$ because $M_1 = M_2 = 1$. The window coefficients can be computed either by using the inverse Chebyshev

© 2003 by CRC Press LLC

relation,[3] or by using the inverse Fourier transform of (91.44). The frequency response of a 2-D window constructed from a 1-D Hamming window of order 13 is shown in Fig. 91.3(c). The size of the window is 13×13.

Example 2: Let us consider the design of a circularly symmetric lowpass filter and a bandpass filter by using the transformation of (91.43). In this case, if one starts with a 1-D lowpass (bandpass) filter as the prototype filter, then the resulting 2-D filter will be a 2-D circularly symmetric lowpass (bandpass) filter due to the almost circularly symmetric nature of the transformation. In this example, the Lagrange filter of order 7 considered in Section 91.2 is used as the prototype. The prototype 1-D bandpass filter of order 15 is designed by using the Parks-McClellan algorithm [41].

It is seen from the above examples that filters designed by the transformation method appear to have better frequency responses than those designed by the windowing or frequency sampling methods. In other words, one can control the 2-D frequency response by controlling the frequency response of the 1-D prototype filter and choosing a suitable 2-D transformation. Furthermore, in some special cases it was shown that minimax optimal filters can be designed by the transformation method [20].

We have considered specific cases of the special transformations given by (91.42). By varying the parameters in (91.42) or expanding the transformation to include additional terms, a wider class of contours can be approximated. Ideally, the frequency transformation approach requires the simultaneous optimal selection of the transformation, $F(\omega_1,\omega_2)$, and the 1-D prototype filter $H_1(\omega)$ to approximate a desired 2-D frequency response. This can be posed as a nonlinear optimization problem. However, a suboptimal two-stage design by separately choosing $F(\omega_1,\omega_2)$ and $H_1(\omega)$ works well in practice. The transformation $F(\omega_1,\omega_2)$ should approximate 1 (–1) in the passband (stopband) of the desired filter. The contour produced by the transformation corresponding to the 1-D passband (stopband) edge frequency, ω_p (ω_s), should ideally map to the given passband (stopband) boundary in the 2-D specifications. However, this cannot be achieved in general given the small number of variable parameters in the transformation. The parameters are therefore selected to minimize a suitable norm of the error between actual and ideal (constant) values of the transformation over the boundaries.

Various transformations and design considerations are described in [37, 38, 40, 43]. The use of this transformation in exact reconstruction filter bank design was proposed in [7].

Filters designed by the transformation method can be implemented in a computationally efficient manner [14, 30]. The key idea is to implement (91.41) instead of implementing the filter by using the direct convolution sum. By implementing the transformation, $F(\omega_1,\omega_2)$, which is an FIR filter of low-order, in a modular structure realizing (91.41) is more advantages than ordinary convolution sum [14, 34].

In the case of circular passband design, it was observed that for low order transformation, the transformation contours exhibit large deviations from circularity. A simple artifice to overcome this problem in approximating wideband responses is to use decimation of a 2-D narrowband filter impulse response [18]. The solution consists of transforming the specifications to an appropriate narrowband design, where the deviation from circularity is smaller. The narrow passband can be expanded by decimation while essentially preserving the circularity of the passband.

Design Using Nonrectangular Transformations and Sampling Rate Conversions

In some filter specifications the desired responses are characterized by ideal frequency responses in which passbands and stopbands are separated by straight-line boundaries that are not necessarily parallel to the frequency axes. Examples of these are the various kinds of fan filters [4, 15, 17, 27] and diamond-shaped filters [6, 48]. Other shapes with straight-line boundaries are also approximated [8, 9, 13, 29, 28, 50]. Several design methods applicable in such cases have been developed and these methods are usually based on transformations related to concepts of sampling rate conversions. Often alternate frequency

[3] $1 = T_0(x)$, $x = T_1(x) - T_0(x)$, $x^2 = \frac{1}{2}(t_0(x) + T_2(x))$, $x^3 = \frac{1}{4}(3T_1(x) + T_3(x))$ etc.

domain interpretations are used to explain the design manipulations. A detailed treatment of these methods is beyond the scope of this chapter. However some key ideas are described, and a specific case of a diamond filter is used to illustrate the methods. The importance of these design methods stems from the implementation efficiency that results from a generalized notion of separable processing.

In the family of methods considered here, manipulations of a separable 2-D response using a combination of several steps is carried out. In the general case of designing filters with straight-line boundaries, it is difficult to describe a systematic procedure. However, in a given design problem, an appropriate set of steps in the design is suggested by the nature of the desired response.

Some underlying ideas can be understood by examining the problem of obtaining a filter with a parallellogram-shaped passband region. The sides of the parallellogram are assumed to be tilted with

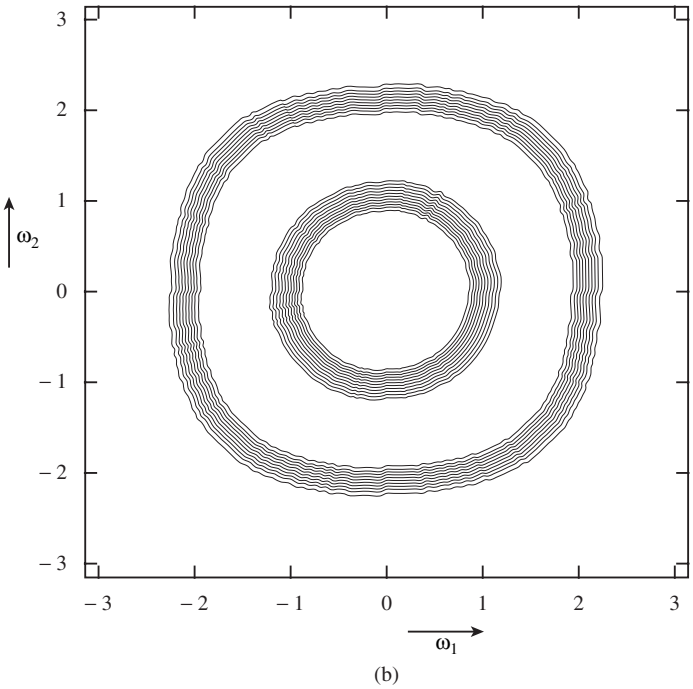
(a)



(b)

FIGURE 91.12 Frequency response and contour plots of the bandpass filter of Example 2.

respect to the frequency axes. One approach to solving this problem is to perform the following series of manipulations on a separable prototype filter with a rectangular passband. The prototype filter impulse response is upsampled on a *nonrectangular* grid. The upsampling is done by an integer factor greater than one and it is defined by a non-diagonal non-singular integer matrix [39]. The upsampling produces a parallellogram by a rotation and compression of the frequency response of the prototype filter together with a change in the periodicity. The matrix elements are chosen to produce the desired orientation in the resulting response. Depending on the desired response, cascading to eliminate unwanted portions of the passband in the frequency response, along with possible shifts and additions, may be used. The nonrectangular upsampling is then followed by a rectangular decimation of the sequence to expand the passband out to the desired size. In some cases the operations of the upsampling transformation and decimation can be combined by the use of nonrectangular decimation of impulse response samples.

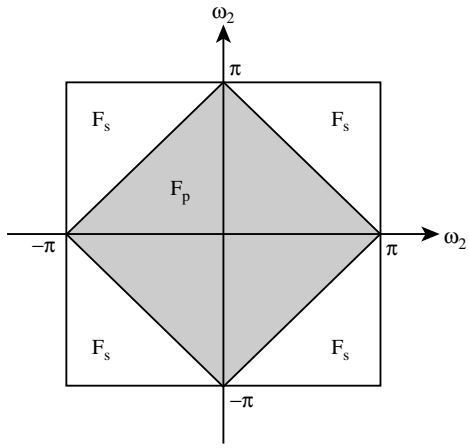

FIGURE 91.13 Ideal frequency respnse of a diamond filter.

Results using such procedures produce efficient filter structures that are implemented with essentially 1-D techniques but where the orientations of processing are not parallel to the sample coordinates.

Consider the case of a diamond filter design shown in Fig. 91.13. Note that the filter in Fig. 91.13 can be obtained from the filter in Fig. 91.14(a) by a transformation of variables. If $F_a(z_1, z_2)$ is the transfer function of the filter approximating the response in Fig. 91.14(a), then the diamond filter transfer function $D(z_1, z_2)$ given by

$$D(z_1, z_2) = F_a\left(z_1^{\frac{1}{2}} z_2^{\frac{1}{2}}, z_1^{-\frac{1}{2}} z_2^{\frac{1}{2}}\right) \tag{91.45}$$

will approximate the response in Fig. 91.1(a). The response in Fig. 91.2(a) can be expressed as the sum of the two responses shown in Fig. 91.2(b) and (c). We observe that if $F_b(z_1, z_2)$ is the transfer function of the filter approximating the response in Fig. 91.2(b) then

$$F_c(z_1, z_2) = F_b(-z_1, -z_2) \tag{91.46}$$

will approximate the response in Fig. 91.14(c). This is due to the fact that negating the arguments shifts the (periodic) frequency response of F_b by (π, π). The response in Fig. 91.14(b) can be expressed as the product of two ideal 1-D lowpass filters, one horizontal and one vertical, which have the response shown in Fig. 91.14(d). This 1-D frequency response can be approximated by a halfband filter. Such an approximation will produce a response in which the transition band straddles both sides of the cutoff frequency boundaries in Fig. 91.14(a). If we wish to constrain the transition band to lie within the boundaries of the diamond-shaped region in Fig. 91.13(a), then we should choose a 1-D filter whose stopband interval is $(\pi/2, \pi)$. Let $H(z)$ be the transfer function of the prototype 1-D lowpass filter approximating the response in Fig. 91.14(d) with a suitably chosen transition boundary. The transfer function $H(z)$ can be expressed as

$$H(z) = T_1(z^2) + zT_2(z^2). \tag{91.47}$$

The transfer function F_a is given by

$$F_a(z_1, z_2) = H(z_1)H(z_2) + H(-z_1)H(-z_2). \tag{91.48}$$

Combining (91.45), (91.47), and (91.48) we get

© 2003 by CRC Press LLC

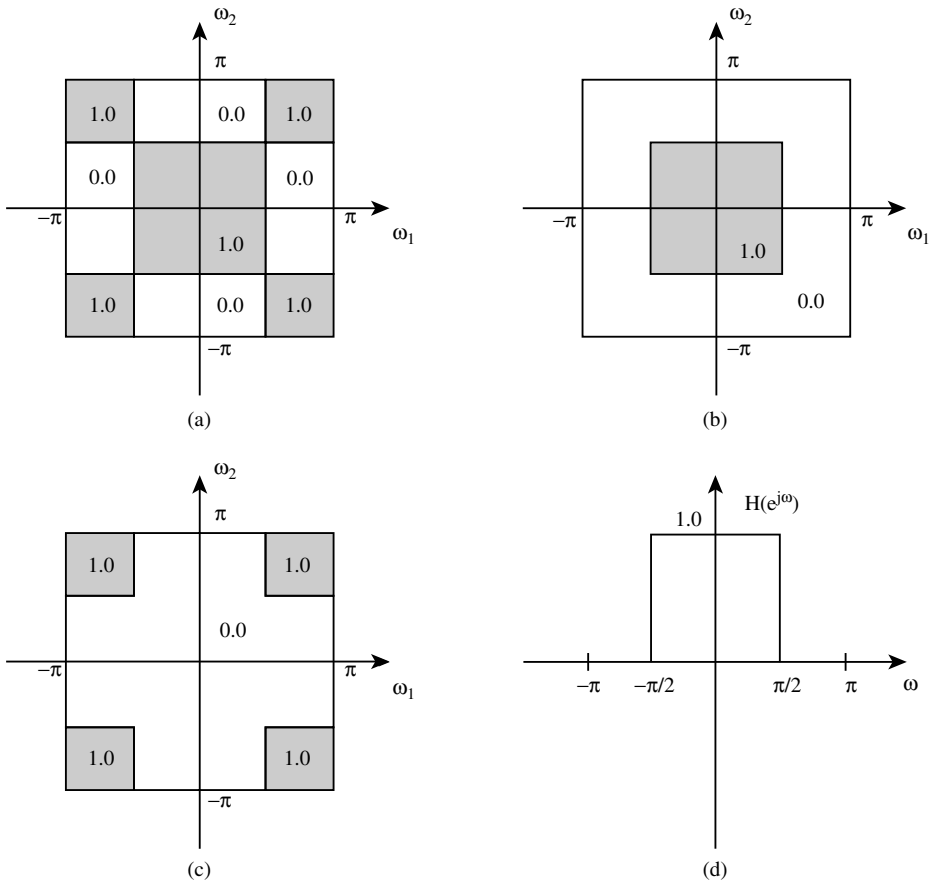

FIGURE 91.14 Ideal frequency responses of the filters (a) $F_a(z_1, z_2)$, (b) $F_b(-z_1, -z_2)$, (c) $F_c(z_1, z_2)$, and (d) $H(z)$ in obtaining a diamond filter.

$$D(z_1, z_2) = 2T_1(z_1, z_2)T_1(z_1^{-1}z_2) + 2z_2T_2(z_1, z_2)T_2(z_1^{-1}z_2). \tag{91.49}$$

As mentioned before, $H(z)$ can be chosen to be a halfband filter with

$$T_1(z^2) = 0.5. \tag{91.50}$$

The filter T_2 can be either FIR or IIR. It should be noted that the result can also be obtained as a nonrectangular downsampling, by a factor 2, of the impulse response of the filter $F_b(-z_1, -z_2)$.

Another approach that utilizes multirate concepts is based on a novel idea of applying frequency masking in the 2-D case [31].

91.5 2-D FIR Filter Implementation

The straightforward way to implement 2-D FIR filters is to evaluate the convolution sum given in (91.1). Let us assume that the FIR filter has L nonzero coefficients in its region of support I. In order to get an output sample, L multiplications and L additions need to be performed. The number of arithmetic operations can be reduced by taking advantage of the symmetry of the filter coefficients, that is, $h(n_1, n_2) = h(-n_1, -n_2)$. For example, let the filter support be a rectangular region, $I = \{n_1 = -N_1, \ldots, 0, 1, \ldots, N_1, n_2 = -N_2, \ldots, 0, 1, \ldots, N_2\}$. In this case,

© 2003 by CRC Press LLC

$$y(n_1,n_2)=\sum_{k_1=-N_1}^{N_1}\sum_{k_2=1}^{N_2}\left[h(k_1,k_2)x(n_1-k_1,n_2-k_2)+x(n_1+k_1,n_2+k_2)\right]$$
$$+h(0,0)x(n_1,n_2)+\sum_{k_1=1}^{N_1}h(k_1,0)\left[x(n_1-k_1,n_2)+x(n_1+k_1,n_2)\right], \tag{91.51}$$

which requires approximately half of the multiplications required in the direct implementation (91.1). Any 2-D FIR filter can also be implemented by using an FFT algorithm. This is the direct generalization of 1-D FFT-based implementation [14, 30]. The number of arithmetic operations may be less than the space domain implementation in some cases.

Some 2-D filters have special structures that can be exploited during implementation. As we pointed out in Section 91.4, 2-D filters designed by McClellan-type transformations can be implemented in an efficient manner [14, 35, 34] by building a network whose basic module is the transformation function which is usually a low order 2-D FIR filter.

Two-dimensional FIR filters that have separable system responses can be implemented in a cascade structure. In general, an arbitrary 2-D polynomial cannot be factored into subpolynomials due to the absence of a counterpart of Fundamental Theorem of Algebra in two or higher dimensions (whereas in 1-D any polynomial can be factored into polynomials of lower orders). Since separable 2-D filters are constructed from 1-D polynomials, they can be factored and implemented in a cascade form. Let us consider (91.35) where $H(z_1,z_2)=H_1(z_1)H_2(z_2)$ which corresponds to $h(n_1, n_2) = h_1(n_1)\ h_2(n_2)$ in space domain. Let us assume that orders of the 1-D filters $h_1(n)$ and $h_2(n)$ are $2N_1+1$ and $2N_2+1$, respectively. In this case the 2-D filter, $h(n_1, n_2)$, has the same rectangular support, I, as in (91.51). Therefore,

$$y(n_1,n_2)=\sum_{k_2=-N_2}^{N_2}h_2(k_2)\sum_{k_1=-N_1}^{N_1}h(k_1)x(n_1-k_1,n_2-k_2). \tag{91.52}$$

The 2-D filtering operation in (91.52) is equivalent to a two-stage 1-D filtering in which the input image, $x(n_1, n_2)$, is first filtered horizontally line by line by $h_1(n)$, then the resulting output is filtered vertically column by column by $h_2(n)$. In order to produce an output sample, the direct implementation requires $(2N_1+1)\times(2N_2+1)$ multiplications, whereas the separable implementation requires $(2N_1 + 1) + (2N_2 + 1)$ multiplications, which is computationally much more efficient than the direct form realization. This is achieved at the expense of memory space (separable implementation needs a buffer to store the results of first stage during the implementation). By taking advantage of the symmetric nature of h_1 and h_2, the number of multiplications can be further reduced.

Filter design methods by imposing structural constraints like cascade, parallel, and other forms are proposed by several researchers including [47, 16]. These filters can be efficiently implemented because of their special structures. Unfortunately, the design procedure requires nonlinear optimization techniques which may be very complicated.

With advances in VLSI technology, the implementation of 2-D FIR filters using high-speed digital signal processors is becoming increasingly common in complex image processing systems.

91.6 Multi-Dimensional Filter Banks and Wavelets

Two-dimensional subband decomposition of signals using filter banks (that implement a 2-D wavelet transform) find applications in a wide range of tasks including image and video coding, restoration, denoising, and signal analysis. For example, in recently finalized JPEG-2000 image coding standard an image is first processed by a 2-D filter bank. Data compression is then carried out in the subband domain.

In most cases, 2-D filter banks are constructed in a separable form with the use of the filters of 1-D filter banks, i.e., as a product of two 1-D filters [49, 52]. We confine our attention to a 2-D four-channel

© 2003 by CRC Press LLC

filter bank obtained from a 1-D two-channel filter bank. Let h_0 and h_1 denote the analysis filters of a 1-D two-channel filter bank. The four analysis filters of the separable 2-D filter bank are given by

$$h_{i,j}(n_1,n_2) = h_i(n_1)h_j(n_2), \quad i,\ j = 0,\ 1, \tag{91.53}$$

The filters h_0 and h_1 can be either FIR or IIR. If they are FIR (IIR), then the 2-D filters, $h_{i,j}$, are also FIR (IIR). Frequency responses of these four filters, $H_{i,j}(\omega_1,\omega_2)$, $i,j = 0,1$, are given by

$$H_{i,j}(\omega_1,\omega_2) = H_i(\omega_1)H_j(\omega_2), \quad i,\ j = 0,\ 1, \tag{91.54}$$

where $H_0(\omega_1)$ and $H_1(\omega_2)$ are the frequency responses of the 1-D low-pass (approximating an ideal cutoff frequency at $\pi/2$) and high-pass filters of a 1-D subband filter bank, respectively [51]. Any 1-D filter bank described in Chapter 89 can be used in (91.53) to design 2-D filter banks. Feature-rich structures for 1-D filter banks are described in [7, 8].

The 2-D signal is decomposed by partitioning its frequency domain support into four rectangular regions of equal areas. The ideal passband regions of the filters, $H_{i,j}(\omega_1,\omega_2)$, are shown in Fig. 91.15. For example, the ideal passband of $H_{0,0}(\omega_1,\omega_2)$ is the square region $[-\pi/2, \pi/2] \times [-\pi/2, \pi/2]$. The 2-D filter bank is shown in Fig. 91.16.

Corresponding 2-D synthesis filters are also constructed in a separable manner from the synthesis filters of the 1-D filter bank. If the 1-D filter bank has the perfect reconstruction (PR) property, then the 2-D filter bank also has the PR property. Subband decomposition filter banks (or filter banks implementing the 2-D wavelet transform) consist of analysis and synthesis filters, upsamplers, and downsamplers as discussed in Chapter 90. In the separable 2-D filter bank, downsampling is carried out both horizontally and vertically as follows:

$$x_0(n_1,n_2) = x_a(2n_1,2n_2) \tag{91.55}$$

Here we consider the input 2-D signal x_a to be an image. The downsampled image x_0 is a quarter-size version of x_a. Only one sample out of four is retained in the downsampling operation described in (91.55). The upsampling operation is the dual of the downsampling operation. In other words, a zero valued sample is inserted in upsampling corresponding to the location of each dropped sample during downsampling.

The implementation of the above filter bank can be carried out separably in a computationally efficient manner as described in Chapter 90 and [52, 49]. The input image is first processed horizontally row by

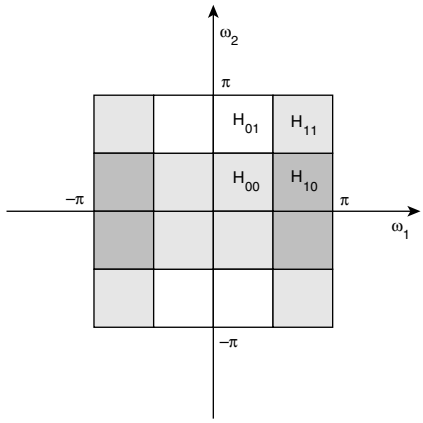

FIGURE 91.15 Ideal passband regions of the separable filters of a rectangular filter bank.

© 2003 by CRC Press LLC

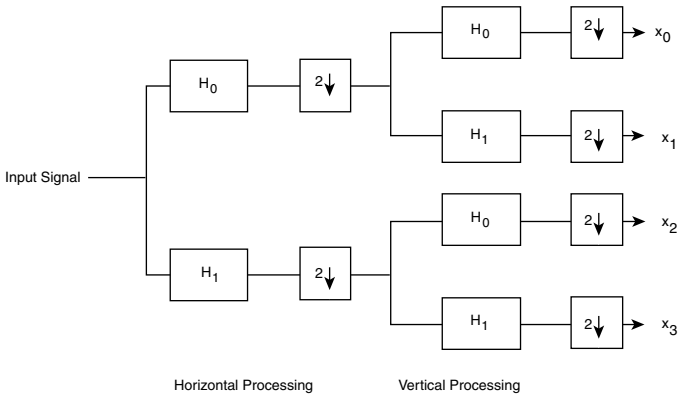

FIGURE 91.16 Block diagram of seperable processing in 2-D filter bank.

row by a 1-D filter bank with filters, h_0 and h_1. After the input signal is horizontally filtered with the 1-D two-channel filter bank, the signal in each channel is downsampled row-wise to yield two images. Each image is then filtered and downsampled vertically by the filter bank. As a result, four quarter-size subimages, x_i, $i = 0, 1, 2, 3$, are obtained. These images are the same as the images obtained by direct implementation of the analysis filter bank shown in Fig. 91.16. The synthesis filter bank is also implemented in a separable manner.

Nonseparable 2-D filter banks [14] are not as computationally efficient as separable filter banks as discussed in Section 91.5.

In two or higher dimensions, downsampling and upsampling are not restricted to the rectangular grid, but can be carried out in a variety of ways. One example of this is quincunx downsampling where the downsampled image x_q is related to the input image x_a as follows:

$$x_q(n_1, n_2) = x_a(n_1 + n_2, n_2 - n_1) \tag{91.56}$$

In this case only the samples for which $n_1 + n_2$ is even are retained in the output. Filter banks employing quincunx and other downsampling strategies are described in [5]-[7], [9], [50], [52]. Filter banks that employ quincunx downsampling have only two channels and the frequency support is partitioned in a diamond-shaped manner as shown in Fig. 91.13. Filters of a quincunx filter bank which have diamond-shaped passbands and stopbands can be designed from a 1-D subband decomposition filter bank using the transformation method described in Eqs. (91.45) through (91.48).

Acknowledgments

The authors would like to express their sincere thanks to Omer Nezih Gerek, Imad Abdel Hafez, and Ahmet Murat Bagci for the help they provided in preparing the figures for the chapter.

92.1 Introduction

A linear 2-D IIR digital filter can be characterized by its transfer function

$$H(z_1, z_2) = \frac{N(z_1, z_2)}{D(z_1, z_2)} = \frac{\sum_{i=0}^{N_2}\sum_{j=0}^{M_2} a_{ij} z_1^{-i} z_2^{-j}}{\sum_{i=0}^{N_1}\sum_{j=0}^{M_1} b_{ij} z_1^{-i} z_2^{-j}} \tag{92.1}$$

where the sampling period $T_i = 2\pi/\omega_{si}$ for $i = 1, 2$ with ω_{si} and the sampling frequencies a_{ij} and b_{ij} are real numbers known as the coefficients of the filter. Without loss of generality we can assume $M_1 = M_2 = N_1 = N_2 = M$ and $T_1 = T_2 = T$. Designing a 2-D filter is to calculate the filter coefficients a_{ij} and b_{ij} in such a way that the amplitude response and/or the phase response (group delay) of the designed filter approximates to some ideal responses while maintaining the stability of the designed filter. The latter requires that

$$D(z_1, z_2) \neq 0 \qquad \text{for } |z_i| \geq 1 \qquad i = 1, 2 \tag{92.2}$$

The amplitude response of the 2-D filter is expressed as

$$M(\omega_1, \omega_2) = \left| H\left(e^{j\omega_1 T}, e^{j\omega_2 T}\right) \right| \tag{92.3}$$

© 2003 by CRC Press LLC

the phase response as

$$\phi(\omega_1,\omega_2)=\arg H\left(e^{j\omega_1 T},\ e^{j\omega_2 T}\right) \tag{92.4}$$

and the two group delay functions as

$$\tau_i(\omega_1,\omega_2)=\frac{d\phi(\omega_1,\omega_2)}{d\omega_i} \qquad i=1,\ 2 \tag{92.5}$$

Equation (92.1) is the general form of transfer functions of the nonseparable numerator and denominator 2-D IIR filters. It can involve two subclasses, namely, the separable product transfer function

$$\begin{aligned} H(z_1,z_2) &= H_1(z_1)H_2(z_2) \\ &= \frac{\sum_{i=0}^{N_2} a_{1i}z_1^{-i}\sum_{j=0}^{M_2} a_{2i}z_2^{-j}}{\sum_{i=0}^{N_1} b_{1i}z_1^{-i}\sum_{j=0}^{M_1} b_{2i}z_2^{-j}} \end{aligned} \tag{92.6}$$

and the separable denominator, nonseparable numerator transfer function given by

$$H(z_1,z_2)=\frac{\sum_{i=0}^{N_2}\sum_{j=0}^{M_2} a_{ij}z_1^{-i}z_2^{-j}}{\sum_{i=0}^{N_1} b_{1i}z_1^{-i}\sum_{j=0}^{M_1} b_{2j}z_2^{-j}} \tag{92.7}$$

The stability constraints for the above two transfer functions are the same as those for the individual two 1-D cases. These are easy to check and correspondingly the transfer function is easy to stabilize if the designed filter is found to be unstable. Therefore, in the design of the above two classes, in order to reduce the stability problem to that of the 1-D case, the denominator of the 2-D transfer function is chosen to have two 1-D polynomials in z_1 and z_2 variables in cascade. However, in the general formulation of nonseparable numerator and denominator filters, this oversimplification is removed. The filters of this type are generally designed either through transformation of 1-D filters, or through optimization approaches, as is discussed in the following.

92.2 Transformation Techniques

Analog Filter Transformations

In the design of 1-D analog filters, a group of analog filter transformations of the form $s = g(s')$ is usually applied to normalized continuous low-pass transfer functions like those obtained by using the Bessel, Butterworth, Chebyshev, and elliptic approximations. These transformations can be used to design low-pass, high-pass, bandpass, or bandstop filters satisfying piecewise-constant amplitude response specifications. Through the application of the bilinear transformation, corresponding 1-D digital filters can be designed, and since 2-D digital filters can be designed in terms of 1-D filters, these transformations are of considerable importance in the design of 2-D digital filters as well. In the 2-D cases, the transformations have a form of

© 2003 by CRC Press LLC

$$s = g(s_1, s_2) \tag{92.8}$$

As a preamble, in this subsection two groups of transformations of interest in the design of 2-D digital filters are introduced, which essentially produce 2-D continuous transfer functions from 1-D ones.

Rotated Filter

The first group of transformations, suggested by Shanks, Treitel, and Justice [1], are of the form

$$g_1(s_1, s_2) = -s_1 \sin\beta + s_2 \cos\beta \tag{92.9a}$$

$$g_2(s_1, s_2) = s_1 \cos\beta + s_2 \sin\beta \tag{92.9b}$$

They map 1-D into 2-D filters with arbitrary directionality in a 2-D frequency response plane. These filters are called rotated filters because they are obtained by rotating 1-D filters.

If $H(s)$ is a 1-D continuous transfer function, then a corresponding 2-D continuous transfer function can be generated as

$$H_{D1}(s_1, s_2) = H(s)\Big|_{s = g_1(s_1, s_2)} \tag{92.10a}$$

$$H_{D2}(s_1, s_2) = H(s)\Big|_{s = g_2(s_1, s_2)} \tag{92.10b}$$

by replacing the s in $H(s)$ with $g_1(s_1, s_2)$ and $g_2(s_1, s_2)$, respectively.

It is easy to show [2] that a transformation of $g_1(s_1, s_2)$ or $g_2(s_1, s_2)$ will give rise to a contour in the amplitude response of the 2-D analog filter that is a straight line rotated by an angle β with respect to the s_1 or s_2 axis, respectively. Figure 92.1 illustrates an example of 1-D to 2-D analog transformation by (92.10a) for $\beta = 0°$ and $\beta = 45°$.

The rotated filters are of special importance in the design of circularly symmetric filters, as will be discussed in Section 92.4.

Transformation Using a Two-Variable Reactance Function

The second group of transformations is based on the use of a two-variable reactance function. One of the transformations was suggested by Ahmadi, Constantinides, and King [3], [4]. This is given by

$$g_3(s_1, s_2) = \frac{a_1 s_1 + a_2 s_2}{1 + b s_1 s_2} \tag{92.11}$$

where a_1, a_2, and b are all positive constants.

Let us consider a 2-D filter designed by using a 1-D analog low-pass filter with cutoff frequency Ω_c. Equation (92.11) results in

$$\Omega_2 = \frac{\Omega_c - a_1 \Omega_1}{a_2 - b \Omega_c \Omega_1} \tag{92.12}$$

The mapping of $\Omega = \Omega_c$ onto the (Ω_1, Ω_2) plane for various values of b is depicted in Fig. 92.2 [5]. The cutoff frequencies along the Ω_1 and Ω_2 axes can be adjusted by simply varying a_1 and a_2. On the other hand, the convexity of the boundary can be adjusted by varying b. We note that b must be greater than zero to preserve stability. Also, it should be noted that $g_3(s_1, s_2)$ becomes a low-pass to bandpass transformation along $s_1 = s_2$, and therefore the designed filter will behave like a bandstop filter along $\Omega_1 = \Omega_2$. This problem can be overcome by using a guard filter of any order.

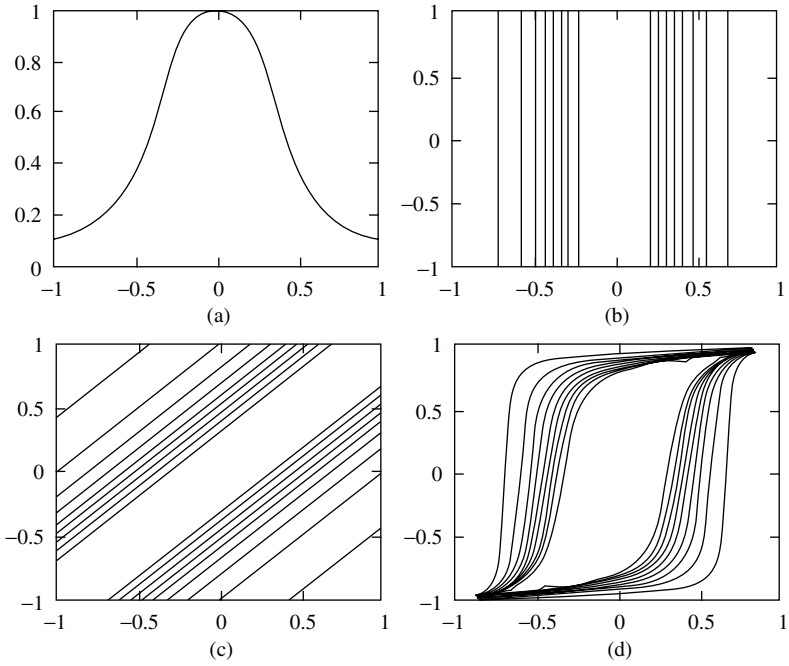

FIGURE 92.1 1-D to 2-D analog filter transformation. (a) Amplitude response of 1-D analog filter. (b) Contour plot of 2-D filter, $\beta = 0°$. (c) Contour plot of 2-D filter, $\beta = 45°$. (d) Contour plot of 2-D filter, $\beta = 45°$, after applying double bilinear transformation.

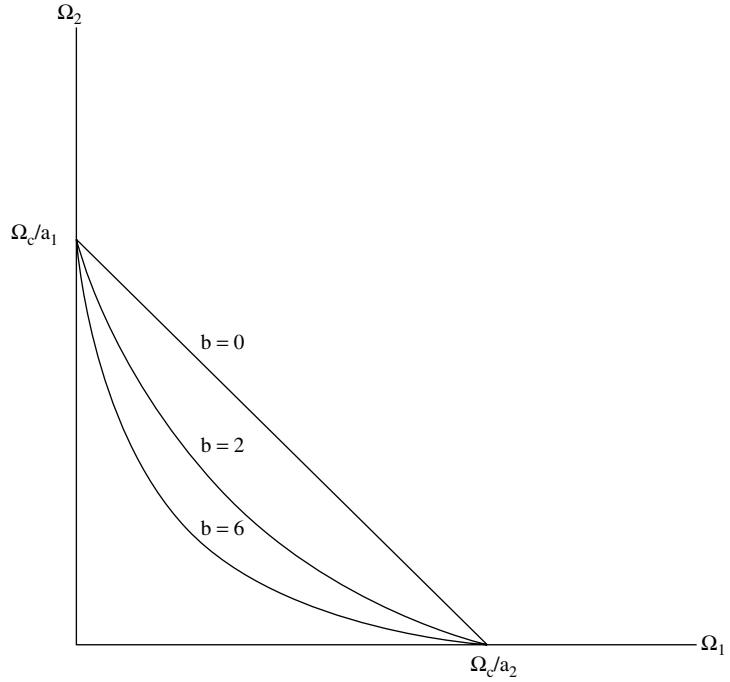

FIGURE 92.2 Plot of (92.12) for different values of *b*.

© 2003 by CRC Press LLC

King and Kayran [6] have extended the above technique by using a higher order reactance function of the form

$$g_4(s_1, s_2) = \frac{a_1 s_1 + a_2 s_2}{1 + b_1\left(s_1^2 + s_2^2\right) + b_2 s_1 s_2} \tag{92.13}$$

and they proved that the stability of $g_4(s_1, s_2)$ is ensured if

$$b_1 > 0 \tag{92.14}$$

and

$$b_1 > \frac{b_2^2}{4} - b_1^2 > 0 \tag{92.15}$$

However, it is necessary as earlier to include a guard filter, which may have the simple form of

$$G(z_1, z_2) = \frac{(1 + z_1)(1 + z_2)}{(d_1 + z_1)(d_2 + z_2)} \tag{92.16}$$

in order to remove the high-pass regions along all radii except the coordinate axes.

Then, through an optimization procedure, the coefficients of $g_4(s_1, s_2)$ and $G(z_1, z_2)$ are calculated subject to the constraints of (92.14) and (92.15), so that the cutoff frequency of the 1-D filter is mapped into a desired cutoff boundary in the (Ω_1, Ω_2) plane.

Spectral Transformations

Spectral transformation is another kind of important transformation in the design of both 1-D and 2-D IIR filters. In this subsection, three groups of spectral transformations are discussed. Among them, the linear transformations map frequency axes onto frequency axes in the (Ω_1, Ω_2) plane, the complex transformation is of wide applications to the design of fan filters, and the Constantinides transformations transform a discrete function into another discrete function and through which any transformation of a low-pass filter to another low-pass, high-pass, bandpass or bandstop filter becomes possible.

Linear Transformations

Consider a group of linear transformations that map frequency axes onto themselves in the (Ω_1, Ω_2) plane. There are eight possible such transformations [7], [8] and they have the algebraic structure of a finite group under the operation of multiplication [2]; each transformation can be expressed as

$$\begin{bmatrix} \omega_1 \\ \omega_2 \end{bmatrix} := D(T) \begin{bmatrix} \omega_1 \\ \omega_2 \end{bmatrix} \tag{92.17}$$

where $D(T)$ is a 2×2 unitary matrix representing transformation T_δ. The eight transformations and their effect on the frequency response of the digital filter are as follows with a multiplication table being illustrated in Table 92.1 [2].

1. Identity (I):

$$D(I) = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}.$$

© 2003 by CRC Press LLC

2. Reflection about the ω_1 axis ($\rho_{\omega 1}$):

$$D(\rho_{\omega 1}) = \begin{bmatrix} 1 & 0 \\ 0 & -1 \end{bmatrix}$$

3. Reflection about the ω_2 axis ($\rho_{\omega 2}$):

$$D(\rho_{\omega 2}) = \begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix}$$

4. Reflection about the ($\rho_{\psi 1}$):

$$D(\rho_{\psi 1}) = \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix}$$

5. Reflection about the ($\rho_{\psi 2}$):

$$D(\rho_{\psi 2}) = \begin{bmatrix} 0 & -1 \\ -1 & 0 \end{bmatrix}$$

6. Counterclockwise rotation by 90° (R_4):

$$D(R_4) = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}$$

7. Counterclockwise rotation by 180° (R_4^2):

$$D(R_4^2) = \begin{bmatrix} -1 & 0 \\ 0 & -1 \end{bmatrix}$$

8. Counterclockwise rotation by 270° (R_4^3):

$$D(R_4^3) = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}$$

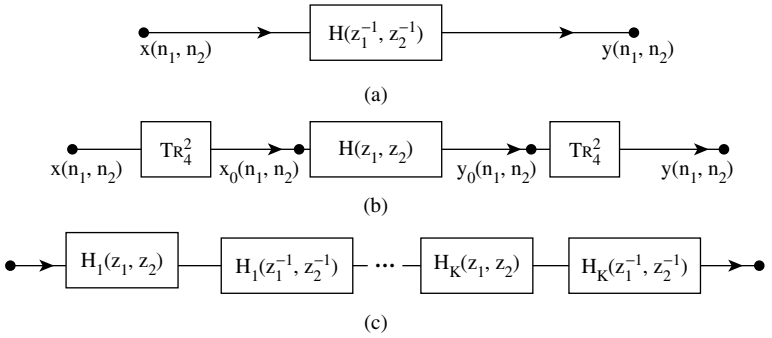

FIGURE 92.3 Design of zero-phase filters: (a) noncausal filter, (b) equivalent causal implementation, (c) cascade zero-phase filter.

In the above symbolic representation, ψ_1 and ψ_2 represent axes that are rotated by 45° in the counterclockwise sense relative to the ω_1 and ω_2 axes, respectively, and R_k denotes rotation by 360°/k in the counterclockwise sense. These transformations could equivalently be defined in the (z_1, z_2) domain by complex conjugating and/or interchanging the complex variables z_1 and z_2 in the filter transfer function.

An important property of the group is that each transformation distributes over a product of functions of ω_1 and ω_2, that is,

$$T_\delta\left[\prod_{i=1}^{K} F_i\left(\omega_1,\omega_2\right)\right] = \prod_{i=1}^{K} T_\delta\left[F_i\left(\omega_1,\omega_2\right)\right] \tag{92.18}$$

where T_δ represents any of the eight transformation operators. The validity of this property follows the definition of the transformations [8].

In the (z_1, z_2) domain, if $H(z_1, z_2)$ represents a causal filter with impulse response $h(n_1, n_2)$, then the filter represented by $H(z_1^{-1}, z_2^{-1})$ will have an impulse response $h(-n_1, -n_2)$, and is therefore, noncausal, since $h(-n_1, -n_2) \neq 0$ for $n_1 < 0$, $n_2 < 0$. Such a filter can be implemented in terms of causal transfer function $H(z_1, z_2)$, i.e., by rotating the n_1 and n_2 axes of the input signal by 180°, processing the rotated signal by the causal filter, and then rotating the axes of the output signal by 180°, as illustrated in Fig. 92.3(b).

Noncausal filters can be used for the realization of zero-phase filters by cascading K pairs of filters whose transfer functions are $H_i(z_1, z_2)$ and $H(z_1^{-1}, z_2^{-1})$ for $i = 1, 2, \ldots, K$, as depicted in Fig. 92.3(c).

Complex Transformation and 2-D Fan Filters

Complex Transformation. A complex transformation is of the form [9]

$$z = e^{\phi} z_1^{\alpha_1/\beta_1} z_2^{\alpha_2/\beta_1} \tag{92.19}$$

by which a 2-D filter $H(z_1, z_2)$ can be derived from 1-D filter $H_1(z)$. The corresponding frequency transformation of (92.19) is

$$\exp\left(j\omega\right) \rightarrow \exp\left\{j\left(\phi + \omega_1 \frac{\alpha_1}{\beta_1} + \omega_2 \frac{\alpha_2}{\beta_2}\right)\right\} \tag{92.20}$$

or

$$\omega \rightarrow \phi + \omega_1 \frac{\alpha_1}{\beta_1} + \omega_2 \frac{\alpha_2}{\beta_2} \tag{92.21}$$

© 2003 by CRC Press LLC

There are three major effects of transformation (92.20) on the resulting filter:

1. Frequency shifting along the ω_1 axis. The frequency response of the resulting filter will be shifted by ϕ along the ω_1 axis.
2. Rotation of the frequency response. The angle of rotation is

$$\theta = \arctan\left(\frac{\alpha_2}{\beta_2}\right) \tag{92.22}$$

   Since the original filter is 1-D and a function of z_1, the angle of rotation will be defined by the fractional power of z_2.
3. Scaling the frequency response along the ω_1 axis. The fractional power of z_1 will scale the frequency response by a factor β_1/α_1. However, the periodicity of the frequency response will be $(\alpha_1/\beta_1)2\pi$ instead of 2π. Other effects may also be specified [9].

   The complex transformation is of importance in the design of fan filters. By using a prototype lowpass filter with a cutoff frequency at $\omega_c = \pi/2$, and the transformation (92.19), one obtains the shifted, scaled, and rotated characteristics in the frequency domain. We denote the transformed filter by

$$H\left(z_1, z_2; \frac{\alpha_1}{\beta_1}, \frac{\alpha_2}{\beta_2}\right) = H_1(z)\Big|_{z = e^{\phi} z_1^{\alpha_1/\beta_1} z_2^{\alpha_2/\beta_2}} \tag{92.23}$$

   In general, the filter coefficients in function H will be complex and the variables z_1 and z_2 will have rational noninteger powers. However, appropriate combinations of transformed filters will remove both of these difficulties, as will be shown in the following.

Symmetric Fan Filters. An ideal symmetric fan filter has the specification of

$$H_{f1}\left(e^{j\omega_1 T}, e^{j\omega_2 T}\right) = \begin{cases} 1 & \text{for } |\omega_1| \geq |\omega_2| \\ 0 & \text{otherwise} \end{cases} \tag{92.24}$$

We introduce transfer function $\hat{H}_1(z_1, z_2)$, $\hat{H}_2(z_1, z_2)$, $\hat{H}_3(z_1, z_2)$, and $\hat{H}_4(z_1, z_2)$, of four filters generated by (92.23) with $(\alpha_1/\beta_1, \alpha_1/\beta_2) = (1/2, 1/2)$ $(-1/2, 1/2)$, $(1/2, -1/2)$, and $(-1/2, -1/2)$, respectively, and $\phi = \pi/2$. The responses of the transformed filters, $\hat{H}_i(z_1, z_2)$, $i = 1, 2, 3, 4$, can be found in Fig. 92.4 together with the prototype filter.

In this design procedure, the filters in Fig. 92.4 will be used as the basic building blocks for a fan filter specified by (92.24). One can construct the following filter characteristics:

$$\begin{aligned} G_{11}(z_1, z_2) = {} & \hat{H}_1(z_1, z_2)\hat{H}_1^*\left(z_1^{-1}, z_2^{-1}\right)\hat{H}_2(z_1, z_2)\hat{H}_2^*\left(z_1^{-1}, z_2^{-1}\right) \\ & + \hat{H}_3(z_1, z_2)\hat{H}_3^*\left(z_1^{-1}, z_2^{-1}\right)\hat{H}_4(z_1, z_2)\hat{H}_4^*\left(z_1^{-1}, z_2^{-1}\right) \end{aligned} \tag{92.25a}$$

$$\begin{aligned} G_{22}(z_1, z_2) = {} & \hat{H}_1(z_1, z_2)\hat{H}_1^*\left(z_1^{-1}, z_2^{-1}\right)\hat{H}_3(z_1, z_2)\hat{H}_3^*\left(z_1^{-1}, z_2^{-1}\right) \\ & + \hat{H}_2(z_1, z_2)\hat{H}_2^*\left(z_1^{-1}, z_2^{-1}\right)\hat{H}_4(z_1, z_2)\hat{H}_4^*\left(z_1^{-1}, z_2^{-1}\right) \end{aligned} \tag{92.25b}$$

which are shown in Fig. 92.5.

© 2003 by CRC Press LLC

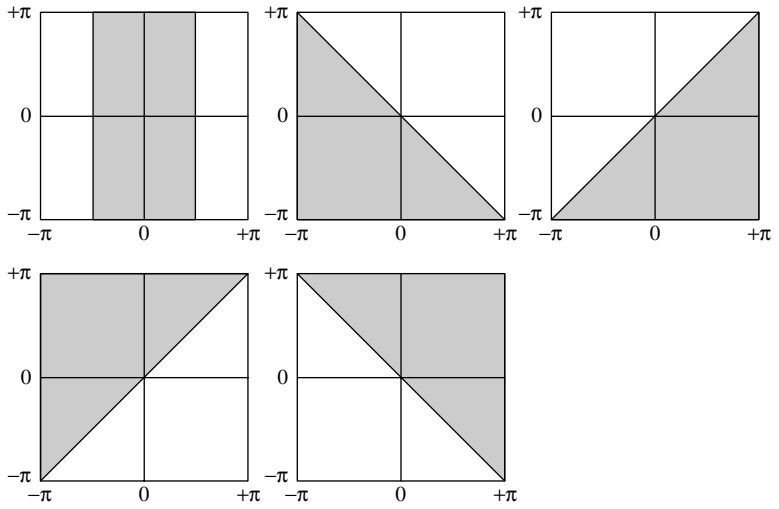

FIGURE 92.4 Basic building blocks of symmetric fan filters.

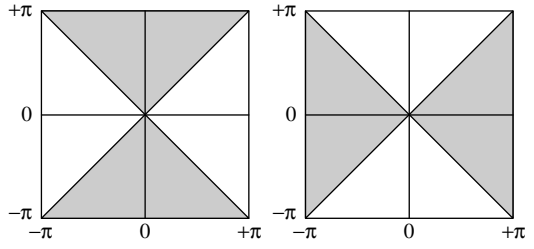

FIGURE 92.5 Amplitude characteristics of $G_{11}(z_1, z_2)$ and $G_{22}(z_1, z_2)$.

Quadrant Fan Filters. The frequency characteristic of a quadrant fan filter is specified as

$$H_{f2}\left(e^{j\omega_1 T}, e^{j\omega_2 T}\right) = \begin{cases} 1 & \text{for } \omega_1\omega_2 \geq 0 \\ 0 & \text{otherwise} \end{cases} \tag{92.26}$$

We consider the same ideal prototype filter. Then the transformed filters $\hat{H}_{14}(z_1, z_2)$, $\hat{H}_{12}(z_1, z_2)$, $\hat{H}_{23}(z_1, z_2)$, and $\hat{H}_{34}(z_1, z_2)$, are obtained via (92.23) with $(\alpha_1/\beta_1, \alpha_2/\beta_2)$ equal to (1, 0), (0, 1), (–1, 0), and (0, –1), respectively, and $\phi = \pi/2$. The subscripts on $\hat{H}$ refer to quadrants to which the low-pass filter characteristics have been shifted. Figure 92.6 illustrates the amplitude responses of these transformed filters together with the prototype.

The filters in Fig. 92.6 will be used as the basic building blocks for fan filters specified by (92.26). In a similar manner to (92.25a) and (92.25b), the filter characteristics $G_{13}(z_1, z_2)$ and $G_{23}(z_1, z_2)$ can be constructed as follows:

$$\begin{aligned} G_{13}(z_1, z_2) = {} & \hat{H}_{12}(z_1, z_2)\hat{H}^*_{12}\left(z_1^{-1}, z_2^{-1}\right)\hat{H}_{14}(z_1, z_2)\hat{H}^*_{14}\left(z_1^{-1}, z_2^{-1}\right) \\ & + \hat{H}_{23}(z_1, z_2)\hat{H}^*_{23}\left(z_1^{-1}, z_2^{-1}\right)\hat{H}_{34}(z_1, z_2)\hat{H}^*_{34}\left(z_1^{-1}, z_2^{-1}\right) \end{aligned} \tag{92.27a}$$

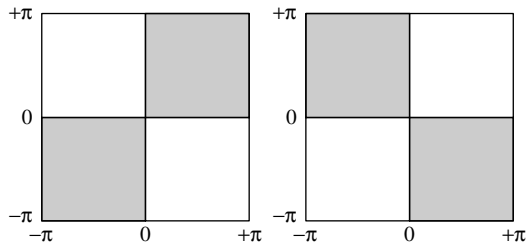

FIGURE 92.7 Two quadrant pass filters.

$$G_{24}(z_1, z_2) = \hat{H}_{12}(z_1, z_2)\hat{H}^*_{12}(z_1^{-1}, z_2^{-1})\hat{H}_{23}(z_1, z_2)\hat{H}^*_{23}(z_1^{-1}, z_2^{-1}) + \hat{H}_{14}(z_1, z_2)\hat{H}^*_{14}(z_1^{-1}, z_2^{-1})\hat{H}_{34}(z_1, z_2)\hat{H}^*_{34}(z_1^{-1}, z_2^{-1}) \tag{92.27b}$$

whose amplitude responses are depicted in Fig. 92.7.

Constantinides Transformations

The so-called Constantinides [10], [19] are of importance in the design of 1-D digital filters, and are of the form

$$z = f(\bar{z}) = e^{jl\pi}\prod_{t=1}^{m}\frac{\bar{z} - a_t^*}{1 - a_t\bar{z}} \tag{92.28}$$

where l and m are integers and a_t^* is the complex conjugate of a_t.

Pendergrass, Mitra, and Jury [11] showed that, in the decision of 2-D IIR filters, this group of transformations is as useful as in 1-D cases. By choosing the parameters l, m, and a_t in (92.28) properly, a set of four specific transformations can be obtained that can be used to transform a low-pass transfer function into a corresponding low-pass, high-pass, bandpass, or a bandstop transfer function. These transformations are summarized in Table 92.2, where subscript i is included to facilitate the application of the transformation to 2-D discrete transfer functions.

© 2003 by CRC Press LLC

Let Ω_i and ω_i for $i = 1, 2$ be the frequency variables in the original and transformed transfer function, respectively. Suppose $H_L(z_1, z_2)$ is a low-pass transfer function with respect to z_i, if each of z_1 and z_2 is transformed to be low-pass, bandpass, or high-pass, then a number of different 2-D filter combinations can be achieved. As an example, some of the possible amplitude responses are illustrated in Fig. 92.8(a)–(f) [2].

92.3 Design of Separable Product Filters

A 2-D IIR filter is characterized by a separable product transfer function of the form

$$H(z_1, z_2) = H_1(z_1)H_2(z_2) \tag{92.29}$$

if its passband or stopband is of the shape of a rectangular domain. The design of such a class of filters can be accomplished by using the method proposed by Hirano and Aggarwal [12]. The method can be used to design filters with quadrantal or half-plane symmetry.

Design of Quadrantally Symmetric Filters

A 2-D filter is said to be quadrantally symmetric if its amplitude response satisfies the equality

$$\left|H(z_1, z_2)\right| = \left|H(z_1^*, z_2^*)\right| = \left|H(z_1^*, z_2)\right| = \left|H(z_1, z_2^*)\right| \tag{92.30}$$

Consider two 1-D bandpass filters specified by two transfer functions $H_1(z)$ and $H_2(z)$, respectively, and let $z = z_1$ in the first one and $z = z_2$ in the second. If their frequency responses can be expressed by

$$\left|H_1(e^{j\omega_1 T_1})\right| = \begin{cases} 1 & \omega_{12} \le \omega_1 < \omega_{13} \\ 0 & 0 \le \omega_1 < \omega_{11} \text{ or } \omega_{14} \le \omega_1 < \infty \end{cases} \tag{92.31a}$$

and

$$\left|H_2(e^{j\omega_2 T_2})\right| = \begin{cases} 1 & \omega_{22} \le \omega_2 < \omega_{23} \\ 0 & 0 \le \omega_2 < \omega_{21} \text{ or } \omega_{24} \le \omega_2 \le \infty \end{cases} \tag{92.31b}$$

respectively, and since

$$\left|H(e^{j\omega_1 T_1}, e^{j\omega_2 T_2})\right| = \left|H_1(e^{j\omega_1 T_1})\right|\left|H_2(e^{j\omega_2 T_2})\right|$$

Equations (92.31a) and (92.31b) give

$$\left|H(e^{j\omega_1 T_1}, e^{j\omega_2 T_2})\right| = \begin{cases} 1 & \omega_{12} \le \omega_1 < \omega_{13} \text{ and } \omega_{22} \le \omega_2 < \omega_{23} \\ 0 & \text{otherwise} \end{cases}$$

Evidently, the 2-D filter obtained will pass frequency components that are in both passband of $H_1(z_1)$ and $H_2(z_2)$; that is, the passband $H_1(z_1, z_2)$ will be a rectangle with sides $\omega_{13} - \omega_{12}$ and $\omega_{23} - \omega_{22}$. On the other hand, frequency components that are in the stopband of either the first filter or the second filter will be rejected. Hence, the stopband of $H(z_1, z_2)$ consists of the domain obtained by combining the stopbands of the two filters.

By a similar method, if each of the two filters is allowed to be a low-pass, bandpass, or high-pass 1-D filter, then nine different rectangular passbands can be achieved, as illustrated in Fig. 92.9. The cascade arrangement of any two of those filters may be referred to as a generalized bandpass filter [12].

Another typical simple characteristic is specified by giving the rectangular stopband region, which is referred to as the rectangular stop filter. Also, there are nine possible types of such a filter which are complementary to that of the generalized bandpass filter shown in Fig. 92.9 (i.e., considering the shadowed region as the stopband). This kind of bandstop filter can be realized in the form of

© 2003 by CRC Press LLC

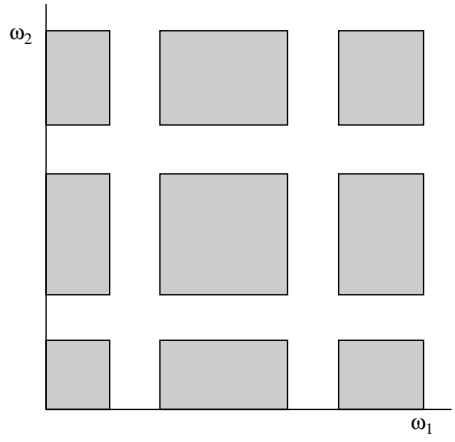

FIGURE 92.9 Idealized amplitude response of generalized bandpass filter.

$$H(z_1, z_2) = H_A(z_1)H_A(z_2) - e^{jk\pi}\left[H_1(z_1)H_2(z_2)\right]^2 \tag{92.32}$$

where $H_1(z_1)H_2(z_2)$ is a generalized bandpass filter described above, and $H_A(z_1)$ and $H_A(z_2)$ are allpass 1-D filters [13] whose poles are poles of $H_1(z_1)$ and $H_2(z_2)$, respectively. Equation (92.32) can be referred to as a generalized bandstop filter.

Extending the principles discussed above, if a 2-D filter is constructed by cascading K 2-D filters with passbands P_i, stopbands S_i, and transfer function $H_i(z_1, z_2)$, the overall transfer function is obtained as

$$H(z_1, z_2) = \prod_{i=1}^{k} H_i(z_i, z_2)$$

and the passband P and stopband S of the cascaded 2-D filter are defined by

$$P = \bigcap P_i \quad \text{and} \quad S = \bigcup_{i=1}^{K} S_i$$

that is, the only frequency components not to be rejected will be those that will be passed by each and every filter in the cascade arrangement.

On the other hand, if a 2-D filter is constructed by connecting K 2-D filters in parallel, then

$$H(z_1, z_2) = \sum_{i=1}^{K} H_i(z_1, z_2)$$

Assuming that all the parallel filters have the same phase shift, and the passband $P_i = 1$ of the various filters are not overlapping, then the passband and stopband of the parallel arrangement is given by

$$P = \bigcup_{i=1}^{K} P_i \quad \text{and} \quad S = \bigcap S_i$$

Parallel IIR filters are more difficult to design than cascade ones, due to the requirement that the phase shifts of the various parallel filters be equal. However, if all the data to be filtered are available at the start of the processing, zero-phase filters can be used.

By combining parallel and cascade subfilters, 2-D IIR filters whose passbands or stopbands are combinations of rectangular regions can be designed, as illustrated by the following example.

© 2003 by CRC Press LLC

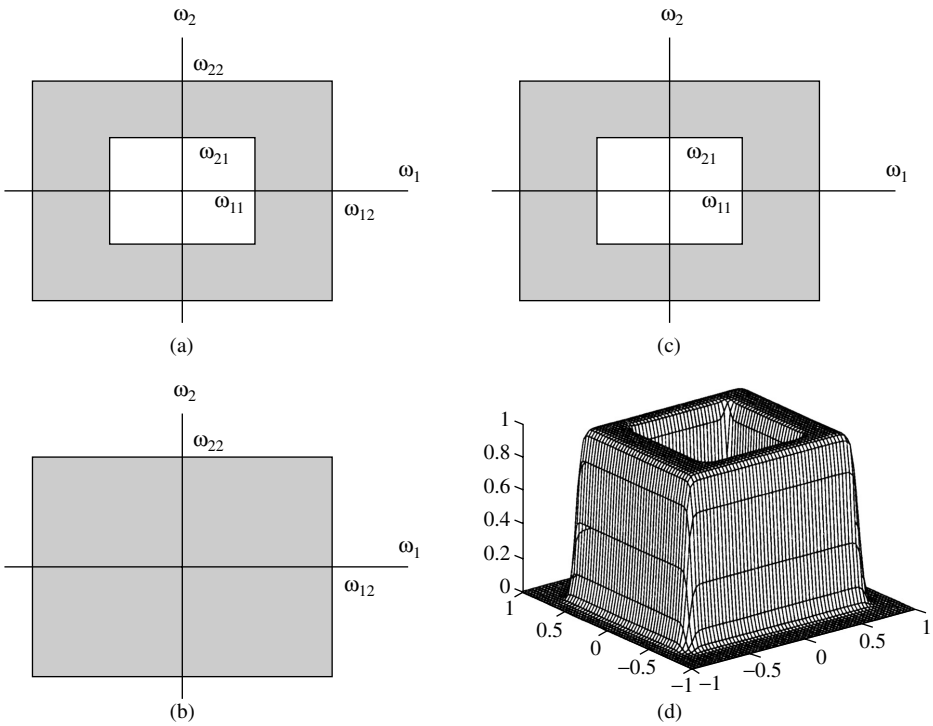

FIGURE 92.10 Amplitude response for the filter of Example 1: (a) specified response; (b) response of the 2-D low-pass filter; (c) response of the 2-D high-pass filter; (d) 3-D plot of the amplitude response of a real 2-D IIR filter.

Example 1. Design a 2-D IIR filter whose passband is the area between two overlapping rectangles, as depicted in Fig. 92.10(a).

Solution.

1. Construct a first 2-D low-pass filter with rectangular passband (ω_{12}, ω_{22}) by using 1-D low-pass filters, as shown in Fig. 92.10(a).
2. Construct a second 2-D low-pass filter with rectangular passband (ω_{11}, ω_{21}) by 1-D low-pass filters. Then using (92.32) to construct a 2-D high-pass filter with rectangular stopband (ω_{11}, ω_{21}), as shown in Fig. 92.10(c).
3. Cascade the first 2-D low-pass filter with the 2-D high-pass filter to obtain the required filter. The amplitude response of a practically designed 2-D filter is in Fig. 92.10(d).

Design of Half-Plane Symmetric Filters

A 2-D filter is said to be half-plane symmetric if its amplitude response satisfies

$$\left|H\left(z_1, z_2\right)\right| = \left|H\left(z_1^*, z_2^*\right)\right| \tag{92.33}$$

but

$$\left|H\left(z_1, z_2\right)\right| \neq \left|H\left(z_1^*, z_2\right)\right| \neq \left|H\left(z_1, z_2^*\right)\right| \tag{92.34}$$

that is, half-plane symmetry does not imply quadrantal symmetry.

© 2003 by CRC Press LLC

The design of those filters can be accomplished by cascading two quadrant pass filters derived previously in the subsection on complex transformations and 2-D fan filters with quadrantally symmetric filters, as is demonstrated in Example 2.

Example 2. Design a 2-D half-plane symmetric filter whose passband is defined in Fig. 92.11(a).

Solution.

1. Follow the steps 1 to 3 in Example 1 to construct a 2-D bandpass filter with the passband being the area between two overlapping rectangles, as shown in Fig. 92.10(a).
2. Construct a two quadrant (first and third quadrants) pass filter as depicted in Fig. 92.7(a).
3. Cascade the 2-D bandpass filter with the two quadrant pass filters to obtain the required filter.

The amplitude response of a practically designed filter is shown in Fig. 92.11(b).

Design of Filters Satisfying Prescribed Specifications

The problem of designing filters that satisfy prescribed specifications to a large extent has been solved for the case of 1-D filters, and by extending the available methods, 2-D IIR filters satisfying prescribed specifications can also be designed.

Assume that we are to design a 2-D low-pass filter with the following specification:

$$\left|H(\omega_1, \omega_2)\right| = \begin{cases} 1 \pm \Delta p & \text{for } 0 \le |\omega_i| \le \omega_{pi} \\ \Delta a & \text{for } \omega_{ai} \le |\omega_i| \le \omega_{si}/2, \qquad i = 1, 2 \end{cases} \tag{92.35}$$

where ω_{pi} and ω_{ai}, $i = 1, 2$ are passband and stopband edges along the ω_1 and ω_2 axes, respectively. The two 1-D filters that are cascaded to form a 2-D one are specified by ω_{pi}, ω_{ai}, δ_{pi} and δ_{ai} ($i = 1, 2$) as the passband edge, stopband edge, passband ripple, and stopband loss, respectively. From (92.29) we have

$$\max\left\{M(\omega_1,\omega_2)\right\} = \max\left\{M_1(\omega_1)\right\}\max\left\{M_2(\omega_2)\right\}$$

and

$$\min\left\{M(\omega_1,\omega_2)\right\} = \min\left\{M_1(\omega_1)\right\}\min\left\{M_2(\omega_2)\right\}$$

Hence the derived 2-D filter will satisfy the specifications of (92.35) if the following constraints are satisfied

$$(1+\delta_{p1})(1+\delta_{p2}) \le 1+\Delta p \tag{92.36}$$

$$(1-\delta_{p1})(1-\delta_{p2}) \ge 1-\Delta p \tag{92.37}$$

$$(1+\delta_{p1})\delta_{a2} \le \Delta a \tag{92.38}$$

$$(1+\delta_{p2})\delta_{a1} \le \Delta a \tag{92.39}$$

$$\delta_{a1}\delta_{a2} \le \Delta a \tag{92.40}$$

Constraints (92.36) and (92.37) can be expressed respectively in the alternative form

$$\delta_{p1} + \delta_{p2} + \delta_{p1}\delta_{p2} \le \Delta p \tag{92.41}$$

and

$$\delta_{p1} + \delta_{p2} - \delta_{p1}\delta_{p2} \le \Delta p \tag{92.42}$$

Hence if (92.41) is satisfied, (92.42) is also satisfied. Similarly, constraints (92.38)–(92.40) will be satisfied if

$$\max\left\{(1+\delta_{p1})\delta_{a2}, (1+\delta_{p2})\delta_{a1}\right\} \le \Delta a \tag{92.43}$$

since $(1 + \delta_{p1}) \gg \delta_{a1}$ and $(1 + \delta_{p2}) \gg \delta_{a2}$. Now if we assume that $\delta_{p1} = \delta_{p2} = \delta_p$ and $\delta_{a1} = \delta_{a2} = \delta_a$, then we can assign

© 2003 by CRC Press LLC

$$\delta_p = (1+\Delta p)^{1/2} - 1 \tag{92.44}$$

and

$$\delta_a = \frac{\Delta a}{(1+\Delta p)^{1/2}} \tag{92.45}$$

so as to satisfy constraints (92.36)–(92.40). And since $\Delta_p \ll 1$, we have

$$\delta_p \approx \frac{\Delta p}{2} \tag{92.46}$$

$$\delta_a \approx \Delta a \tag{92.47}$$

Consequently, if the maximum allowable passband and stopband errors Δp and Δa are specified, the maximum passband ripple A_p and the maximum stopband attenuation A_a and dB for the two 1-D filters can be determined as

$$A_p = 20\log\frac{1}{1-\delta_p} = 20\log\frac{2}{2-\Delta p} \tag{92.48}$$

and

$$A_a = 20\log\frac{1}{\delta_p} = 20\log\frac{1}{\Delta a} \tag{92.49}$$

Finally, if the passband and stopband edges ω_{pi} and ω_{ai} are also specified, the minimum order and the transfer function of each of the two 1-D filters can readily be obtained using any of the approaches of the previous subsections. Similar treatments for bandpass, bandstop, and high-pass filters can be carried out.

Example 3 [12]. Design a zero-phase filter whose amplitude response is specified in Fig. 92.12(a), with A_P = 3dB, A_a = 20 dB.

Solution.

1. Decomposition: Because there are no contiguous passbands between the characteristics of the first and third quadrants and that of the second and fourth quadrants, in the first step of design, the required 2-D filter can be decomposed into two subfilters $H_{13}(z_1, z_2)$ and $H_{24}(z_1, z_2)$, which represent the characteristics of the first and third quadrants and that of the second and fourth quadrants, respectively. By connecting $H_{13}(z_1, z_2)$ and $H_{24}(z_1, z_2)$, in parallel, the required characteristics of the 2-D filter specified in Fig. 92.12(a) can then be realized.

$$H(z_1, z_2) = H_{13}(z_1, z_2) + H_{24}(z_1, z_2)$$

   i. Decomposition of $H_{13}(z_1, z_2)$: To accomplish the design of $H_{13}(z_1, z_2)$, further decompositions should be made. The characteristics of the first and third quadrants can be realized by cascading three subfilters, i.e., a two quadrant filter $G_{13}(z_1, z_2)$ [as shown in Fig. 92.7(a)], a low-pass filter $H_L(z_1, z_2)$ [as shown in Fig. 92.12(b)], and a rectangular stop filter $H_s(z_1, z_2)$ [as shown in Fig. 92.12(c)],

$$H_{13}(z_1, z_2) = G_{13}(z_1, z_2) H_L(z_1, z_2) H_S(z_1, z_2)$$

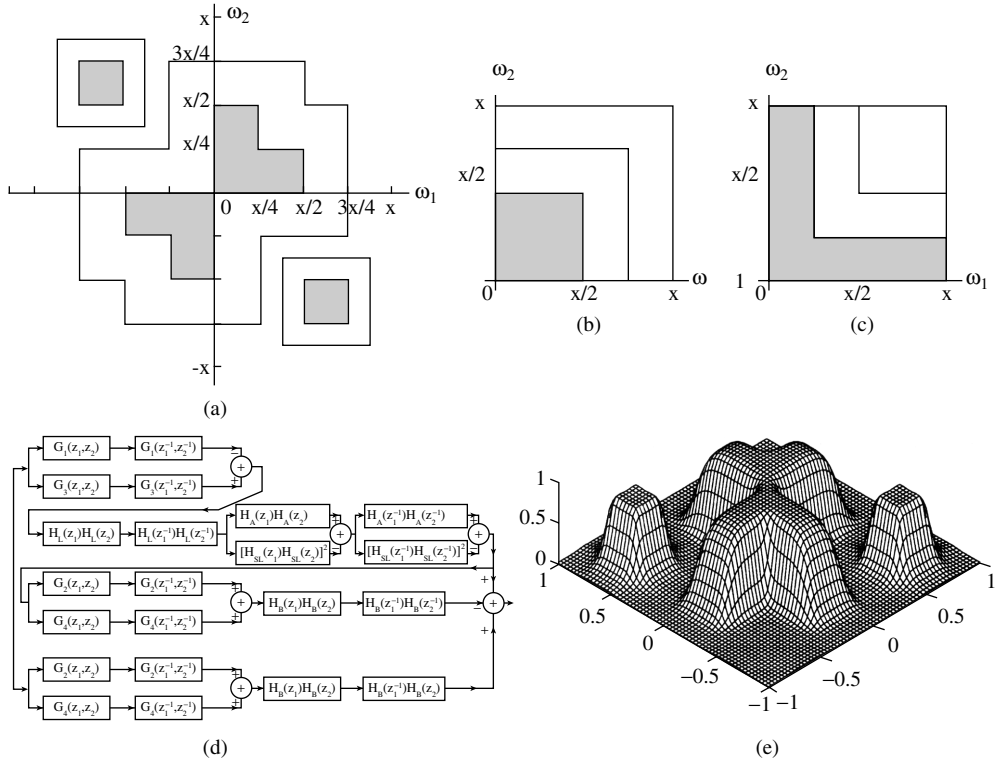

FIGURE 92.12 Amplitude responses of the filters in Example 3: (a) the given characteristics; (b) rectangular pass subfilter; (c) rectangular step subfilter; (d) final configuration of the 2-D filter; (e) 3-D plot of the ampitude response of the resulting 2-D filter.

furthermore, the rectangular stop filter $H_S(z_1, z_2)$ can be designed by allpass filter $H_A(z_1, z_2)$ and low-pass filter $H_{SL}(z_1, z_2)$, using (92.32)

$$H_S(z_1, z_2) = H_A(z_1, z_2) - \left[H_{SL}(z_1, z_2)\right]^2$$

ii. Decomposition of $H_{24}(z_1, z_2)$: Similarly, $H_{24}(z_1, z_2)$ can be decomposed into the cascade of a two quadrant filter $G_{24}(z_1, z_2)$ [as is shown in Fig. 92.7(b)], and a bandpass filter $H_B(z_1, z_2)$ which can be realized by using two 1-D bandpass filters for both directions.

$$H_{24}(z_1, z_2) = G_{24}(z_1, z_2) H_B(z_1, z_2)$$

The final configuration of the desired filter $H(z_1, z_2)$ is illustrated in Fig. 92.12(d), with the final transfer function being of the form

$$H(z_1, z_2) = H_{13}(z_1, z_2) + H_{24}(z_1, z_2) - H_{13}(z_1, z_2) H_{24}(z_1, z_2)$$

where the purpose of the term $H_{13}(z_1, z_2)H_{24}(z_1, z_2)$, is to remove the overlap that may be created by adding $H_{13}(z_1, z_2)$ and $H_{24}(z_1, z_2)$.

2. Design of all the subfilters: At this point, the problem is to derive the two quadrant subfilters $G_{13}(z_1, z_2)$ and $G_{24}(z_1, z_2)$, the low-pass subfilters $H_L(z_1, z_2)$ and $H_{SL}(z_1, z_2)$, the allpass subfilter $H_A(z_1, z_2)$, and the bandstop filter $H_B(z_1, z_2)$.

Note the symmetry of the given characteristics, the identical 1-D sections can be used to develop all the above 2-D subfilters, and the given specifications can easily be combined into the designs of all the 1-D sections.

3. By connecting all the 2-D subfilters in cascade or parallel as specified in Fig. 92.12(d), the required 2-D filter is obtained. The 3-D plot of the amplitude response of the final resulting 2-D filter is depicted in Fig. 92.12(e).

92.4 Design of Circularly Symmetric Filters

Design of LP Filters

As mentioned in the first subsection in Section 92.2, rotated filters can be used to design circularly symmetric filters. Costa and Venetsanopoulos [14] and Goodman [15] proposed two methods of this class, based on transforming an analog transfer function or a discrete one by rotated filter transformation, respectively. The two methods lead to filters that are, theoretically, unstable but by using an alternative transformation suggested by Mendonca et al. [16], this problem can be eliminated.

Design Based on 1-D Analog Transfer Function

Costa and Venetsanopoulos [14] proposed a method to design circularly symmetric filters. In their method, a set of 2-D analog transfer functions is first obtained by applying the rotated filter transformation in (92.9a) for several different values of the rotation angle β to a 1-D analog low-pass transfer function. A set of 2-D discrete low-pass functions are then deduced through the application of the bilinear transformation. The design is completed by cascading the set of 2-D digital filters obtained. The steps involved are as follows.

STEP 1. Obtain a stable 1-D analog low-pass transfer function

$$H_{Al}(s) = \frac{Ns}{Ds} = K_0 \frac{\prod_{i=1}^{M}(s - z_{ai})}{\prod_{i=1}^{N}(s - p_{ai})} \tag{92.50}$$

where z_{ai} and p_{ai} for $i = 1, 2, \ldots$, are the zeros and poles of $H_{A1}(s)$, respectively, and K_0 is a multiplier constant.

STEP 2. Let β_k for $k = 1, 2, \ldots, K$ be a set of rotation angles defined by

$$\beta_k = \begin{cases} \left(\frac{2k-1}{2K} + 1\right)\pi & \text{for even } K \\ \left(\frac{k-1}{K} + 1\right)\pi & \text{for even } K \end{cases} \tag{92.51}$$

STEP 3. Apply the transformation of (92.9a) to obtain a 2-D analog transfer function as

$$H_{A2k}(s_1, s_2) = H_{Al}(s)\Big|_{s=-s_1 \sin\beta_k + s_2 \cos\beta_k} \tag{92.52}$$

for each rotation angle β_k identified in Step 2.

STEP 4. Apply the double bilinear transformation to $H_{A2k}(s_1, s_2)$ to obtain

$$H_{D2k}(z_1, z_2) = H_{A2k}(s_1, s_2)\Big|_{s_i = 2(z_i - 1)/T_i(z_i + 1)} \quad i = 1, 2 \tag{92.53}$$

© 2003 by CRC Press LLC

Assuming that $T_1 = T_2 = T$, (92.50) and (92.53) yield

$$H_{D2k}(z_1, z_2) = K_1 \prod_{i=1}^{M_0} H_{2i}(z_1, z_2) \tag{92.54}$$

where

$$H_{2i}(z_1, z_2) = \frac{a_{11i} + a_{21i} z_1 + a_{12i} z_2 + a_{22i} z_1 z_2}{b_{11i} + b_{21i} z_1 + b_{12i} z_2 + b_{22i} z_1 z_2} \tag{92.55}$$

$$K_1 = K_0 \left(\frac{T}{2}\right)^{N-M} \tag{92.56}$$

$$\begin{aligned}
a_{11i} &= -\cos \beta_k + \sin \beta_k - \frac{Tz_{ai}}{2} \\
a_{21i} &= -\cos \beta_k - \sin \beta_k - \frac{Tz_{ai}}{2} \quad \text{for } 1 \le i \le M \\
a_{12i} &= \cos \beta_k + \sin \beta_k - \frac{Tz_{ai}}{2} \\
a_{22i} &= \cos \beta_k - \sin \beta_k - \frac{Tz_{ai}}{2} \\
a_{11i} &= a_{12i} = a_{21i} = a_{22i} = 1 \quad \text{for } M \le i \le M_0
\end{aligned} \tag{92.57a}$$

$$\begin{aligned}
b_{11i} &= -\cos \beta_k + \sin \beta_k - \frac{Tp_{ai}}{2} \\
b_{21i} &= -\cos \beta_k - \sin \beta_k - \frac{Tp_{ai}}{2} \quad \text{for } 1 \le i \le N \\
b_{12i} &= \cos \beta_k + \sin \beta_k - \frac{Tp_{ai}}{2} \\
b_{22i} &= \cos \beta_k - \sin \beta_k - \frac{Tp_{ai}}{2} \\
b_{11i} &= b_{12i} = b_{21i} = b_{22i} = 1 \quad \text{for } N \le i \le M_0
\end{aligned} \tag{92.57b}$$

and

$$M_0 = \max(M, N)$$

STEP 5. Cascade the filters obtained in Step 4 to yield an overall transfer function

$$H(z_1, z_2) = \prod_{k=1}^{K} H_{D2k}(z_1, z_2)$$

It is easy to find that, at point $(z_1, z_2) = (-1, -1)$, both the numerator and denominator polynomials of $H_{2i}(z_1, z_2)$ assume the value of zero. And thus each $H_{2i}(z_1, z_2)$ has nonessential singularity of the second kind on the unit bicircle

© 2003 by CRC Press LLC

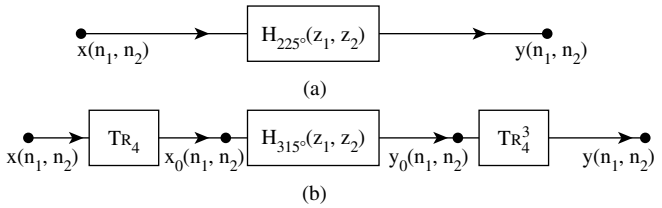

FIGURE 92.13 Realization of subfilter for rotation angle in the range $180° < \beta_k < 270°$.

$$U^2 = \left\{(z_1, z_2): |z_1| = 1, |z_2| = 1\right\}$$

The nonessential singularity of each $H_{2i}(z_1, z_2)$ can be eliminated and, furthermore, each subfilter can be stabilized by letting

$$b'_{12i} = b_{12i} + \varepsilon b_{11i} \tag{92.58a}$$

$$b'_{22i} = b_{22i} + \varepsilon b_{21i} \tag{92.58b}$$

where ε is a small positive constant. With this modification, the denominator polynomial of each $H_{2i}(z_1, z_2)$ is no longer zero and, furthermore, the stability of the subfilter can be guaranteed if

$$\mathrm{Re}\left(p_{ai}\right) < 0 \tag{92.59}$$

and

$$270° < \beta_k < 360° \tag{92.60}$$

As can be seen in (92.51), half of the rotation angles are in the range $180° < \beta_k < 270°$ and according to the preceding stable conditions they yield unstable subfilters. However, the problem can easily be overcome by using rotation angles in the range given by (92.60) and the rotating the transfer function of the subfilter by –90° using linear transformations described in the first subsection in Section 92.2. For example, an effective rotation angle $\beta_k = 225°$ is achieved by rotating the input data by 90°, filtering using a subfilter rotated by 315°, and then rotating the output data by –90°, as shown in Fig. 92.13.

In addition, a 2-D zero-phase filter can be designed by cascading subfilters for rotation angles $\pi + \beta_k$ for $k = 1, 2, \ldots, N$. The resulting transfer function is given by

$$H\left(z_1, z_2\right) = \prod_{k=1}^{K} H_{D2k}\left(z_1, z_2\right) H_{D2k}\left(z_1, z_2\right)$$

where the noncausal sections can be realized as illustrated in Fig. 92.3.

Design Based on 1-D Discrete Transfer Function

The method proposed by Goodman [15] is based on the 1-D discrete transfer function transformation. In the method, a 1-D discrete transfer is first obtained by applying the bilinear transformation to a 1-D analog transfer function. Then, through the application of an allpass transformation that rotates the contours of the amplitude of the 1-D discrete transfer function, a corresponding 2-D transfer function is obtained. The steps involved are as follows.

STEP 1. Obtain a stable 1-D analog low-pass transfer function $H_{A1}(s)$ of the form given by (92.50).

STEP 2. Apply the bilinear transformation to $H_{A1}(s)$ to obtain

$$H_{D1}\left(z\right) = H_{Al}\left(s\right)\Big|_{s=2(z-1)/T(z+1)} \tag{92.61}$$

© 2003 by CRC Press LLC

STEP 3. Let β_k for $k = 1, 2, \ldots, K$ be a set of rotation angles given by (92.51).

STEP 4. Apply the allpass transformation defined by

$$z = f_k(z_1, z_2) = \frac{1 + c_k z_1 + d_k z_2 + e_k z_1 z_2}{e_k + d_k z_1 + c_k z_2 + z_1 z_2} \tag{92.62}$$

where

$$c_k = \frac{1 + \sin\beta_k + \cos\beta_k}{1 - \sin\beta_k + \cos\beta_k} \tag{92.63a}$$

$$d_k = \frac{1 - \sin\beta_k - \cos\beta_k}{1 - \sin\beta_k + \cos\beta_k} \tag{92.63b}$$

$$e_k = \frac{1 + \sin\beta_k - \cos\beta_k}{1 - \sin\beta_k + \cos\beta_k} \tag{92.63c}$$

to obtain the 2-D discrete transfer function

$$H_{D2k}(z_1, z_2) = H_{D1}(z)\Big|_{z=f_k(z_1, z_2)} \tag{92.64}$$

for $k = 1, 2, \ldots, K$. The procedure yields the 2-D transfer function of (92.64), as can be easily demonstrated, and by cascading the rotated subfilters $H_{D2k}(z_1, z_2)$ the design can be completed.

The method of Goodman is equivalent to that of Costa and Venetsanopoulos and consequently, the resulting filter is subject to the same stability problem due to the nonessential singularity of the second kind at point $(z_1, z_2) = (-1, -1)$. To achieve a stable design, Goodman suggested that the transfer function $H_{D2k}(z_1, z_2)$ for $k = 1, 2, \ldots, K$ be obtained directly by minimizing an appropriate objective function subject to the constraints

$$c_k + d_k - e_k \le 1 - \varepsilon$$

$$c_k - d_k + e_k \le 1 - \varepsilon$$

$$-c_k + d_k + e_k \le 1 - \varepsilon$$

$$-c_k - d_k - e_k \le 1 - \varepsilon$$

through an optimization procedure. If ε is a small positive constant, the preceding constraints constitute necessary and sufficient conditions for stability and, therefore, such an approach will yield a stable filter.

Elimination of Nonessential Singularities

To eliminate the nonessential singularities in the preceding two methods, Mendonca et al. [16] suggested a new transformation of the form

$$s = g_5(s_1, s_2) = \frac{\cos\beta_k s_1 + \sin\beta_k s_2}{1 + c s_1 s_2} \tag{92.65}$$

by combining the transformations in (92.9a) and (92.11) to replace the transformation (92.9a). If we ensure that

$$\cos\beta_k > 0, \qquad \sin\beta_k > 0, \qquad \text{and } c > 0$$

then the application of this transformation followed by the application of the double bilinear transformation yields stable 2-D digital filters that are free of nonessential singularities of the second kind. If, in addition

© 2003 by CRC Press LLC

$$c = \frac{1}{\omega_{\max}^2}$$

then local-type preservation can be achieved on the set Ω_2 given by

$$\Omega_2 = \left\{(\omega_1, \omega_2): \omega_1 \geq 0,\ \omega_2 \geq 0,\ \omega_1\omega_2 \leq \omega_{\max}\right\}$$

and if $\omega_{\max} \to \infty$, then a global-type preservation can be approached as closely as desired.

By using the transformation of (92.65) instead of that in (92.9a) in the method of Costa and Venetsanopoulos, the transfer function of (92.54) becomes

$$H_{D2k}(z_1, z_2) = K_1 P_{D2}(z_1, z_2) \times \prod_{i=1}^{M_0} \frac{a_{11i} + a_{21i}z_1 + a_{12i}z_2 + a_{22i}z_1z_2}{b_{11i} + b_{21i}z_1 + b_{12i}z_2 + b_{22i}z_1z_2} \tag{92.66}$$

where

$$K_1 = K_0\left(\frac{T}{2}\right)^{N-M} \tag{92.67a}$$

$$P_{D2}(z_1, z_2) = \left[1 + \frac{4c}{T^2} + \left(1 - \frac{4c}{T^2}\right)z_1 + \left(1 - \frac{4c}{T^2}\right)z_2 + \left(1 + \frac{4c}{T^2}\right)z_1z_2\right]^{N-M} \tag{92.67b}$$

and

$$a_{11i} = -\cos\beta_k - \sin\beta_k - \left(\frac{T}{2} + \frac{2c}{T}\right)z_{ai}$$

$$a_{21i} = \cos\beta_k - \sin\beta_k - \left(\frac{T}{2} + \frac{2c}{T}\right)z_{ai} \qquad \text{for } 1 \leq i \leq M$$

$$a_{12i} = -\cos\beta_k + \sin\beta_k - \left(\frac{T}{2} - \frac{2c}{T}\right)z_{ai}$$

$$a_{22i} = \cos\beta_k + \sin\beta_k - \left(\frac{T}{2} + \frac{2c}{T}\right)z_{ai}$$

$$a_{11i} = a_{21i} = a_{12i} = a_{22i} = 1 \qquad \text{for } M \leq i \leq M_0$$

$$b_{11i} = -\cos\beta_k - \sin\beta_k - \left(\frac{T}{2} + \frac{2c}{T}\right)p_{ai}$$

$$b_{21i} = \cos\beta_k - \sin\beta_k - \left(\frac{T}{2} - \frac{2c}{T}\right)p_{ai} \qquad \text{for } 1 \leq i \leq N$$

$$b_{12i} = -\cos\beta_k + \sin\beta_k - \left(\frac{T}{2} - \frac{2c}{T}\right)p_{ai}$$

$$b_{22i} = \cos\beta_k + \sin\beta_k - \left(\frac{T}{2} - \frac{2c}{T}\right)p_{ai}$$

$$b_{11i} = b_{21i} = b_{12i} = b_{22i} = 1 \qquad \text{for } N \leq i \leq M_0$$

$$M_0 = \max(M, N)$$

© 2003 by CRC Press LLC

An equivalent design can be obtained by applying the allpass transformation of (92.62) in Goodman's method with

$$c_k = \frac{1+\cos\beta_k - \sin\beta_k - 4c/T^2}{1-\cos\beta_k - \sin\beta_k + 4c/T^2}$$

$$d_k = \frac{1-\cos\beta_k + \sin\beta_k - 4c/T^2}{1-\cos\beta_k - \sin\beta_k + 4c/T^2}$$

$$c_k = \frac{1+\cos\beta_k + \sin\beta_k + 4c/T^2}{1-\cos\beta_k - \sin\beta_k + 4c/T^2}$$

Realization of HP, BP, and BS Filters

Consider two zero-phase rotated subfilters that were obtained from a 1-D analog high-pass transfer function using rotating angles $-\beta_1$ and β_1, where $0° < \beta_1 < 90°$. The idealized contour plots of the two subfilters are shown in Fig. 92.14(a) and (b). If these two subfilters are cascaded, the amplitude response of the combination is obtained by multiplying the amplitude responses of the subfilters at corresponding points. The idealized contour plot of the composite filter is thus obtained as illustrated in Fig. 92.14(c). As can be seen, the contour plot does not represent the amplitude response of a 2-D circularly symmetric high-pass filter, and, therefore, the design of high-pass filters cannot readily be achieved by simply cascading rotated subfilters as in the case of low-pass filters. However, the design of these filters can be accomplished through the use of a combination of cascade and parallel subfilters [16].

If the above rotated subfilters are connected in parallel, we obtain a composite filter whose contour plot is shown in Fig. 92.14(d). By subtracting the output of the cascade filter from the output of the parallel filter, we achieve an overall filter whose contour plot is depicted in Fig. 92.14(e). Evidently, this plot resembles the idealized contour plot of a 2-D circularly symmetric high-pass filter, and, in effect, following this method a filter configuration is available for the design of high-pass filters.

The transfer function of the 2-D high-pass filter is then given by

$$\hat{H}_1 = \overline{H}_1 = H^{\beta_1} + H^{-\beta_1} - H^{\beta_1} H^{-\beta_1} \tag{92.68}$$

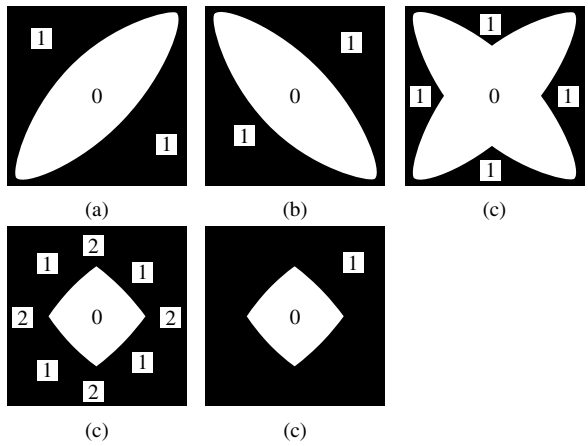

FIGURE 92.14 Derivation of 2-D high-pass filter. (a) Contour plot of subfilter rotated by $-\beta_1$. (b) Contour plot of subfilter rotated by β_1. (c) Contour plot of subfilters in (a) and (b) connected in cascade. (d) Contour plot of subfilters in (a) and (b) connected in parallel. (e) Contour plot obtained by subtracting the amplitude response in (c) from that of (d).

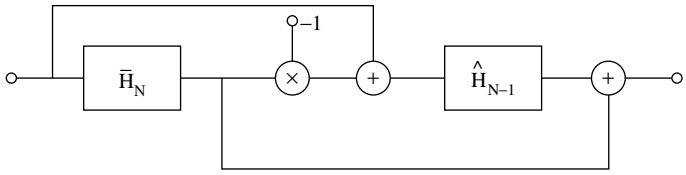

FIGURE 92.15 2-D high-pass filter configuration.

where

$$H^{\beta_1} = H_1(z_1, z_2)H_1(z_1^{-1}, z_2^{-1})$$

and

$$H^{-\beta_1} = H_1(z_1, z_2^{-1})H_1(z_1^{-1}, z_2)$$

represent zero-phase subfilters rotated by angle β_1 and $-\beta_1$, respectively.

The above approach can be extended to two or more rotation angles in order to improve the degree of circularity. For N rotation angles, $\hat{H}_N$ is given by the recursive relation

$$\hat{H}_N = \hat{H}_{N-1} + \overline{H}_N - \hat{H}_{N-1}\overline{H}_N \tag{92.69}$$

where

$$\overline{H}_N = H^{\beta_N} + H^{-\beta_N} - H^{\beta_N}H^{-\beta_N}$$

and $\hat{H}_{N-1}$ can be obtained from $\overline{H}_{N-1}$ and $\hat{H}_{N-2}$. The configuration obtained is illustrated in Fig. 92.15, where the realization of $\hat{H}_{N-1}$ is of the same as that of $\hat{H}_N$.

As can be seen in Fig. 92.15, the complexity of the high-pass configuration tends to increase rapidly with the number of rotations, and consequently, the number of rotations should be kept to a minimum. It should also be mentioned that the coefficients of the rotated filters must be properly adjusted, by using (92.65), to ensure that the zero-phase is approximated. However, the use of this transformation leads to another problem: the 2-D digital transfer function obtained has spurious zeros at the Nyquist points. These zeros are due to the fact that the transformation in (92.65) does not have type preservation in the neighborhoods of the Nyquist points but their presence does not appear to be of serious concern.

With the availability of circularly symmetric low-pass and high-pass filters, bandpass and bandstop filters with circularly symmetric amplitude responses can be readily obtained. A bandpass filter can be obtained by connecting a low-pass filter and a high-pass filter with overlapping passbands in cascade, whereas a bandstop filter can be realized by connecting a low-pass filter and a high-pass filter with overlapping passbands in parallel.

Design of Filters Satisfying Prescribed Specifications

A similar approach to that described in the third subsection in Section 92.3 can be used for the design of circularly symmetric filters satisfying prescribed specifications. Assume that the maximum/minimum passband and the maximum stopband gain of the 2-D filter are $(1 \pm \Delta p)$ and Δa, respectively, if K rotated filter sections are cascaded where half of the rotations are in the range of 180° to 270° and the other half are in the range 270° to 360°. Then, we can assign the passband ripple δ_p and the stop band loss δ_a to be [2]

$$\delta_p = \frac{\Delta p}{K} \tag{92.70}$$

© 2003 by CRC Press LLC

and

$$\delta_a = \Delta a^{2/K} \tag{92.71}$$

The lower (or upper) bound of the passband gain would be achieved if all the rotated sections were to have minimum (or maximum) passband gains at the same frequency point. Although it is possible for all the rotated sections to have minimum (or maximum) gains at the origin of the (ω_1, ω_2) plane, the gains are unlikely to be maximum (or minimum) together at some other frequency point and, in effect, the preceding estimate for δ_p is low. A more realistic value for δ_p is

$$\delta_p = \frac{2\Delta p}{K} \tag{92.72}$$

If Δp and Δa are prescribed, then the passband ripple and minimum stophand attenuation of the analog filter can be obtained from (92.72) and (92.71) as

$$A_p = 20 \log\left[\frac{K}{K - 2\Delta p}\right] \tag{92.73}$$

and

$$A_a = \frac{40}{K} \log\left[\frac{1}{\Delta a}\right] \tag{92.74}$$

If the passband Ω_p and stophand Ω_a are also prescribed, the minimum order and the transfer function of the analog filter can be determined using the method in preceding sections.

Example 4. Using the method of Costa and Venetsanopoulos, design a circularly symmetric low-pass filter satisfying the following specifications:

$$\omega_{s1} = \omega_{s2} = 2\pi \text{ rad/s}$$

$$\omega_p = 0.4\pi \text{ rad/s}, \qquad \omega_a = 0.6\pi \text{ rad/s}$$

$$\delta_p = \delta_a = 0.1$$

Solution. The filter satisfying prescribed specifications can be designed through the following steps:

1. Select a prototype of approximation and suitably select the number of rotations K.
2. Calculate rotation angles by (92.51).
3. Determine A_p and A_a from δ_p and δ_a, respectively, using (92.73) and (92.74). Calculate the prewarped Ω_p and Ω_a, from ω_p, and ω_a, respectively.
4. Use above calculated specifications to obtain the prewarped 1-D analog transfer function.
5. Apply the transformations of (92.52), (92.53), (92.57), and (92.58) to obtain K rotated subfilters.
6. Cascade all the rotated subfilters.

The 3-D plot of the amplitude response of the resulting filter is shown in Fig. 92.16, where $K = 10$.

92.5 Design of 2-D IIR Filters by Optimization

In the preceding subsections, several methods for the solution of approximation problems in 2-D IIR filters have been described. These methods lead to a complete description of the transfer function in closed form, either in terms of its zeros and poles or its coefficients. They are, as a consequence, very efficient and lead to very precise designs. Their main advantage is that they are applicable only for the

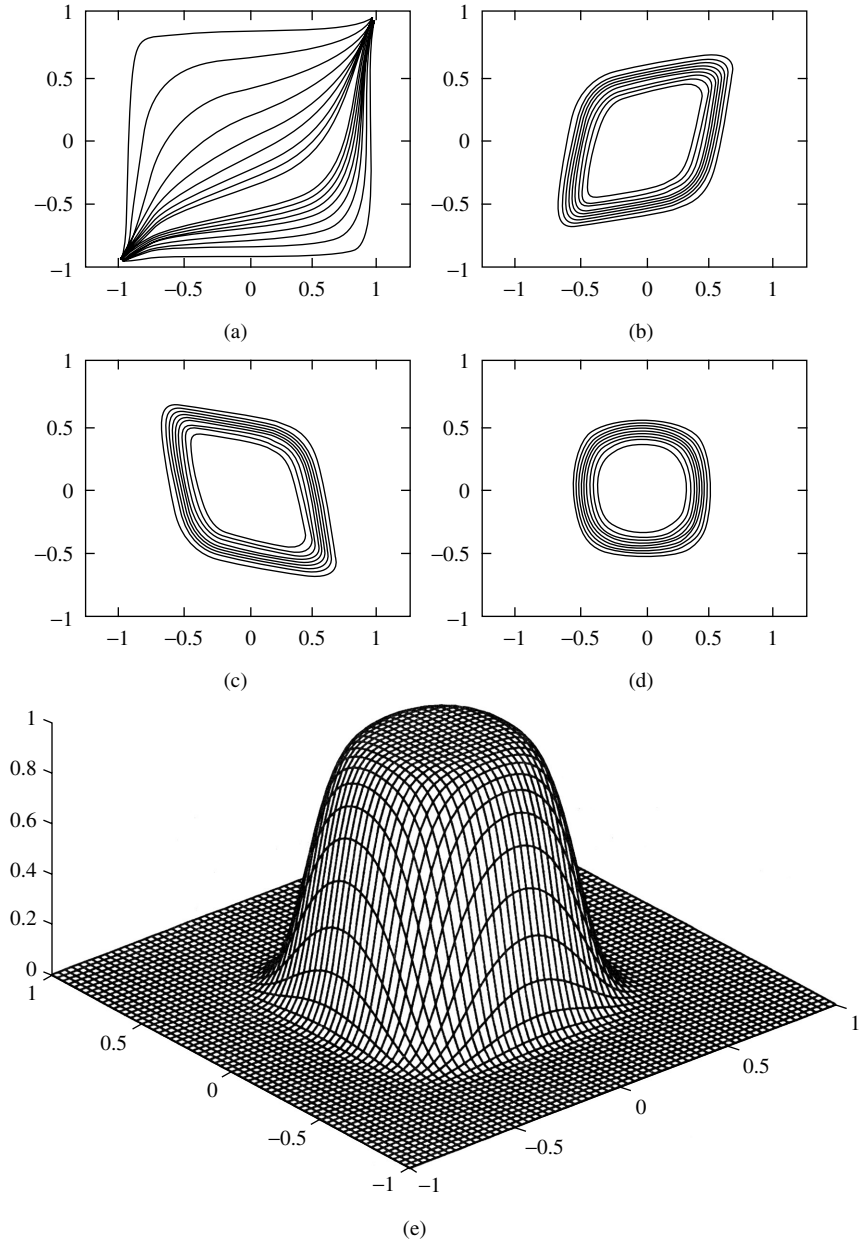

FIGURE 92.16 The amplitude response of a circularly symmetric filter in Example 4. (a) Subfilter for rotation angle of 243°. (b) Subfilters for rotation angles of 189°, 207°, 225°, 243°, and 261° in cascade. (c) Subfilters for rotation angles of 279°, 297°, 315°, 333°, and 351° in cascade. (d) All 10 subfilters in cascade. (e) 3-D plot of the amplitude response of the resulting 2-D low-pass filter.

design of filters with piecewise-constant amplitude responses. In the following subsections, the optimization methods for the design of 2-D IIR filters are considered. In these methods, a discrete transfer function is assumed and an error function is formulated on the basis of some desired amplitude and/or phase response. These methods are iterative and, as a result, they usually involve a large amount of computation. However, unlike the closed-form methods, they are suitable for the design of filters having arbitrary amplitude or phase responses.

Design by Least *p*th Optimization

The least *p*th optimization method has been used quite extensively in the past in a variety of applications. In this approach, an objective function in the form of a sum of elemental error functions, each raised to the *p*th power, is first formulated and is then minimized using any one of the available unconstrained optimization methods [17].

Problem Formulation

Consider the transfer function

$$H(z_1, z_2) = H_0 \prod_{k=1}^{K} \frac{N_k(z_1, z_2)}{D_k(z_1, z_2)} = H_0 \prod_{k=1}^{K} \frac{\sum_{l=0}^{L_{1k}} \sum_{m=0}^{M_{1k}} a_{lm}^{(k)} z_1^{-l} z_2^{-m}}{\sum_{l=0}^{L_{2k}} \sum_{m=0}^{M_{2k}} b_{lm}^{(k)} z_1^{-l} z_2^{-m}} \tag{92.75}$$

where $N_k(z_1, z_2)$ and $D_k(z_1, z_2)$ are polynomials of order equal to or less than 2 and H_0 is a constant, and let

$$\mathbf{x} = \begin{bmatrix} \mathbf{a}^T & \mathbf{b}^T & H_0 \end{bmatrix}^T \tag{92.76}$$

where

$$\mathbf{a} = \begin{bmatrix} a_{10}^{(1)} & a_{20}^{(1)} & \ldots & a_{L_{11}M_{11}}^{(1)} & a_{10}^{(2)} & a_{20}^{(2)} & \ldots & a_{L_{12}M_{12}}^{(2)} & \ldots & a_{L_{1K}M_{1K}}^{(K)} \end{bmatrix}^T$$

and

$$\mathbf{b} = \begin{bmatrix} b_{10}^{(1)} & b_{20}^{(1)} & \ldots & b_{L_{11}M_{11}}^{(1)} & b_{10}^{(2)} & a_{20}^{(2)} & \ldots & b_{L_{12}M_{12}}^{(2)} & \ldots & b_{L_{2K}M_{2K}}^{(K)} \end{bmatrix}^T$$

are row vectors whose elements are the coefficients of $N_k(z_1, z_2)$ and $D_k(z_1, z_2)$, respectively. An objective function can be defined in terms of the L_p norm of $\mathbf{E}(\mathbf{x})$ as

$$J(\mathbf{x}) = L_p = \left\| \mathbf{E}(\mathbf{x}) \right\|_p = \left[\sum_{i=1}^{K} \left| E_{mn}(\mathbf{x}) \right|^p \right]^{1/p} \tag{92.77}$$

where p is an even positive integer,

$$E_{mn}(\mathbf{x}) = \mathbf{M}(\mathbf{m}, \mathbf{n}) - \mathbf{M}_1(m, n) \tag{92.78}$$

and

$$M(m, n) = \left| H\left(e^{j\omega_{1m}T_1}, e^{j\omega_{2n}T_2} \right) \right| \qquad m = 1, \ \ldots, M, \ n = 1, \ \ldots, N$$

are samples of the amplitude response of the filter at a set of frequency pairs $(\omega_{1m}, \omega_{2n})$ ($m = 1, \ldots, M$, $n = 1, \ldots, N$) with

$$\omega_{1m} = \frac{\omega_{s1}(m-1)}{2(M-1)} \qquad \omega_{2n} = \frac{\omega_{s2}(n-1)}{2(N-1)}$$

© 2003 by CRC Press LLC

$M_1(m, n)$ represents the desired amplitude response at frequencies $(\omega_{1m}, \omega_{2n})$.

Several special cases of the L_p norm are of particular interest. The L_1 norm, namely

$$L_1 = \sum_{i=1}^{K} \left| E_{mn}(x) \right|$$

is the sum of the magnitudes of the elements of $\mathbf{E}(\mathbf{x})$; the L_2 norm given by

$$L_2 = \left[\sum_{i=1}^{K} \left| E_{mn}(\mathbf{x}) \right|^2 \right]^{1/2}$$

is the well-known Euclidean norm; and L_2^2 is the sum of the squares of the elements of $\boldsymbol{E}(\mathbf{x})$. In the case where $p \to \infty$ and

$$E_M(\mathbf{x}) = \max_{m,n} \left\{ E_{mn}(\mathbf{x}) \right\} \neq 0$$

we can write

$$\begin{aligned} L_\infty &= \lim_{\mathrm{p}\to\infty} \left\{ \sum_{k=1}^{K} \left| E_{mn}(\mathbf{x}) \right|^p \right\}^{1/\mathrm{p}} \\ &= E_M(\mathbf{x}) = \lim_{p\to\infty} \left\{ \sum_{k=1}^{K} \left| \frac{E_{mn}(\mathbf{x})}{E_M(\mathbf{x})} \right|^p \right\}^{1/\mathrm{p}} \\ &= E_M(\mathbf{x}) \end{aligned} \tag{92.79}$$

The design task at hand amounts to finding a parameter vector $\mathbf{x}$ that minimizes the least pth objective function $J(\mathbf{x})$ defined in (92.77). If $J(\mathbf{x})$ is defined in terms of L_2^2, a least-squares solution is obtained; if the L_∞ norm is used, a so-called minimax solution is obtained, since in this case the largest element in $E(\mathbf{x})$ is minimized.

Quasi-Newton Algorithms

The design problem described above can be solved by using any one of the standard unconstrained optimization algorithms. A class of such algorithms that has been found to be very versatile, efficient, and robust is the class of quasi-Newton algorithms [17]–[19]. These are based on the principle that the minimum point $\mathbf{x}^\star$ of a quadratic convex function $J(\mathbf{x})$ of N variables can be obtained by applying the correction

$$\boldsymbol{\delta} = -\mathbf{H}^{-1}\boldsymbol{\gamma}$$

to an arbitrary point $\mathbf{x}$, that is

$$\mathbf{x}^\star = \mathbf{x} + \mathbf{d}$$

where vector

$$\mathbf{g} = \nabla J(\mathbf{x}) = \left[\frac{\partial J}{\partial x_1}, \frac{\partial J}{\partial x_2}, \cdots, \frac{\partial J}{\partial x_N} \right]^T$$

© 2003 by CRC Press LLC

and $N \times N$ matrix

$$\mathbf{H} = \begin{vmatrix} \dfrac{\partial^2 J(\mathbf{x})}{\partial x_1^2} & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_1 \partial x_2} & \cdots & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_1 \partial x_N} \\ \dfrac{\partial^2 J(\mathbf{x})}{\partial x_2 \partial x_1} & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_2^2} & \cdots & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_2 \partial x_N} \\ \cdots & \cdots & \cdots & \cdots \\ \dfrac{\partial^2 J(\mathbf{x})}{\partial x_N \partial x_1} & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_N \partial x_2} & \cdots & \dfrac{\partial^2 J(\mathbf{x})}{\partial x_N^2} \end{vmatrix}$$

are the gradient vector and Hessian matrix of $J(\mathbf{x})$ at point $\mathbf{x}$, respectively.

The basic quasi-Newton algorithm as applied to the 2-D IIR filter design problem is as follows [20].

Algorithm 1: Basic Quasi-Newton Algorithm

STEP 1. Input $\mathbf{x}_0$ and ε. Set $\mathbf{S}_0 = \mathbf{I}_N$, where $\mathbf{I}_N$ is the $N \times N$ unity matrix and N is the dimension of $\mathbf{x}$, and set $k = 0$. Compute $\mathbf{g}_0 = -\mathbf{J}(\mathbf{x}_0)$.

STEP 2. Set $\mathbf{d}_k = -\mathbf{S}_k\mathbf{g}_k$ and find α_k, the value of α that minimizes $\mathbf{J}(\mathbf{x}_k + \alpha\mathbf{d}_k)$, using a line search.

STEP 3. Set $\boldsymbol{\delta}_k = \alpha_k\mathbf{d}_k$ and $x_{k+1} = \mathbf{x}_k + \boldsymbol{\delta}_k$.

STEP 4. If $\|\delta_k\| < \varepsilon$, then output $\mathbf{x}^\star = \mathbf{x}_{k+1}$, $\mathbf{J}(\mathbf{x}^\star) = \mathbf{J}(\mathbf{x}_{k+1})$ and stop, else go to step 5.

STEP 5. Compute $\mathbf{g}_{k+1} = J(\mathbf{x}_{k+1})$ and set $\gamma_k = \mathbf{g}_{k+1} - \mathbf{g}_k$.

STEP 6. Compute $\mathbf{S}_{k+1} = \mathbf{S}_k + \mathbf{C}_k$, where $\mathbf{C}_k$ is a suitable matrix correction.

STEP 7. Check $\mathbf{S}_{k+1}$ for positive definiteness and if it is found to be nonpositive definite force it to become positive definite.

STEP 8. Set $k = k + 1$ and go to step 2.

The correction matrix C_k required in step 6 can be computed by using either the Davidon-Fletcher-Powell (DFP) formula

$$\mathbf{C}_k = \frac{\mathbf{d}_k\mathbf{d}_k^T}{\mathbf{g}_k^T\mathbf{g}_k} \frac{\mathbf{S}_k\mathbf{g}_k\mathbf{g}_k^T\mathbf{S}}{\mathbf{g}_k^T\mathbf{S}_k\mathbf{g}_k} \tag{92.80}$$

or the Broyden-Fletcher-Goldfarb-Shanno (BFGS) formula

$$\mathbf{C}_k = \left(1 + \frac{\mathbf{g}_k^T\mathbf{S}_k\mathbf{g}_k}{\mathbf{d}_k^T\mathbf{d}_k}\right) \frac{\mathbf{d}_k\mathbf{d}_k^T}{\mathbf{g}_k^T\mathbf{d}_k} - \frac{\mathbf{d}_k\mathbf{g}_k^T\mathbf{S}_k + \mathbf{S}_k\mathbf{g}_k\mathbf{d}_k^T}{\mathbf{g}_k^T\mathbf{d}_k} \tag{92.81}$$

Algorithm 1 eliminates the need to calculate the second derivatives of the objective function; in addition, the matrix inversion is unnecessary. However, matrices $\mathbf{S}_1$, $\mathbf{S}_2$, …, $\mathbf{S}_k$ need to be checked for positive definiteness and may need to be manipulated. This can be easily done in practice by diagonalizing $\mathbf{S}_{k+1}$

© 2003 by CRC Press LLC

and then replacing any nonpositive diagonal elements with corresponding positive ones. However, this would increase the computational burden quite significantly. The amount of computation required to complete a design is usually very large, due with the large numbers in 2-D digital filters and the large number of sample points needed to construct the objective function. Generally, the computational load can often be reduced by starting with an approximate design based on some closed-form solution. For example, the design of circularly or elliptical symmetric filters may start with filters that have square or rectangular passbands and stopbands.

Example 5 [20]. Design a circularly symmetric low-pass filter of order (2, 2) with $\omega_{p1} = \omega_{p2} = 0.08\pi$ rad/s and $\omega_{a1} = \omega_{a2} = 0.12\pi$ rad/s, assuming that $\omega_{s1} = \omega_{s2} = 2\pi$ rad/s.

Solution.

1. Construct the ideal discrete amplitude response of the filter

$$M_I(m,n) = \begin{cases} 1 & \text{for } \left(\omega_{1m}^2 + \omega_{2n}^2\right) \le 0.008\pi \\ 0.5 & \text{for } 0.08\pi \le \left(\omega_{1m}^2 + \omega_{2n}^2\right) \le 0.12\,\pi \\ 0 & \text{otherwise} \end{cases}$$

   where

$$\left\{\omega_{1m}\right\} = \left\{\omega_{2n}\right\} = 0,\ 0.02\pi,\ 0.04\pi,\ 0.2\pi,\ \ 0.4\pi,\ 0.6\pi,\ 0.8\pi,\ \pi$$

2. To reduce the amount of computation, a 1-D low-pass filter with passband edge $\omega_p = 0.08\pi$ and stopband edge $\omega_a = 0.1\ \pi$ is first obtained with the 1-D transfer function being

$$H_1(z) = 0.11024\,\frac{1 - 1.64382\,z^{-1} + z^{-2}}{1 - 1.79353 z^{-1} + 0.84098 z^{-2}}$$

   and then a 2-D transfer function with a square passband is obtained as

$$H(z_1, z_2) = H_1(z_1) H_1(z_2)$$

3. Construct the objective function of (92.77), using algorithm 1 to minimize the objective function $J(\mathbf{x})$. After 20 more iterations the algorithm converges to $H(z_1,z_2) = 0.00895$

$$\times \frac{\begin{bmatrix} 1 & z_1^{-1} & z_1^{-2} \end{bmatrix} \begin{vmatrix} 1.0 & -1.62151 & 0.99994 \\ -1.62151 & 2.63704 & -1.62129 \\ 0.99994 & -1.62129 & 1.00203 \end{vmatrix} \begin{vmatrix} 1 \\ z_2^{-1} \\ z_2^{-2} \end{vmatrix}}{\begin{bmatrix} 1 & z_1^{-1} & z_1^{-2} \end{bmatrix} \begin{vmatrix} 1.0 & -1.78813 & 0.82930 \\ -1.78813 & 3.20640 & -1.49271 \\ 0.82930 & -1.49271 & 0.69823 \end{vmatrix} \begin{vmatrix} 1 \\ z_2^{-1} \\ z_2^{-2} \end{vmatrix}}$$

The amplitude response of the final optimal filter is depicted in Fig. 92.17.

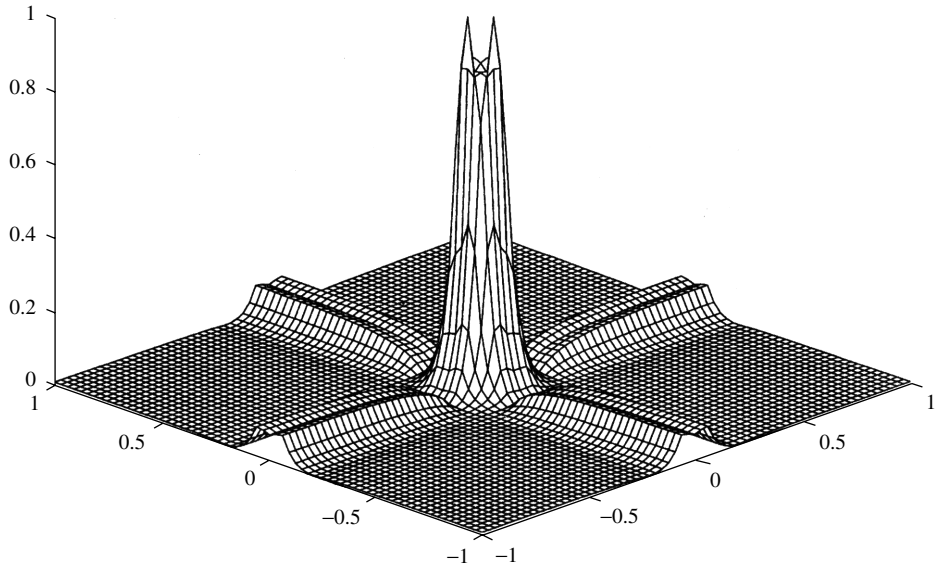

FIGURE 92.17 Amplitude response of the 2-D optimal filter in Example 5.

Minimax Algorithms

Least pth Minimax Algorithm. When a objective function is formulated in terms of the L_p norm of the error function and then minimizing $J(\mathbf{x})$ for increasing values of p, such an objective function can be obtained as

$$\mathcal{J}(x) = E_M(x)\left\{\sum_{i=1}^{m}\left|\frac{E(x,\omega_{1i},\omega_{2i})}{E_M(x)}\right|^p\right\}^{1/p} \tag{92.82}$$

where

$$E_M(\mathbf{x}) = \max_{1\le i\le m}\{E_i(\mathbf{x})\} = \max_{1\le i\le m}\{E_i(\mathbf{x},\omega_{1i},\omega_{2i})\} \tag{92.83}$$

A minimax algorithm based on $J(\mathbf{x})$ is as follows [21].

Algorithm 2: Least-*p*th Minimax Algorithm

STEP 1. Input $\mathbf{x}_0$ and ε. Set $k = 1$, $p = 1$, $\mu = 2$, $\mathbf{E}_0 = 10^{99}$.

STEP 2. Initialize frequencies ω_{1i}, ω_{2i} for $i = 1, 2, \ldots, m$.

STEP 3. Using point $\mathbf{x}_{k-1}$ as initial point, minimize $J(\mathbf{x})$ with respect to $\mathbf{x}$ to obtain $\mathbf{x}_k$. Set $\mathbf{E}_k = E(\mathbf{x}_k)$.

STEP 4. If $|E_{k-1} - E_k| < \varepsilon$, then output $\mathbf{x}^* = \mathbf{x}_k$ and $\mathbf{E}_k$ and stop. Else, set $p = \mu p$, $k = k + 1$ and go to step 3.

The minimization in step 3 can be carried out using Algorithm 1 or any other unconstrained optimization algorithms.

Charalambous Minimax Algorithm. The preceding algorithm gives excellent results except that it requires a considerable amount of computation. An alternative and much more efficient algorithm is the minimax

© 2003 by CRC Press LLC

algorithm proposed by Charalambous and Antoniou [22], [23]. This algorithm is based on principles developed by Charalambous [24] and involves the minimization of the objective function $J(\mathbf{x}, \zeta, \lambda)$, defined by

$$J(\mathbf{x},\zeta,\lambda) = \sum_{i\in I_1} \frac{1}{2}\lambda_i \left[J_i(\mathbf{x}, \zeta)\right]^2 + \sum_{i\in I_2} \frac{1}{2}\left[J_i(\mathbf{x}, \zeta)\right]^2 \tag{92.84}$$

where ζ and λ_i for i = 1, 2, …, m are constants,

$$J_i(\mathbf{x}, \zeta) = E_i(\mathbf{x}) - \zeta$$

$$I_1 = \left\{i : J_i(\mathbf{x}, \zeta) > 0 \quad \textbf{and} \quad \lambda_i > 0\right\}$$

and

$$I_2 = \left\{i : J_i(\mathbf{x}, \zeta) > 0 \quad \textbf{and} \quad \lambda_i > 0\right\}$$

The factor 1/2 in (92.84) is included for the purpose of simplifying the gradient that is given by

$$\nabla J(\mathbf{x}, \zeta, \lambda) = \sum_{i\in I_1} \lambda_i J_i(\mathbf{x}, \zeta)\nabla J_i(x,\zeta) + \sum_{i\in I_2} J_i(\mathbf{x}, \zeta)\nabla J_i(\mathbf{x}, \zeta) \tag{92.85}$$

It can be shown that, if

1. the second-order sufficient conditions for a minimum hold at $x^\star$,
2. $\lambda_i = \lambda_i^*$, i = 1, 2, …, m, where $\lambda_i^\star$ are the minimax multipliers corresponding to a minimum optimum solution $\mathbf{x}^\star$ and
3. $E(\mathbf{x}^\star) - \xi$ is sufficiently small then $\mathbf{x}^\star$ is a strong local minimum point of $J(\mathbf{x}, \xi,\lambda)$.

Condition 1 is usually satisfied in practice. Therefore, a local minimum point x* can be found by forcing λ_i to approach $\lambda_i^\star$ (i = 1,2, …, m) and making $E(\mathbf{x}^\star) - \xi$ sufficiently small. These two constraints can be simultaneously satisfied by applying the following algorithm.

Algorithm 3: Charalambous Minimax Algorithm

STEP 1. Set $\xi = 0$ and $\lambda_i = 1$ for i = 1, 2,…, m. Initialize **x**.

STEP 2. Minimize function $J(\mathbf{x},\xi, \lambda)$ to obtain **x**.

STEP 3. Set

$$S = \sum_{i\in I_1} \lambda_i j_i(\mathbf{x},\xi) + \sum_{i\in I_2} J_i(\mathbf{x},\xi)$$

and update λ_i and ξ as

$$\lambda_i = \begin{cases} \lambda_i J_i(\mathbf{x},\xi)/S & \text{if } \mathbf{J}_i(\mathbf{x},\xi) \geq 0,\ \lambda_i \geq 0 \\ J_i(\mathbf{x},\xi)/S & \text{if } \mathbf{J}_i(\mathbf{x},\xi) \geq 0,\ \lambda = 0 \\ 0 & \text{if } \mathbf{J}_i(\mathbf{x},\xi) < 0 \end{cases}$$

$$\xi = \sum_{i=1}^{m} \lambda_i \mathbf{E}_i(\mathbf{x})$$

© 2003 by CRC Press LLC

STEP 4. Stop if

$$\frac{E_M(\mathbf{x})-\xi}{E_M(\mathbf{x})} \le \varepsilon$$

otherwise go to step 2.

The parameter ε is a prescribed termination tolerance. When the algorithm converges, conditions 2 and 3 are satisfied and $\mathbf{x} = \mathbf{x}^*$. The unconstrained optimization in step 2 can be accomplished by applying a quasi-Newton algorithm.

Example 6 [23]. Design a 2-D circularly symmetric filter with the same specifications as in Example 5, using algorithm 3.

Solution.

1. Construct the ideal discrete amplitude response of the filter. Since the passband and stopband contours are circles, the sample points can be placed on arcs of a set of circles centered at the origin. Five circles with radii

   $$r_1 = 0.3\omega_p, \qquad r_2 = 0.6\omega_p, \qquad r_3 = 0.8\omega_p, \qquad r_4 = 0.9\omega_p, \qquad \text{and} \qquad r_5 = \omega_p$$

   are placed in the passband and five circles with radii

   $$r_6 = \omega_a, \qquad r_7 = \omega_a + 0.1(\pi - \omega_a), \qquad r_8 = \omega_a + 0.2(\pi - \omega_a),$$
   $$r_9 = \omega_a + 0.55(\pi - \omega_a), \qquad \text{and} \qquad r_{10} = \pi$$

   are placed in the stopband.

   For circularly symmetric filters, the amplitude is uniquely specified by the amplitude response in the sector $[0^o, 45^o]$. Therefore, six equally spaced points on each circle described above between 0^o and 45^o are chosen. These points plus the origin $(\omega_1, \omega_2) = (0,0)$ form a set of 61 sample points.
2. Select the 2-D transfer function. Because a circularly symmetric filter has a transfer function with separable denominator [24], we can select the transfer function to be of the form

   $$H(z_1, z_2) = H_0(z_1, z_2)^{-1} \times \prod_{k=1}^{K} \frac{z_1 z_2 + z_1^{-1} z_2^{-1} + a_k\left(z_1 + z_1^{-1} + z_2 + z_2^{-1}\right) + z_1^{-1} z_2 + z_1 z_2^{-1} + b_k}{\left(1 + c_k z_1^{-1} + d_k z_1^{-2}\right)\left(1 + c_k z_2^{-1} + d_k z_2^{-2}\right)} \tag{92.86}$$

   with parameter H_0 fixed as $H_0 = (0.06582)^2$, $K = 1$, $\varepsilon = 0.01$.
3. Starting from

   $$a_1^{(0)} = -1.514, \qquad b_1^{(0)} = (a_1^{(0)})^2, \qquad c_1^{(0)} = -1.784, \qquad d_1^{(0)} = 0.8166$$

   and algorithm 3 yields the solution

   $$a_1^* = 1.96493, \qquad b_1^* = -10.9934, \qquad c_1^* = -1.61564, \qquad d_1^* = 0.66781$$
   $$E_M(\mathbf{x}) = 0.37995$$

The 3-D plot of the amplitude response of the resulting filter is illustrated in Fig. 92.18.

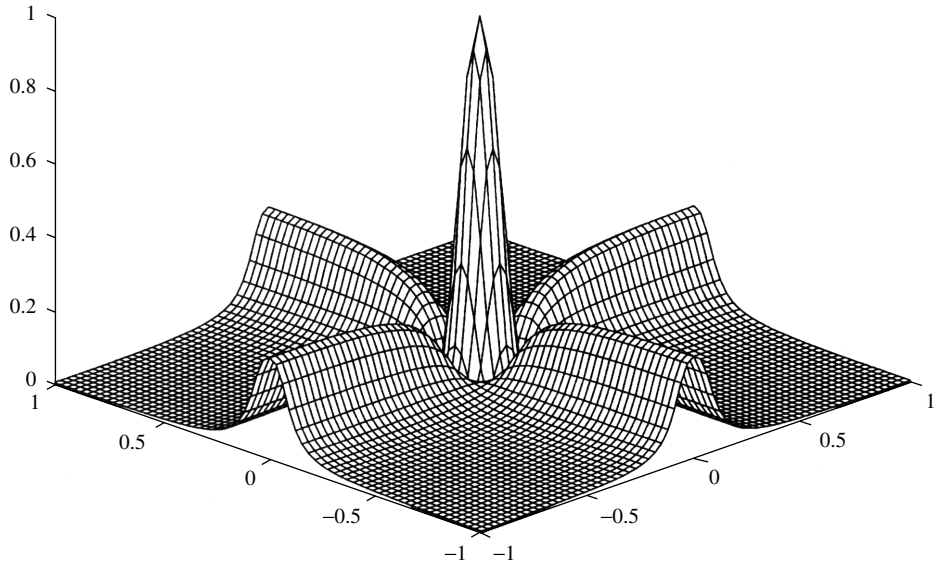

FIGURE 92.18 3-D plot of the amplitude response of the filter in Example 6.

Design by Singular-Value Decomposition

As will be seen, an important merit of the design methods of 2-D IIR filters based on singular-value decomposition (SVD) is that the required 2-D filter is decomposed into a set of 1-D digital subfilters, which are much easier to design by optimization than the original 2-D filters.

Problem Formulation

In a quadrantally symmetric filter, $H(z_1, z_2)$ has a separable denominator [24]. Therefore, it can be expressed as

$$H(z_1, z_2) = \sum_{i=1}^{K} f_i(z_1) g_i(z_2) \tag{92.87}$$

In effect, a quadrantally symmetric filter can always be realized using a set of K parallel sections where the ith section is a separable subfilter characterized by the transfer function $f_i(z_1)\, g_i(z_2)$.

Consider the desired amplitude response sample of 2-D filter $H(z_1, z_2)$, we form a 2-D amplitude specification matrix **A** as

$$\mathbf{A} = \begin{vmatrix} a_{11} & a_{12} & \cdots & a_{1L} \\ a_{21} & a_{22} & \cdots & a_{2L} \\ \cdots & \cdots & \cdots & \cdots \\ a_{M1} & a_{M1} & \cdots & a_{ML} \end{vmatrix} \tag{92.88}$$

where $\{a_{ml}\}$ is a desired amplitude response sampled at frequencies $(\omega_{1l}, \omega_{2m}) = (\pi\mu_l/T_i, \pi\nu_m/T_2)$, with

$$\mu_l = \frac{l-1}{L-1}, \quad \nu_m = \frac{m-1}{M-1} \quad \text{for } 1 \le l \le L, \qquad 1 \le m \le M$$

© 2003 by CRC Press LLC

that is,

$$a_{ml} = \left| H\left(e^{j\pi\mu_1}, e^{j\pi\nu_m}\right) \right|$$

If the matrix **A** can be decomposed into the form of

$$\mathbf{A} = \sum_{i=1}^{r} \mathbf{F}_i \mathbf{G}_i \tag{92.89}$$

then, by using the column vectors F_i and row vectors $\boldsymbol{G}_i$, we can construct matrices

$$\mathbf{F} = \begin{bmatrix} \mathbf{F}_1 & \mathbf{F}_2 & \cdots & \mathbf{F}_r \end{bmatrix} \tag{92.90}$$

$$\mathbf{G} = \begin{bmatrix} \mathbf{G}_1 & \mathbf{G}_2 & \cdots & \mathbf{G}_r \end{bmatrix}^T \tag{92.91}$$

If all elements of **F** and **G** are nonnegative then they can be regarded as the amplitude specifications matrices of an r-input/1-output 1-D filter $F(z_1)$ and a 1-input/*r*-output 1-D filter $G(z_2)$,

$$F(z_1) = \left[f_1(z_1),\ f_2(z_1), \cdots,\ f_r(z_1) \right] \tag{92.92}$$

$$G(z_2) = \left[g_1(z_2), g_2(z_2), \ldots, g_r(z_2) \right]^T \tag{92.93}$$

Therefore, the 2-D filter of (92.87) can be approximated by

$$H(z_1, z_2) = F(z_1) G(z_2) \tag{92.94}$$

In this subsection, two design procedures are described that can be applied to the design of 2-D IIR filters whose amplitude responses are quadrantally symmetric.

Method of Antoniou and Lu

Antoniou and Lu proposed a method of 2-D IIR filter based on the SVD of the amplitude response matrix **A** [26]. The SVD of matrix **A** gives [27]

$$\mathbf{A} = \sum_{i=1}^{r} \sigma_i \mathbf{u}_i \mathbf{v}_i^T = \sum_{i=1}^{r} \mathbf{f}_i \mathbf{g}_i^T \tag{92.95}$$

where σ_i are the singular values of **A** such that $\sigma_1 \le \sigma_2 \le \cdots \le \sigma_r \le 0$ is the rank of **A**, $\mathbf{u}_i$ and $\mathbf{v}_i$ are the *i*th eigenvector of $\mathbf{AA}^T$ and $\mathbf{A}^T\mathbf{A}$, respectively, $\boldsymbol{\phi}_i = \sigma_i^{1/2}\mathbf{u}_i$, $\boldsymbol{\gamma}_i = \sigma_i^{1/2}\ \mathbf{v}_i$, and $\{\boldsymbol{\Phi}_i\colon 1 \le i \le r\}$ and $\{\boldsymbol{\gamma}_i\colon 1 \le i \le r\}$ are sets of orthogonal *L*-dimensional and *M*-dimensional vectors, respectively.

An important property of the SVD can be stated as

$$\left\| \mathbf{A} - \sum_{i=1}^{K} \mathbf{F}_i \mathbf{g}_i^{\mathrm{T}} \right\| = \min_{\phi, \gamma} \left\| \mathbf{A} - \sum_{i=1}^{K} \bar{\mathbf{F}}_i \bar{\mathbf{g}}_i^{T} \right\| \quad \text{for } 1 \le K \le r \tag{92.96}$$

where $\bar{\boldsymbol{\phi}}_i \in R^L$, $\bar{\boldsymbol{\gamma}}_i \in R^M$.

To design a 2-D IIR filter by SVD, two steps are involved, namely

STEP 1. Design of the main section.

STEP 2. Design of the error correction sections as will be detailed below.

© 2003 by CRC Press LLC

Design of the Main Section. Note that (92.95) can be written as

$$\mathbf{A} = \mathbf{f}_1 \mathbf{g}_1^T + \varepsilon_1 \tag{92.97}$$

where $\varepsilon_1 = \sum_{i=2}^{r} \mathbf{\Phi}_i \boldsymbol{\gamma}_i^T$. And since all the elements of $\mathbf{A}$ are nonnegative, if follows that all elements of $\boldsymbol{\phi}_1$ and $\boldsymbol{\gamma}_1$ are nonnegative.

On comparing (92.97) with (92.95) and assuming that $K = 1$ and that $\boldsymbol{\phi}_1$, $\boldsymbol{\gamma}_1$ are sampled versions of the desired amplitude responses for the 1-D filters characterized by $f_1(z_1)$ and $g_1(z_2)$, respectively, a 2-D filter can be designed through the following procedures:

1. Design 1-D filters F_1 and G_1 characterized by $f_1(z_1)$ and $g_1(z_2)$.
2. Connect filters F_1 and G_1 in cascade, i.e.

$$H_1(z_1, z_2) = f_1(z_1)\, g_1(z_2)$$

Step 1 above can be carried out by using an optimization algorithm such as the quasi-Newton algorithm or the minimax algorithm.

Since $f_1(z_1)\, g_1(z_2)$ corresponds to the largest singular value σ_1, the subfilter characterized by $f_1(z_1)\, g_1(z_2)$ is said to be the main section of the 2-D filter.

Design of the Error Correction Sections. The approximation error of $H_1(z_1, z_2)$ can be reduced by realizing more of the terms in (92.95) by means of parallel filter sections. From (92.97), we can write

$$\mathbf{A} = \mathbf{f}_1 \mathbf{g}_1^{\mathbf{T}} + \mathbf{f}_2 \mathbf{g}_2^T + \varepsilon_{21} \tag{92.98}$$

Since ϕ_2 and λ_2 may have some negative components, a careful treatment in (92.98) is necessary.

Let ϕ_2^- and γ_2^- be the absolute values of the most negative components of ϕ_2 and γ_2, respectively. If

$$\mathbf{e}_\phi = \begin{bmatrix} 1 & 1 & \cdots & 1 \end{bmatrix}^T \in R^L \quad \textbf{and} \quad \mathbf{e}_\gamma = \begin{bmatrix} 1 & 1 & \cdots & 1 \end{bmatrix}^T \in R^M$$

then all components of

$$\boldsymbol{\phi}_{2p} = \boldsymbol{\phi}_2 + \boldsymbol{\phi}_2^- \boldsymbol{\varepsilon}_\phi \quad \boldsymbol{\alpha\nu\delta}\ \boldsymbol{\gamma}_{2p} = \boldsymbol{\gamma}_2 + \boldsymbol{\gamma}_2^- \boldsymbol{\varepsilon}_\gamma$$

are nonnegative. If it is possible to design 1-D linear-phase or zero-phase filters characterized by $f_1(z_1)$, $g_1(z_2)$, $f_{2p}(z_1)$, and $g_{2p}(z_2)$, such that

$$f_1\left(e^{j\pi\mu_i}\right) = \left| f_1\left(e^{j\pi\mu_i}\right)\right| e^{j\alpha_1\mu_i}$$

$$g_1\left(e^{j\pi\nu_m}\right) = \left| g_1\left(e^{j\pi\nu_m}\right)\right| e^{j\alpha_2\nu_m}$$

and

$$f_{2p}\left(e^{j\pi\mu_i}\right) = \left| f_{2p}\left(e^{j\pi\mu_i}\right)\right| e^{j\alpha_1\mu_i}$$

$$g_{2p}\left(e^{j\pi\nu_m}\right) = \left| g_{2p}\left(e^{j\pi\nu_m}\right)\right| e^{j\alpha_2\nu_m}$$

for $1 \le l \le L, \le m \le M$, where

$$\left| f_1\left(e^{j\pi\mu_1}\right)\right| \approx \phi_{1l}$$

$$\left| g_1\left(e^{j\pi\nu_m}\right)\right| \approx \gamma_{1m}$$

© 2003 by CRC Press LLC

$$\left|f_{2p}\left(e^{j\pi\mu_l}\right)\right| \approx \phi_{2lp}$$

$$\left|g_{2p}\left(e^{j\pi\nu_m}\right)\right| \approx \gamma_{2mp}$$

In above ϕ_{1l}, ϕ_{2lp}, γ_m, γ_{2mp} represent the lth component of ϕ_1, ϕ_{2p} and mth component of $\boldsymbol{\gamma}_1$ and $\boldsymbol{\gamma}_{2p}$, respectively. α_1 and α_2 are constants that are equal to zero if zero-phase filters are to be designed. Let

$$\alpha_1 = -\pi n_1, \quad \alpha_2 = -\pi n_2 \text{ with integers } n_1, n_2 \geq 0 \tag{92.99}$$

and define

$$f_2(z_1) = f_{2p}(z_1) - \phi_2^- z_1^{-n_1} \tag{92.100}$$

$$g_2(z_2) = g_{2p}(z_2) - \gamma_2^- z_2^{-n_2} \tag{92.101}$$

It follows that

$$f_2\left(e^{j\pi\mu_l}\right) = \left[f_{2p}\left(e^{j\pi\mu_l}\right) - \phi_2^-\right] e^{-j\pi n_1\mu_l} \approx \phi_{2l} e^{-j\pi\mu_l n_1}$$

$$g_2\left(e^{j\pi\nu_m}\right) = \left[g_{2p}\left(e^{j\pi\nu_m}\right) - \gamma_2^-\right] e^{-j\pi n_2\nu_m} \approx \gamma_{2m} e^{-j\pi\gamma_m n_2}$$

Furthermore, if we form

$$H_2(z_1, z_2) = f_1(z_1) g_1(z_2) + f_2(z_1) g_2(z_2) \tag{92.102}$$

then

$$\begin{aligned} \left|H_2\left(e^{j\pi\mu_l}, e^{j\pi\nu_m}\right)\right| &= \left|f_1\left(e^{j\pi\mu_l}\right) g_1\left(e^{j\pi\nu_m}\right) + f_2\left(e^{j\pi\mu_l}\right) g_2\left(e^{j\pi\nu_m}\right)\right| \\ &\approx \left|\phi_{1l}\gamma_{1m} + \phi_{2l}\,\gamma_{2m}\right| \end{aligned} \tag{92.103}$$

Follow this procedure, K–1 correction sections characterized by $f_2(z_1)\, g_2(z_2)$, $\cdots$, $g_k(z_1)\, g_k(z_2)$ can be obtained, and $H_k(z_1, z_2)$ can be formed as

$$H_k(z_1, z_2) = \sum_{i=1}^{K} f_i(z_i) g_i(z_2) \tag{92.104}$$

and from (92.96) we have

$$\begin{aligned} \left\|\mathbf{A} - \left|H_k\left(e^{j\pi\mu_l}, e^{j\pi\nu_m}\right)\right|\right\| &\approx \left\|\mathbf{A} - \sum_{i=1}^{K} \mathbf{f}_i \mathbf{g}_i^T\right\| \\ &\leq \|\varepsilon_K\| = \min_{\bar{\phi}_i, \bar{\gamma}_i} \left\|\sum_{i=1}^{K} \bar{\mathbf{f}}_i \bar{\mathbf{g}}_i^T\right\| \end{aligned} \tag{92.105}$$

In effect, a 2-D filter consisting of K sections is obtained whose amplitude response is a minimal mean-square-error approximation to the desired amplitude response.

The method leads to an asymptotically stable 2-D filter, provided that all 1-D subfilters employed are stable. The general configuration of the 2-D filter obtained is illustrated in Fig. 92.19, where the various 1-D subfilters may be either linear-phase or zero-phase filters.

If linear-phase subfilters are to be used, the equalities in (92.99) must be satisfied. This implies that the subfilters must have constant group delays. If zero-phase subfilters are employed, where $f_i(z_1)$ and $f_i(z_1^{-1})$, and $g_i(z_2)$ and $g_i(z_2^{-1})$ contribute equally to the amplitude response of the 2-D filter. The design can be accomplished by assuming that the desired amplitude responses for subfilters F_i, G_i are $\boldsymbol{\phi}_i^{1/2}$, $\boldsymbol{\gamma}_i^{1/2}$, for $i = 1, 2, k, \cdots, K$, respectively.

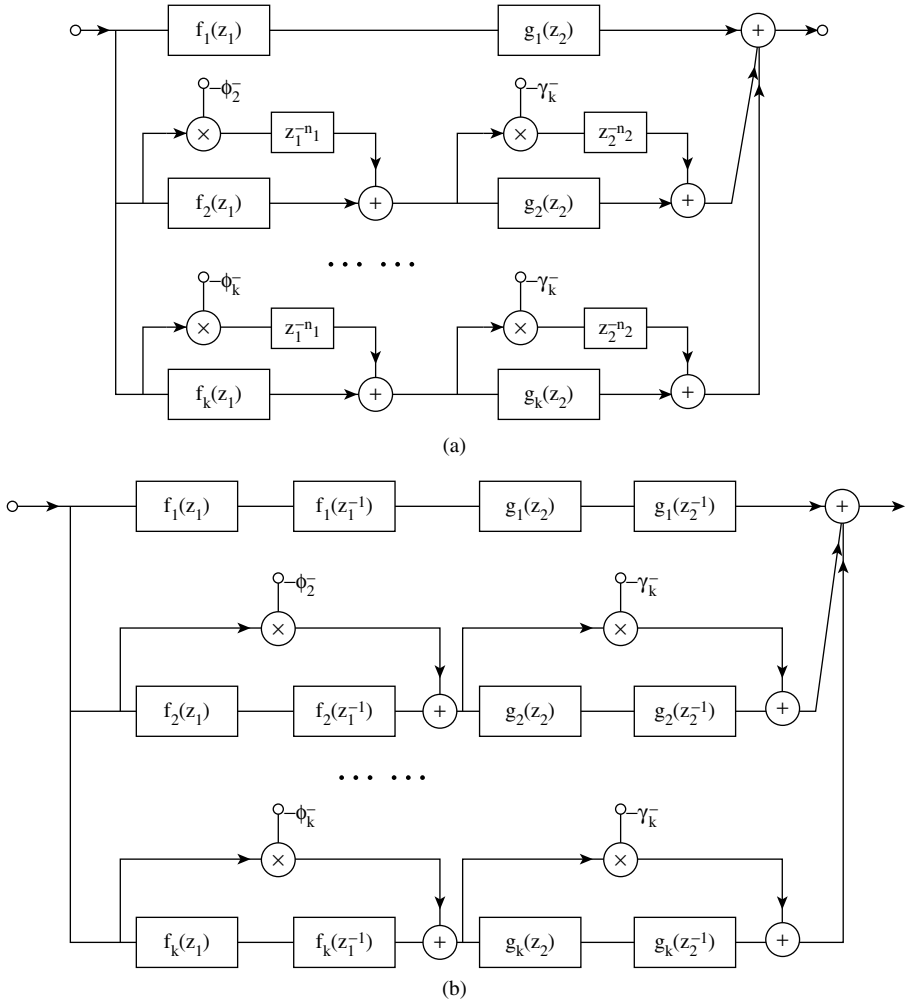

FIGURE 92.19 Configurations of 2-D IIR filter by SVD. (a) General structure of 2-D filter. (b) Structure using zero-phase IIR filters.

Error Compensation Procedure. When the main section and correction sections are designed by an optimization procedure as described above, approximation errors inevitably occur that will accumulate and manifest themselves as the overall error. The accumulation of error can be reduced by the following compensation procedure.

When filters F_1 and G_1 are designed, the approximation error matrix $\mathbf{E}_1$ can be calculated as

$$\mathbf{E}_1 = \mathbf{A} - f_1\left(e^{j\pi\mu_l}\right)g_1\left(e^{j\pi\nu_m}\right) \tag{92.106}$$

and then perform SVD on $\mathbf{E}_1$ to obtain

$$\mathbf{E}_1 = S_{22}\mathbf{f}_{22}\mathbf{g}_{22}^T + \cdots + S_{r2}\mathbf{f}_{r2}\mathbf{g}_{r2}^T \tag{92.107}$$

Data $\boldsymbol{\phi}_{22}$ and $\boldsymbol{\gamma}_{22}$ can be used to deduce filters $f_2(z_1)$ and $g_2(z_2)$. Thus, the first correction section can be designed. Next, form the error matrix $\mathbf{E}_2$ as

$$\mathbf{E}_2 = \mathbf{E}_1 - S_{22}f_2\left(e^{j\pi\mu_l}\right)g_2\left(e^{j\pi\nu_m}\right) \tag{92.108}$$

© 2003 by CRC Press LLC

and then perform SVD on $\mathbf{E}_2$ to obtain

$$\mathbf{E}_2 = \mathbf{S}_{33}\mathbf{f}_{33}\mathbf{g}_{33}^T + \ldots + S_{r3}\mathbf{f}_{r3}\mathbf{g}_{r3}^T \tag{92.109}$$

and use data $\boldsymbol{\phi}_{33}$ and $\boldsymbol{\gamma}_{33}$ to design the second correction section. The procedure is continued until the norm of the error matrix becomes sufficiently small that a satisfactory approximation to the desired amplitude response is reached.

Design of 1-D filters by using optimization can sometimes yield unstable filters. This problem can be eliminated by replacing poles outside the unit circle of the z plane by their reciprocals and simultaneously adjusting the multiplier constant to compensate for the change in gain [19].

Example 7 [26]. Design a circularly symmetric, zero-phase 2-D filter specified by

$$\left|H(\omega_1, \omega_2)\right| = \begin{cases} 1 & \text{for } \left(\omega_1^2 + \omega_2^2\right)^{1/2} \le 0.35\pi \\ 0 & \text{for } \left(\omega_1^2 + \omega_2^2\right)^{1/2} \ge 0.65\,\pi \end{cases}$$

assuming that $\omega_{s1} = \omega_{s2} = 2\pi$.

Solution.

1. Construct a sampled amplitude response matrix. By taking $L = M = 21$ and assuming that the amplitude response varies linearly with the radius in the transition band, the amplitude response matrix can be obtained as

$$\mathbf{A} = \begin{vmatrix} \mathbf{A}_1 & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \end{vmatrix}_{21\times 21}$$

where

$$\mathbf{A} = \begin{vmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 0.75 & 0.5 & 0.25 & 0 & 0 & 0 & 0 \\
1 & 1 & 1 & 0.75 & 0.75 & 0.5 & 0.25 & 0 & 0 & 0 & 0 & 0 \\
1 & 0.75 & 0.75 & 0.5 & 0.5 & 0.25 & 0 & 0 & 0 & 0 & 0 & 0 \\
0.75 & 0.5 & 0.5 & 0.25 & 0.25 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0.5 & 0.25 & 0.25 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0.25 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{vmatrix}$$

The ideal amplitude response of the filter is illustrated in Fig. 92.20(a).

© 2003 by CRC Press LLC

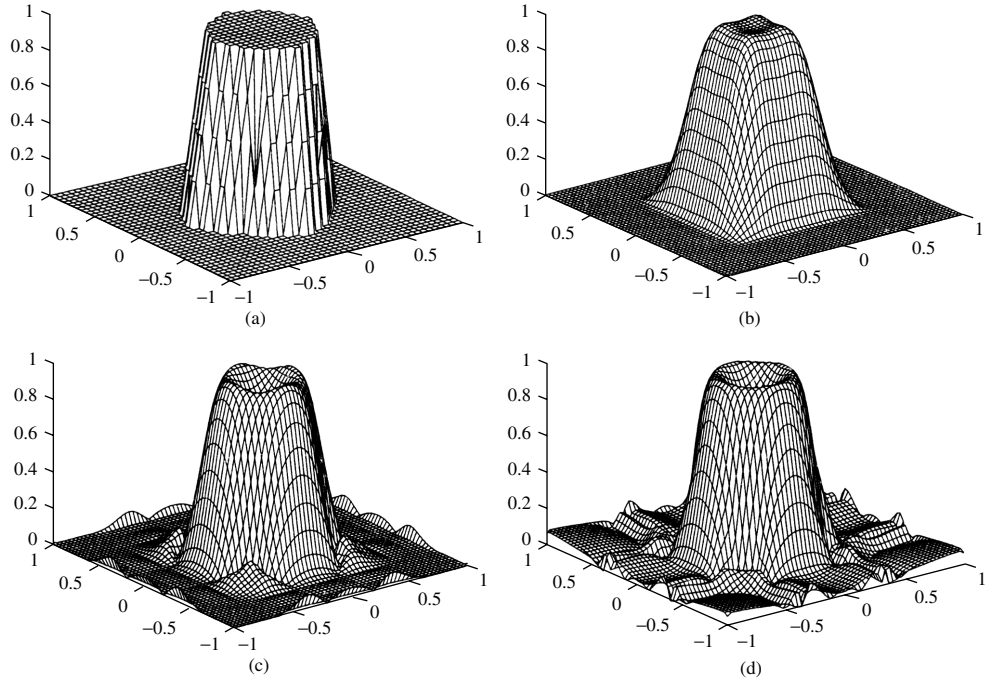

FIGURE 92.20 Amplitude responses of (a) the ideal circularly symmetric 2-D filter, (b) the main section, (c) the main section plus the first correction, (d) the main section plus the first and second correction sections.

2. Perform SVD to matrix **A** to obtain the amplitude response of the main section of the 2-D filter. It is worth noting that when a circularly symmetric 2-D filter is required, matrix **A** is symmetric and, therefore, (92.95) becomes

$$\mathbf{A} = \sum_{i=1}^{r} S_i \mathbf{f}_i \mathbf{f}_i^T \tag{92.110}$$

where $S_1 = 1$ and $S_i = \pm 1$ or -1, for $2 \le i \le r$. This implies that each parallel section requires only one 1-D subfilter to be designed. As a consequence the design work is reduced by 50 percent.

When vector $\boldsymbol{\phi}_1$ is obtained, by selecting a fourth-order approximation and after optimization, the transfer function of the main section $f_1(z)$ is obtained.

3. Design the correction sections. Successively perform SVD to the error $\mathbf{E}_1$ and $\mathbf{E}_2$, and apply the preceding design technique; the transfer functions of the first and second correction sections can be obtained.

The transfer function of the main section and the first and second correction sections are listed in Table 92.3. And the amplitude responses of (i) the main section, (ii) the main section plus the first correction, and (iii) the main section plus the first and second correction sections are depicted in Fig. 92.20(b)–(d).

Method of Deng and Kawamata

In decomposing 2-D amplitude specifications into 1-D ones, the conventional SVD cannot avoid the problem that the 1-D amplitude specifications that result are often negative. Since negative values cannot be viewed as amplitude response, the problem of 1-D digital filter design becomes intricate. Deng and Kawamata [28] proposed a procedure that guarantees all the decomposition results to be always non-negative and thus simplifies the design of correction sections.

TABLE 92.3 Design Based on Fourth-Order Subfilters (Example 7)

The main section	$f_1(z)=0.1255\dfrac{\left(z^2+0.7239z+1\right)\left(z^2+1.6343z+1\right)}{\left(z^2+0.1367z+1\right)\left(z^2-0.5328z+0.2278\right)}$
The first correction section	$f_2(z)=0.6098\dfrac{\left(z^2+1.1618z+0.1661\right)\left(z^2+0.8367z+0.9958\right)}{\left(z^2+0.9953z\right)\left(z^2+0.5124z+0.32\right)}$
	$S_2=-1,\ \phi_2^-=0.6266$
The second correction section	$f_3(z)=0.4630\dfrac{\left(z^2+1.5381z+0.4456\right)\left(z^2-1.397z+1.1191\right)}{\left(z^2+2.0408z-1\right)\left(z^2-0.7092z+0.6961\right)}$
	$S_3=+1,\ \phi_3^-=0.2764$

The method decomposes the matrix **A** into the form

$$\mathbf{A}=\sum_{i=1}^{r}S_i\mathbf{F}_i\mathbf{G}_i \tag{92.111}$$

where all the elements of $\mathbf{F}_i$ and $\mathbf{G}_i$ are nonnegative and the decomposition error

$$\mathbf{E}=\left\|\mathbf{A}-\sum_{i=1}^{r}\mathbf{S}_i\mathbf{F}_i\mathbf{G}_i\right\| \tag{92.112}$$

is sufficiently small, and $S_i = 1$ or -1 for $i = 1, 2 \ldots, r$.

The design procedure can be desired as follows.

STEP 1. Let $\mathbf{A}_1^+=\mathbf{A},\ \mathbf{A}_1^-=0$, and perform the SVD on $\mathbf{A}_1^+$ as

$$\mathbf{A}_1^+=\sum_{i=1}^{r_1}\sigma_{1i}\mathbf{u}_{1i}\mathbf{v}_{1i}\approx\mathbf{F}_1^+\,\mathbf{G}_1^+ \tag{92.113}$$

where σ_{1i} is the ith singular value of $\mathbf{A}_1^+(\sigma_{11}\ge\sigma_{12}\ge\cdots\ge\sigma_{1r_1})$ and $\mathbf{F}_1^+=u_{11}\sigma_{11}^{1/2},\ \mathbf{G}_1^+=\sigma_{11}^{1/2}v_{11}$.

Let

$$\mathbf{F}_1=\mathbf{F}_1^+,\mathbf{G}_1=\mathbf{G}_1^+,S_1=1 \tag{92.114}$$

all the elements of $\mathbf{F}_1$ and $\mathbf{G}_1$ are nonnegative.

STEP 2. Calculate the approximation error matrix $\mathbf{A}_2$ and decompose it into the sum of $\mathbf{A}_2^+$ and $\mathbf{A}_2^-$ as

$$\mathbf{A}_2=\mathbf{A}-S_1\mathbf{F}_1\mathbf{G}_1=\mathbf{A}_2^++\mathbf{A}_2^- \tag{92.115}$$

where

$$\mathbf{A}_2^+(m,n)=\begin{cases}A_2(m,n) & if\ A_2(m,n)\ge 0\\ 0 & \text{otherwise}\end{cases} \tag{92.116}$$

and

$$\mathbf{A}_2^-(m,n)=\begin{cases}A_2(m,n) & \text{if } A_2(m,n)\le 0\\ 0 & \text{otherwise}\end{cases} \tag{92.117}$$

© 2003 by CRC Press LLC

To determine S_2 and $\mathbf{F}_2$ and $\mathbf{G}_2$ for approximating $\mathbf{A}_2$ as accurately as possible, the following three steps are involved.

1. Perform the SVD on $\mathbf{A}_2^+$ and approximate it as

$$\mathbf{A}_2^+ = \sum_{i=1}^{r_2} \mathbf{s}_{2i}\mathbf{u}_{2i}\mathbf{v}_{2i} \approx \mathbf{F}_2^+\mathbf{G}_2^+ \tag{92.118}$$

where $\mathbf{F}_2^+ = \mathbf{u}_{21}\sigma_{21}^{1/2}$, $\mathbf{G}_2^+ = \sigma_{21}^{1/2}\mathbf{v}_{21}$. All the elements of $\mathbf{F}_2^+$ and $\mathbf{G}_2^+$ and G* are nonnegative. If $\mathbf{F}_2 = \mathbf{F}_2^+$, $\mathbf{G}_2 = \mathbf{G}_2^+$, and $S_2 = 1$, the approximation error is

$$\mathbf{E}_2^+ = \left\| \mathbf{A} - \sum_{i=1}^{2} \mathbf{S}_i\mathbf{F}_i\mathbf{G}_i \right\| \tag{92.119}$$

2. Perform the SVD on $-\mathbf{A}_2^-$ and approximate it as

$$-\mathbf{A}_2^- = \sum_{i=1}^{r_{2-}} \sigma_{2i-}\,\mathbf{u}_{2i-}\mathbf{v}_{2i-} \approx \mathbf{F}_2^-\,\mathbf{G}_2^- \tag{92.120}$$

where $\mathbf{F}_2^- = \mathbf{u}_{21-}\ \sigma_{21-}^{1/2}$, $\mathbf{G}_2^- = \sigma_{21-}^{1/2}\mathbf{v}_{21-}$, and r_{2-} is the rank of $-\mathbf{A}_2^-$. All the elements of $\mathbf{F}_2^-$ and $\mathbf{G}_2^-$ are nonnegative. If $\mathbf{F}_2 = \mathbf{F}_2^-$, $\mathbf{G}_2 = \mathbf{G}_2^-$, and $S_2 = 1$, the approximation error $\mathbf{E}_2^-$ is

$$\mathbf{E}_2^- = \left\| \mathbf{A} - \sum_{i=1}^{2} S_i\mathbf{F}_i\mathbf{G}_i \right\| \tag{92.121}$$

3. According to the results from steps 1 and 2, the optimal vectors $\mathbf{F}_2$ and $\mathbf{G}_2$ for approximating $\mathbf{A}$ are determined as

$$\mathbf{F}_2 = \mathbf{F}_2^+,\ \mathbf{G}_2 = \mathbf{G}_2^+,\ S_2 = 1 \quad \text{if } \mathbf{E}_2^+ \le \mathbf{E}_2^-$$

$$\mathbf{F}_2 = \mathbf{F}_2^-,\ \mathbf{G}_2 = \mathbf{G}_2^-,\ S_2 = -1 \quad \text{if } \mathbf{E}_2^+ \ge \mathbf{E}_2^-$$

Successively decomposing the approximation error matrices $\mathbf{A}j$ ($j = 3, 4, \cdots, r$) in the same way above described, a good approximation of matrix $\mathbf{A}$ can be obtained as in (92.111).

STEP 3. With the matrix $\mathbf{A}$ being decomposed into nonnegative vectors, the 1-D subfilters are designed through an optimization procedure, and a 2-D filter can then be readily realized, as shown in Fig. 92.21.

It is noted that, in addition to SVD based methods as described in this subsection, design method based on other decomposition is also possible [29].

Design Based on Two-Variable Network Theory

Ramamoorthy and Bruton proposed a design method of 2-D IIR filters that always guarantees the stability of a filter and that involves the application of two-variable (2-*V*) strictly Hurwitz polynomials [30]. A 2-*V* polynomial $b(s_1, s_2)$ is said to be strictly Hurwitz if

$$b(s_1, s_2) \neq 0 \quad \text{for} \quad \mathrm{Re}\{s_1\} \ge 0 \quad \text{and} \quad \mathrm{Re}\{s_2\} \ge 0 \tag{92.122}$$

In their method, a family of 2-*V* strictly Hurwitz polynomials is obtained by applying network theory [31], [32] to the frequency-independent, 2-*V* lossless network illustrated in Fig. 92.22. The network has

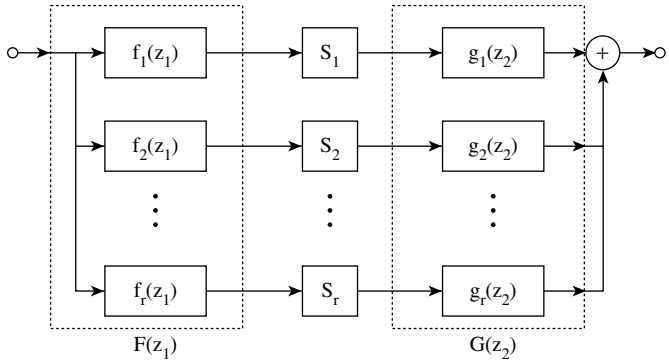

FIGURE 92.21 2-D filter realization based on iterative SVD.

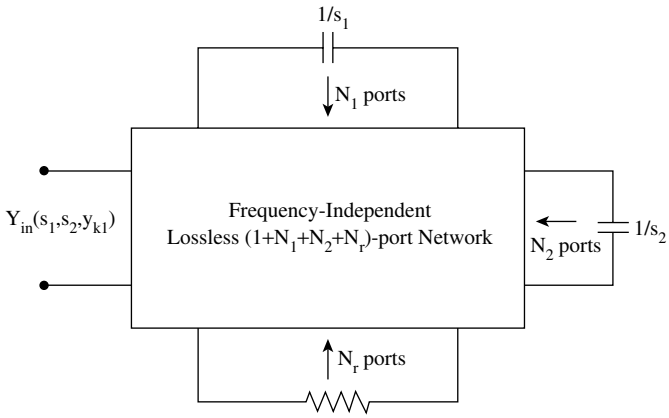

FIGURE 92.22 A $(1 + N_1 + N_2 + N_r)$-port 2-*V* lossless network.

$1 + N_1 + N_2 + N_r$ ports and N_1 and N_2 are terminated in unit capacitors in complex variables s_1 and s_2, respectively, and N_r is terminated in unit resistors. Since the network is lossless and frequency independent, its admittance matrix **Y** is a real and skew-symmetric matrix given by

$$\mathbf{Y} = \begin{vmatrix} 0 & y_{12} & y_{12} & \cdots & y_{1N} \\ -y_{12} & 0 & y_{23} & \cdots & y_{2N} \\ -y_{13} & -Y_{23} & 0 & \cdots & y_{3N} \\ \cdots\cdots & & & & \\ -y_{1N} & -y_{2N} & -y_{3N} & \cdots & 0 \end{vmatrix} = \begin{vmatrix} \mathbf{Y}_{11} & \mathbf{Y}_{12} \\ -\mathbf{Y}_{12}^T & \mathbf{Y}_{22} \end{vmatrix} \quad N = 1 + N_1 + N_2 + N_r \tag{92.123}$$

If we define

$$\mathbf{Y}_{22}(s_1, s_2, y_{kl}) = \mathbf{Y}_{22} + \mathbf{diag}\left\{1 \cdots 1 \;\; \overset{N_r}{s_1 \cdots s_1} \;\; \overset{N_1}{s_2 \cdots s_2} \;\; \overset{N_2}{}\right\} \tag{92.124}$$

TABLE 92.4 2-*V* Strictly Hurwitz Polynomials

N_1	N_2	N	$\Delta(s_1, s_2, y_{kl})$
1	1	4	$s_1s_2 + y_{24}^2 s_1 + y_{23}^2 s_2 + y_{34}^2$
2	1	5	$s_1^2 s_2 + y_{25}^2 s_1^2 + \left(y_{23}^2\right)\left(y_{23}^2 + y_{24}^2\right)s_1 s_2 + \left(y_{35}^2 + y_{45}^2\right)s_1 + y_{34}^2 s_2$ $+ \left(y_{23}y_{46} - y_{24}y_{35} + y_{25}y_{34}\right)^2$
2	2	6	$s_1^2 s_2^2 + \left(y_{23}^2 + y_{24}^2\right)s_1 s_2^2 + \left(y_{25}^2 + y_{26}^2\right)s_1^2 s_2 + y_{56}^2 s_1^2 + y_{34}^2 s_2^2$ $+ \left(y_{35}^2 + y_{36}^2 - y_{45}^2 + y_{46}^2\right)s_1 s_2 + y_{34}^2 s_2 + \left[\left(y_{23}y_{56} - y_{25}y_{36} + y_{26}y_{35}\right)^2\right.$ $\left. + \left(y_{24}y_{56} - y_{25}y_{46} + y_{26}y_{45}\right)^2\right]s_1 + \left[\left(y_{23}y_{45} - y_{24}y_{35} + y_{25}y_{34}\right)^2\right.$ $\left. + \left(y_{23}y_{46} - y_{24}y_{36} + y_{26}y_{34}\right)^2\right]s_2 + \left(y_{34}y_{56} - y_{35}y_{46} + y_{36}y_{45}\right)^2$

and

$$\mathbf{\Delta}(s_1, s_2, y_{kl}) = \det\left[\mathbf{\Psi}_{22}(s_1, s_2, y_{kl})\right] \tag{92.125}$$

where diag$(1\cdots1 \quad s_1\cdots s_1 \quad s_2\cdots s_2)$ represents a diagonal matrix in which each of the first N_r elements is unity, each of the next N_1 elements is s_1, and each of the last N_2, elements is s_2. Then, from the network theory, the input admittance at port 1 is given by

$$\begin{aligned}\mathbf{Y_{in}}(s_1, s_2, y_{kl}) &= \frac{\mathbf{Y}_{12}\mathbf{adj}\left[\mathbf{Y}_{22}(s_1, s_2, y_{kl})\right]\mathbf{Y}_{12}^T}{\det\left[\mathbf{Y}_{22}(s_1, s_2, y_{kl})\right]} \\ &= \frac{p(s_1, s_2, y_{kl})}{\Delta(s_1, s_2, y_{kl})}\end{aligned} \tag{92.126}$$

where $\Delta(s_1, s_2, y_{kl})$ is defined by (92.125) and is a strictly Hurwitz polynomial for any set of real values of the $(N-1)$ $(N-2)/2$ independent parameters $\{y_{kl}: 1 < k < l \le N\}$. Table 92.4 lists polynomial $\Delta(s_1, s_2, y_{kl})$ for $N_r = 1$ $(N_1, N_2) = (2, 1)$ and $(N_1, N_2) = (2, 2)$ [30].

Having obtained the parameterized strictly Hurwitz polynomial $\Delta(s_1, s_2, y_{kl})$ the design procedure of a 2-D IIR filter can be summarized as follows.

STEP 1. Construct a parameterized analog transfer function of the 2-D IIR filter, by using the Hurwitz polynomial $\Delta(s_1, s_2, y_{kl})$

$$H(s_1, s_2, y_{kl}, a_{ij}) = \frac{p(s_1, s_2)}{\Delta(s_1, s_2, y_{kl})} \tag{92.127}$$

where

$$p(s_1, s_2) = \sum_{i=1}^{N_1}\sum_{j=1}^{N_2} a_{ij}s_1^i s_2^j$$

is an arbitrary 2-*V* polynomial in s_1 and s_2 with degree in each variable not greater than the corresponding degree of the denominator.

© 2003 by CRC Press LLC

STEP 2. Perform the double bilinear transformation to the parameterized analog transfer function obtained in step 1.

$$H\left(z_1, z_2, y_{kl}, a_{ij}\right) = \left.\frac{p\left(s_1, s_2\right)}{\Delta\left(s_1, s_2, y_{kl}\right)}\right|_{s_i = 2\left(z_i - 1\right)/T_i\left(z_i + 1\right),\ i = 1,\ 2} \tag{92.128}$$

STEP 3. Construct an objective function according to the given design specifications and the parameterized discrete transfer function obtained in step 2.

$$J\left(\mathbf{x}\right) = \sum_{n_1} \sum_{n_2} \left[M\left(n_1, n_2\right) - M_I\left(n_1, n_2\right)\right]^p \tag{92.129}$$

where p is an even positive, $M(n_1, n_2)$ and $M_I(n_1, n_2)$ are the actual and desired amplitude responses, respectively, of the required filter at frequencies $(\omega_{1n_1}, \omega_{1n_2})$, and $\mathbf{x}$ is the vector consisting of parameters $\{y_{kl}: 1 < k < l \le N\}$ and $\{a_{ij}, 0 \le i \le N_1, 0 \le j \le N_2\}$.

STEP 4. Apply an optimization algorithm to find the optimal vector $\mathbf{x}$ that minimizes the objective function and substitute the resulting x into (92.128) to obtain the required transfer function $H(z_1, z_2)$.

Example 8[33]. By using the preceding approach, design a 2-D circularly symmetric low-pass filter of order (5, 5) with $\omega_p = 0.2\ \pi$, assuming that $\omega_{s1} = \omega_{s2} = 1.2\ \pi$.

Solution.

1. Construct the desired amplitude response of the desired filter

$$M_I\left(\omega_{1n_1}, \omega_{2n_2}\right) = \begin{cases} 1 & \text{for } \left(\omega_{1n_1}^2 + \omega_{2n_2}^2\right) \le 0.2\ \pi \\ 0 & \text{otherwise} \end{cases}$$

   where

$$\omega_{1n_1} = \begin{cases} 0.01\pi n_2 & \text{for } 0 \le n_1 \le 20 \\ 0.01\pi n_1 & \text{for } 21 \le n_1 \le 24 \end{cases}$$

   and

$$\omega_{2n_2} = \omega_{1(24 - n_2)} \qquad \text{for } 0 \le n_2 \le 24$$

2. Construct the 2-D analog transfer function and perform double bilinear transformation to obtain the discrete transfer function. The analog transfer function at hand is assumed to be an all-pole transfer function of the form

$$\mathbf{H}\left(s_1, s_2, \mathbf{x}\right) = \frac{1}{\mathbf{D}\left(s_1, s_2, y_{kl}\right)}$$

   Therefore, the corresponding discrete transfer function can be written as

$$H\left(z_1, z_2, \mathbf{x}\right) = \frac{A\left(z_1 + 1\right)^5 \left(z_2 + 1\right)^5}{\sum_{i=0}^{5} \sum_{j=0}^{5} b_{ij}\, z_1^i z_2^j} \tag{92.130}$$

93.1 Introduction

Two-dimensional (2-D) digital filters find applications in many fields such as image processing and seismic signal processing. Design of 2-D digital filters is more complicated than 1-D digital filters because of the increase in the number of coefficients with the increase in the dimension and also the difficulty of testing their stability. Fortunately, 2-D frequency responses possess many types of symmetries and the presence of these symmetries can be used to reduce the complexity of the design as well as the implementation of these filters. Symmetry in a frequency response induces certain constraints on the coefficients of the filters, which in turn reduces the filter design complexity. Therefore, a study of the symmetries of the filter frequency responses and the resulting constraints on the filter coefficients is undertaken in this chapter. As there is a close relation between digital and analog filter functions, symmetry properties are discussed in this chapter for both analog and digital domain functions. In the following, symmetries are defined, the symmetry constraints on polynomials are derived, procedures to design 2-D filters employing symmetry constraints are presented, and finally several examples are presented to illustrate the application of symmetry-based design procedure.

93.2 Definitions and Notations

Definition 1: Frequency Response

Let $P(s_1, s_2)$ be a 2-D s-domain polynomial with complex coefficients. Its frequency response is given by $P(j\omega_1, j\omega_2)$ where ω_1 and ω_2 are the radian frequencies. The magnitude squared function of the frequency response is given by:

$$\begin{aligned} F(\omega_1, \omega_2) &= P(j\omega_1, j\omega_2) \cdot P^*(-j\omega_1, -j\omega_2) \\ &= P(s_1, s_2) \cdot P^*(-s_1, -s_2)\big|_{s_i = j\omega_i}, \qquad \text{i} = 1, 2 \end{aligned} \tag{93.1}$$

where P^* is obtained by complex conjugating the coefficients of P.

For a 2-D z-domain polynomial $Q(z_1, z_2)$ with complex coefficients, its frequency response is given by $Q(e^{j\theta_1}, e^{j\theta_2})$. Note that $\theta_i = \omega_i T$, where ω_1 and ω_2 are the same analog radian frequencies as above, and T is the sampling period. The magnitude squared function of the frequency response is given by:

$$\begin{aligned} F(\theta_1, \theta_2) &= Q(e^{j\theta_1}, e^{j\theta_2}) \cdot Q^*(e^{-j\theta_1}, e^{-j\theta_2}) \\ &= Q(z_1, z_2) \cdot Q^*(z_1^{-1}, z_2^{-1})\big|_{z_i = e^{j\theta_i}}, \quad \text{i} = 1, 2 \end{aligned} \tag{93.2}$$

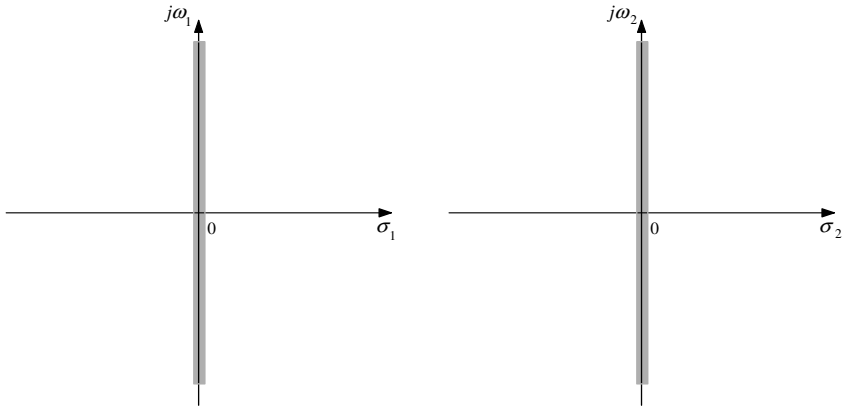

FIGURE 93.1 (s_1, s_2) biplane. (The frequency response is evaluated on the imaginary axes, $s_i = j\omega_i$.)

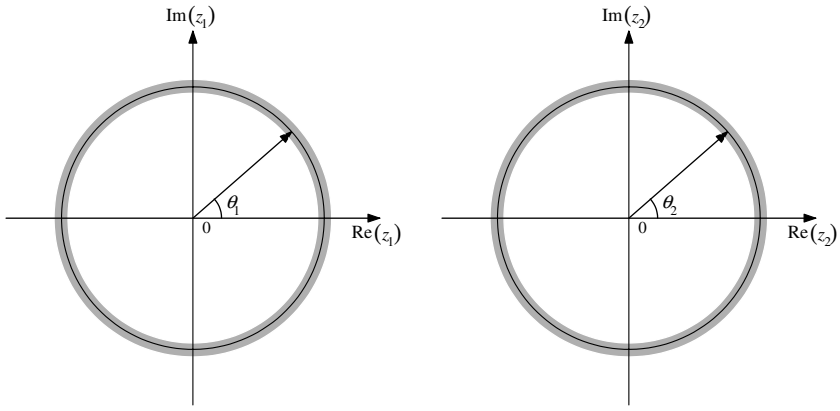

FIGURE 93.2 (z_1, z_2) biplane. (The frequency response is evaluated on the unit circles, $z_i = e^{j\theta_i}$.)

© 2003 by CRC Press LLC

where Q^* is obtained by complex conjugating the coefficients of Q.

It can be seen that if P and Q are real coefficient polynomials, $F(\omega_1,\omega_2) = F(-\omega_1,-\omega_2)$ and $F(\theta_1,\theta_2) = F(-\theta_1,-\theta_2)$. Therefore, a real polynomial, analog or digital, always possesses 180° rotational symmetry (defined later as centro symmetry).

Definition 2: Paraconjugate Operation

The paraconjugate of an analog polynomial $P(s_1,s_2)$ is defined as:

$$P_*(s_1,s_2) = P^*(-s_1,-s_2) \tag{93.3}$$

The subscript "*" indicates the paraconjugate of a polynomial, whereas the superscript "*" indicates the complex conjugation of coefficients alone.

Then in terms of the paraconjugate of a polynomial, the magnitude squared function of $P(s_1,s_2)$ can be expressed as:

$$F(\omega_1,\omega_2) = P(s_1,s_2)\cdot P_*(s_1,s_2)\Big|_{s_i=j\omega_i\ ,\ i=1,2} \tag{93.4}$$

The paraconjugate operation can also be performed w.r.t. a single variable, s_1 or s_2:

$$P_{*_{s_1}}(s_1,s_2) = P^*(-s_1,s_2) \tag{93.5}$$

$$P_{*_{s_2}}(s_1,s_2) = P^*(s_1,-s_2) \tag{93.6}$$

The paraconjugate of a discrete-time polynomial $Q(z_1,z_2)$ is called the inverse polynomial, and is defined as:

$$Q_*(z_1,z_2) = Q^*(z_1^{-1},z_2^{-1}) \tag{93.7}$$

It may be noted that $Q(z_1,z_2)$ is considered to be a pseudo-polynomial, which may have negative powers as well.

The inverse operation for discrete-time polynomials can also be performed w.r.t. a single variable, z_1 or z_2.

$$Q_{*_{z_1}}(z_1,z_2) = Q^*(z_1^{-1},z_2) \tag{93.8}$$

$$Q_{*_{z_2}}(z_1,z_2) = Q^*(z_1,z_2^{-1}) \tag{93.9}$$

Definition 3: Self-Paraconjugate Polynomial

$P(s_1,s_2)$ is said to be self-paraconjugate or para-even if:

$$P_*(s_1,s_2) = P(s_1,s_2) \tag{93.10}$$

Henceforth, $P_e(s_1,s_2)$ will denote a para-even polynomial.

A polynomial can also be para-even w.r.t. a single variable s_i:

$$P_{*_{s_i}}(s_1,s_2) = P(s_1,s_2) \tag{93.11}$$

An example of a polynomial that is para-even w.r.t. s_1 is: $P_{e,s_1}(s_1,s_2) = s_1^{\,2} + s_2 + 1$.

© 2003 by CRC Press LLC

Definition 4: Anti-Self-Paraconjugate Polynomial

$P(s_1, s_2)$ is said to be anti-self-paraconjugate or para-odd if:

$$P_*(s_1, s_2) = -P(s_1, s_2) \tag{93.12}$$

Henceforth, $P_o(s_1, s_2)$ will denote a para-odd polynomial.

A polynomial can also be para-odd w.r.t. a single variable s_i:

$$P_{*_{s_i}}(s_1, s_2) = -P(s_1, s_2) \tag{93.13}$$

Para-even and para-odd in (s_1, s_2) correspond to self-inverse and anti-self-inverse in (z_1, z_2), respectively.

A discrete-time polynomial $Q(z_1, z_2)$ is self-inverse if:

$$Q_*(z_1, z_2) = Q(z_1, z_2) \tag{93.14}$$

$Q(z_1, z_2)$ is anti-self-inverse if:

$$Q_*(z_1, z_2) = -Q(z_1, z_2) \tag{93.15}$$

The discrete-time polynomial can also be self-inverse or anti-self-inverse w.r.t. a single variable, z_1 or z_2.

Property 1: Unique Decomposition of Polynomials

Any analog polynomial can be expressed as the sum of a para-even and a para-odd polynomial. That is,

$$P(s_1, s_2) = P_e(s_1, s_2) + P_o(s_1, s_2) \tag{93.16}$$

From the above, $P_e(s_1, s_2)$ and $P_o(s_1, s_2)$ are given by:

$$P_e(s_1, s_2) = \frac{P(s_1, s_2) + P_*(s_1, s_2)}{2} \tag{93.17}$$

$$P_o(s_1, s_2) = \frac{P(s_1, s_2) - P_*(s_1, s_2)}{2} \tag{93.18}$$

The same holds when we deal with the operation w.r.t. a single variable s_i:

$$P(s_1, s_2) = P_{e,s_i}(s_1, s_2) + P_{o,s_i}(s_1, s_2) \tag{93.19}$$

where

$$P_{e,s_i}(s_1, s_2) = \frac{P(s_1, s_2) + P_{*_{s_i}}(s_1, s_2)}{2} \tag{93.20}$$

$$P_{o,s_i}(s_1, s_2) = \frac{P(s_1, s_2) - P_{*_{s_i}}(s_1, s_2)}{2} \tag{93.21}$$

In (93.20) and (93.21), if $i = 1$, then we have a polynomial restricted in s_1 and general in s_2. In such a case, we can further decompose into para-even and para-odd w.r.t. s_2 variable. In other words, $P(s_1, s_2)$ can be expressed as:

$$P(s_1, s_2) = P_{e,s_1,s_2}(s_1, s_2) + P_{o,s_1,s_2}(s_1, s_2) + P_{o,s_1;e,s_2}(s_1, s_2) + P_{e,s_1;o,s_2}(s_1, s_2) \tag{93.22}$$

© 2003 by CRC Press LLC

More specifically,

$$P(s_1,s_2) = P_1(s_1^2,s_2^2) + s_1 s_2 P_2(s_1^2,s_2^2) + s_1 P_3(s_1^2,s_2^2) + s_2 P_4(s_1^2,s_2^2) \tag{93.23}$$

The above (s_1,s_2) decomposition is the most general w.r.t. para-conjugate operation. It compares as follows to the standard decomposition in discrete-time (z_1,z_2):

$$Q(z_1,z_2) = Q_1(x_1,x_2) + y_1 y_2 Q_2(x_1,x_2) + y_1 Q_3(x_1,x_2) + y_2 Q_4(x_1,x_2) \tag{93.24}$$

where $x_i = z_i + z_i^{-1}$ and $y_i = z_i - z_i^{-1}$, $i = 1, 2$.

93.3 Symmetry Definitions

Centro Symmetry

$F(\omega_1, \omega_2)$ is said to possess centro symmetry if

$$F(\omega_1,\omega_2) = F(-\omega_1,-\omega_2), \quad \forall\ (\omega_1,\omega_2) \tag{93.25}$$

Quadrantal Symmetry

$F(\omega_1, \omega_2)$ is said to possess quadrantal symmetry if

$$F(\omega_1,\omega_2) = F(-\omega_1,\omega_2) = F(\omega_1,-\omega_2) = F(-\omega_1,-\omega_2), \quad \forall\ (\omega_1,\omega_2) \tag{93.26}$$

Diagonal Symmetry

$F(\omega_1, \omega_2)$ is said to possess diagonal symmetry if

$$F(\omega_1,\omega_2) = F(\omega_2,\omega_1) = F(-\omega_1,-\omega_2) = F(-\omega_2,-\omega_1), \quad \forall\ (\omega_1,\omega_2) \tag{93.27}$$

Fourfold (90°) Rotational Symmetry

$F(\omega_1, \omega_2)$ is said to possess fourfold (90°) rotational symmetry if

$$F(\omega_1,\omega_2) = F(-\omega_2,\omega_1) = F(-\omega_1,-\omega_2) = F(\omega_2,-\omega_1), \quad \forall\ (\omega_1,\omega_2) \tag{93.28}$$

Octagonal Symmetry

$F(\omega_1, \omega_2)$ is said to possess octagonal symmetry if

$$\begin{aligned} F(\omega_1,\omega_2) &= F(\omega_2,\omega_1) = F(-\omega_2,\omega_1) = F(-\omega_1,\omega_2) = F(-\omega_1,-\omega_2) \\ &= F(-\omega_2,-\omega_1) = F(\omega_2,-\omega_1) = F(\omega_1,-\omega_2), \qquad \forall\ (\omega_1,\omega_2) \end{aligned} \tag{93.29}$$

The following are some important observations:

a) Since real polynomials always satisfy $F(\omega_1,\omega_2) = F(-\omega_1,-\omega_2)$ (centro symmetry), $F(\omega_1,\omega_2) = F(\omega_1,-\omega_2)$ is enough to ensure quadrantal symmetry, and $F(\omega_1,\omega_2) = F(\omega_2,\omega_1)$ is enough to ensure diagonal symmetry. For fourfold 90° rotational symmetry, the condition $F(\omega_1,\omega_2) = F(-\omega_2,\omega_1)$ is sufficient.

b) Octagonal symmetry is a combination of quadrantal, diagonal, and fourfold rotational symmetries. The presence of any two of the three symmetries implies the existence of the third, and is sufficient to guarantee octagonal symmetry.

© 2003 by CRC Press LLC

TABLE 93.1 Definitions of Various Symmetries in Discrete Domain in Terms of (θ_1,θ_2)

1. Centro symmetry	$F(\theta_1,\theta_2) = F(-\theta_1,-\theta_2),\ \forall\ (\theta_1,\theta_2)$
2. Quadrantal symmetry	$F(\theta_1,\theta_2) = F(-\theta_1,\theta_2) = F(\theta_1,-\theta_2)$ $= F(-\theta_1,-\theta_2),\ \forall\ (\theta_1,\theta_2)$
3. Diagonal symmetry	$F(\theta_1,\theta_2) = F(\theta_2,\theta_1) = F(-\theta_1,-\theta_2)$ $= F(-\theta_2,-\theta_1),\ \forall\ (\theta_1,\theta_2)$
4. Fourfold (90°) rotational symmetry	$F(\theta_1,\theta_2) = F(-\theta_2,\theta_1) = F(-\theta_1,-\theta_2)$ $= F(\theta_2,-\theta_1),\ \forall\ (\theta_1,\theta_2)$
5. Octagonal symmetry	$F(\theta_1,\theta_2) = F(\theta_2,\theta_1) = F(-\theta_2,\theta_1)$ $= F(-\theta_1,\theta_2) = F(-\theta_1,-\theta_2)$ $= F(-\theta_2,-\theta_1) = F(\theta_2,-\theta_1)$ $= F(\theta_1,-\theta_2),\quad \forall\ (\theta_1,\theta_2)$

The symmetry definitions discussed before are given w.r.t. the analog frequencies, (ω_1, ω_2). Since the digital frequency response is expressed in terms of (θ_1,θ_2), and $\theta_i = \omega_i T$, we can restate the symmetry conditions for discrete domain in terms of (θ_1,θ_2) (Table 93.1).

Figures 93.3 through 93.6 graphically show the various symmetries. The values of the magnitude function in the shaded regions are the same.

93.4 Spectral Forms for Magnitude Squared Function

In this section, we present the spectral forms of the magnitude squared function for the various symmetries.

Recall that the magnitude square function, $F(\omega_1, \omega_2)$, of a polynomial $P(s_1, s_2)$ is defined as:

$$F(\omega_1, \omega_2) = P(s_1, s_2) \cdot P(-s_1, -s_2)\Big|_{s_i = j\omega_i}, \quad \text{i} = 1, 2 \tag{93.30}$$

Analogous to (93.23), we can express the general magnitude squared function as:

$$F(\omega_1, \omega_2) = F_1(\omega_1^2, \omega_2^2) + \omega_1\omega_2 F_2(\omega_1^2, \omega_2^2) + j\omega_1 F_3(\omega_1^2, \omega_2^2) + j\omega_2 F_4(\omega_1^2, \omega_2^2) \tag{93.31}$$

A polynomial with real coefficients always possesses centro symmetry in its magnitude response. So,

$$F(\omega_1, \omega_2) = F(-\omega_1, -\omega_2)$$

Using (93.31), this can be written as:

$$\begin{aligned} & F_1(\omega_1^2, \omega_2^2) + \omega_1\omega_2 F_2(\omega_1^2, \omega_2^2) + j\omega_1 F_3(\omega_1^2, \omega_2^2) + j\omega_2 F_4(\omega_1^2, \omega_2^2) \\ & \quad = F_1(\omega_1^2, \omega_2^2) + \omega_1\omega_2 F_2(\omega_1^2, \omega_2^2) - j\omega_1 F_3(\omega_1^2, \omega_2^2) - j\omega_2 F_4(\omega_1^2, \omega_2^2) \\ \Leftrightarrow \quad & \omega_1 F_3(\omega_1^2, \omega_2^2) + \omega_2 F_4(\omega_1^2, \omega_2^2) = -\omega_1 F_3(\omega_1^2, \omega_2^2) - \omega_2 F_4(\omega_1^2, \omega_2^2) \end{aligned} \tag{93.32}$$

The above is only possible if $F_3(\omega_1^2, \omega_2^2) = 0$ and $F_4(\omega_1^2, \omega_2^2) = 0$.

Thus,

$$F(\omega_1, \omega_2) = F_1(\omega_1^2, \omega_2^2) + \omega_1\omega_2 F_2(\omega_1^2, \omega_2^2) \tag{93.33}$$

Using analytic continuation and (93.30), this can be written as:

$$\begin{aligned} P(s_1, s_2) \cdot P(-s_1, -s_2) &= F_1(s_1^2, s_2^2) + s_1 s_2 F_2(s_1^2, s_2^2) \\ &= \sum_{i=0}^{m_1}\sum_{j=0}^{n_1} a_{ij} s_1^{2i} s_2^{2j} + s_1 s_2 \sum_{i=0}^{m_2}\sum_{j=0}^{n_2} b_{ij} s_1^{2i} s_2^{2j} \end{aligned} \tag{93.34}$$

The above is the spectral form of the magnitude squared function possessing centro symmetry.

Now, for a real-coefficient $P(s_1, s_2)$ to possess quadrantal symmetry in its magnitude squared response, we need:

$$F(\omega_1, \omega_2) = F(\omega_1, -\omega_2)$$

Using (93.33), this can be written as:

$$F_1(\omega_1^2, \omega_2^2) + \omega_1\omega_2 F_2(\omega_1^2, \omega_2^2) = F_1(\omega_1^2, \omega_2^2) - \omega_1\omega_2 F_2(\omega_1^2, \omega_2^2) \tag{93.35}$$

The above is only possible if $F_2(\omega_1^2, \omega_2^2) = 0$. Thus,

$$F(\omega_1, \omega_2) = F_1(\omega_1^2, \omega_2^2) \tag{93.36}$$

where $a_{ij}=a_{ji}$ and $b_{ij}=b_{ji}$.	where $c_{ij}=c_{ji}$ and $d_{ij}=d_{ji}$.
Fourfold (90°) Rotational Symmetry	Fourfold (90°) Rotational Symmetry
$P(s_1,s_2)\cdot P(-s_1,-s_2)=\sum_{i=0}^{m_1}\sum_{j=0}^{n_1}a_{ij}s_1^{2i}s_2^{2j}+s_1s_2\sum_{i=0}^{m_2}\sum_{j=0}^{n_2}b_{ij}s_1^{2i}s_2^{2j}$	$Q(z_1,z_2)\cdot Q(z_1^{-1},z_2^{-1})=\sum_{i=0}^{m_1}\sum_{j=0}^{n_1}c_{ij}x_1^ix_2^j+y_1y_2\sum_{i=0}^{m_2}\sum_{j=0}^{n_2}d_{ij}x_1^ix_2^j$
where $a_{ij}=a_{ji}$ and $b_{ij}=-b_{ji}$.	where $c_{ij}=c_{ji}$ and $d_{ij}=-d_{ji}$.
Octagonal Symmetry	Octagonal Symmetry
$P(s_1,s_2)\cdot P(-s_1,-s_2)=\sum_{i=0}^{m_1}\sum_{j=0}^{n_1}a_{ij}s_1^{2i}s_2^{2j}$	$Q(z_1,z_2)\cdot Q(z_1^{-1},z_2^{-1})=\sum_{i=0}^{m_1}\sum_{j=0}^{n_1}c_{ij}x_1^ix_2^j$
where $a_{ij}=a_{ji}$.	where $c_{ij}=c_{ji}$.

[a] $x_i=z_i+z_i^{-1}$ and $y_i=z_i-z_i^{-1}$, $i=1,2$.

and so the spectral form for the magnitude squared function that possesses quadrantal symmetry is:

$$\begin{aligned}P(s_1,s_2)\cdot P(-s_1,-s_2)&=F_1(s_1^2,s_2^2)\\&=\sum_{i=0}^{m_1}\sum_{j=0}^{n_1}a_{ij}s_1^{2i}s_2^{2j}\end{aligned}\tag{93.37}$$

We can obtain the spectral forms for the other symmetries in a similar manner. They are listed in Table 93.2, together with the spectral forms for the z-domain functions.

93.5 Determination of 2-D Polynomials Possessing Various Symmetries

In this section, we present the polynomial factors that possess symmetry in their magnitude responses. We begin by showing the conditions that the s-domain polynomials must satisfy in order to possess the required symmetry. Then, the s-domain polynomial factors that satisfy those conditions are given. (The proof is provided for quadrantal symmetry). Finally, at the end of the section, the z-domain polynomial factors possessing symmetry are listed, alongside the analog polynomial factors.

© 2003 by CRC Press LLC

Quadrantal Symmetry for Analog Polynomials

Theorem 1

A polynomial $P(s_1,s_2)$ possesses quadrantal symmetry in its magnitude response if its factors either alone or jointly satisfy one of the following conditions:

1. $P(s_1,s_2) = P(s_1,-s_2)$ (93.38)
2. $P(s_1,s_2) = -P(s_1,-s_2)$ (93.39)
3. $P(s_1,s_2) = P(-s_1,s_2)$ (93.40)
4. $P(s_1,s_2) = -P(-s_1,s_2)$ (93.41)
5. $P(s_1,s_2) = P_1(s_1,s_2)\cdot P_1(s_1,-s_2)$ (93.42)
6. $P(s_1,s_2) = P_1(s_1,s_2)\cdot P_1(-s_1,s_2)$ (93.43)

Proof of Theorem 1

From Section 93.3, a magnitude squared response possesses quadrantal symmetry if:

$$F(\omega_1,\omega_2) = F(\omega_1,-\omega_2) \tag{93.44}$$

Applying (93.1), this can be written as:

$$P(j\omega_1,j\omega_2)\cdot P(-j\omega_1,-j\omega_2) = P(j\omega_1,-j\omega_2)\cdot P(-j\omega_1,j\omega_2)$$

Using analytic continuation, this becomes:

$$P(s_1,s_2)\cdot P(-s_1,-s_2) = P(s_1,-s_2)\cdot P(-s_1,s_2) \tag{93.45}$$

If we assume $P(s_1,s_2)$ to be irreducible, the unique factorization property of 2-variable polynomials states that $P(s_1,s_2)$ should satisfy one of the following two conditions:

i) $P(s_1,s_2) = k_1\cdot P(s_1,-s_2)$ where k_1 is a real constant. (93.46)

ii) $P(s_1,s_2) = k_2\cdot P(-s_1,s_2)$ where k_2 is a real constant. (93.47)

We first consider case (i) above. Substituting $s_2 = -s_2$ into (93.46), we obtain:

$$P(s_1,-s_2) = k_1\cdot P(s_1,s_2)$$

Substitute this back into (93.46), we get:

$$P(s_1,s_2) = k_1^{\,2}\cdot P(s_1,s_2) \tag{93.48}$$

© 2003 by CRC Press LLC

So, $k_1^2 = 1$, i.e., $k_1 = +1$ or -1. Thus, (93.46) becomes:

$$P(s_1, s_2) = \pm 1 \cdot P(s_1, -s_2) \tag{93.49}$$

With that, we have the first two conditions of Theorem 1, (93.38) and (93.39).

We now work on case (ii). Substituting $s_1 = -s_1$ into (93.47), we have:

$$P(-s_1, s_2) = k_2 \cdot P(s_1, s_2) \tag{93.50}$$

Substitute (93.50) back into (93.47), we get $k_2^2 = 1$, i.e., $k_2 = +1$ or -1. This gives us the next two conditions for Theorem 1, (93.40) and (93.41).

Thus far, we have assumed $P(s_1,s_2)$ to be irreducible. If $P(s_1,s_2)$ is reducible, then it can be expressed as a product of irreducible factors:

$$P(s_1, s_2) = k \cdot \prod_{i=1}^{N} P_i(s_1, s_2) \tag{93.51}$$

Let $P_i(s_1,s_2)$ be one such irreducible factor in $P(s_1,s_2)$. Invoking the unique factorization property on (93.45), we can see that $P_i(s_1,s_2)$ must be present in either $P(s_1,-s_2)$ or $P(-s_1,s_2)$ and thus must satisfy one of the following four conditions:

(a) $P_i(s_1, s_2) = k_1 \cdot P_i(s_1, -s_2)$
(b) $P_i(s_1,s_2) = k_2 \cdot P_j(s_1,s_2)$ where $i \neq j$
(c) $P_i(s_1,s_2) = k_3 \cdot P_i(-s_1,s_2)$
(d) $P_i(s_1,s_2) = k_4 \cdot P_j(-s_1,s_2)$ where $i \neq j$

Case (a) and (c) are identical to the ones for irreducible polynomials, so the previous results apply. We need only investigate cases (b) and (d) here.

For case (b),

$$P_i(s_1, s_2) = k_2 \cdot P_j(s_1, -s_2) \tag{93.52}$$

We solve for $P_j(s_1,s_2)$ by multiplying both sides by $1/k_2$ and substituting $s_2 = -s_2$:

$$P_j(s_1, s_2) = \frac{1}{k_2} \cdot P_i(s_1, -s_2) \tag{93.53}$$

$P_i(s_1,s_2) \cdot P_j(s_1,s_2)$ is a factor in $P(s_1,s_2)$. Using (93.53), this can be expressed as:

$$P_i(s_1, s_2) \cdot P_j(s_1, s_2) = P_i(s_1, s_2) \cdot \frac{1}{k_2} \cdot P_i(s_1, -s_2) \tag{93.54}$$

So, $P_i(s_1,s_2) \cdot P_i(s_1,-s_2)$ is a possible factor in $P(s_1,s_2)$. This proves (93.42) in Theorem 1.

Now, we work on case (d),

$$P_i(s_1, s_2) = k_4 \cdot P_j(-s_1, s_2) \tag{93.55}$$

Solving for $P_j(s_1,s_2)$:

$$P_j(s_1, s_2) = \frac{1}{k_4} \cdot P_i(-s_1, s_2) \tag{93.56}$$

Now using (93.56), the product of $P_i(s_1,s_2) \cdot P_j(s_1,s_2)$ can be expressed as:

$$P_i(s_1, s_2) \cdot P_j(s_1, s_2) = P_i(s_1, s_2) \cdot \frac{1}{k_4} \cdot P_i(-s_1, s_2) \tag{93.57}$$

© 2003 by CRC Press LLC

Therefore, $P_i(s_1,s_2) \cdot P_i(-s_1,s_2)$ is a factor in $P(s_1,s_2)$ and this corresponds to (93.43) in Theorem 1. This concludes the proof for Theorem 1.

Theorem 1 specifies the conditions each factor of a polynomial should satisfy to ensure quadrantal symmetry in the magnitude response of the overall polynomial. However, these conditions (except 5 and 6) do not show the way of generating the polynomial factor that possesses the symmetry. In the following, we will derive the forms of the polynomial factors that satisfy conditions 1 to 4 of Theorem 1.

Corollary of Condition 1

Using (93.23), we can write (93.38) as the following:

$$\begin{aligned} & P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ & \qquad = P_1\left(s_1^2, s_2^2\right) - s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) - s_2 P_4\left(s_1^2, s_2^2\right) \\ \Leftrightarrow \quad & s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) = -s_1 s_2 P_2\left(s_1^2, s_2^2\right) - s_2 P_4\left(s_1^2, s_2^2\right) \end{aligned}$$

The above is only possible if $P_2(s_1^2, s_2^2) = 0$ and $P_4(s_1^2, s_2^2) = 0$.

Therefore,

$$P\left(s_1, s_2\right) = P_1\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right)$$

This can be expressed as:

$$P_5\left(s_1, s_2^2\right) \tag{93.58}$$

Corollary of Condition 2

Using (93.23), we can write (93.39) as the following:

$$\begin{aligned} & P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ & \qquad = -P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) - s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ \Leftrightarrow \quad & P_1\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) = -P_1\left(s_1^2, s_2^2\right) - s_1 P_3\left(s_1^2, s_2^2\right) \end{aligned}$$

The above is only possible if $P_1(s_1^2, s_2^2) = 0$ and $P_3(s_1^2, s_2^2) = 0$. So,

$$P\left(s_1, s_2\right) = s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right)$$

This can be expressed as:

$$s_2 \cdot P_5\left(s_1, s_2^2\right) \tag{93.59}$$

Corollary of Condition 3

Using (93.23), we can write (93.40) as the following:

$$\begin{aligned} & P_1\left(s_1^2, s_2^2\right) + s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ & \qquad = P_1\left(s_1^2, s_2^2\right) - s_1 s_2 P_2\left(s_1^2, s_2^2\right) - s_1 P_3\left(s_1^2, s_2^2\right) + s_2 P_4\left(s_1^2, s_2^2\right) \\ \Leftrightarrow \quad & s_1 s_2 P_2\left(s_1^2, s_2^2\right) + s_1 P_3\left(s_1^2, s_2^2\right) = -s_1 s_2 P_2\left(s_1^2, s_2^2\right) - s_1 P_3\left(s_1^2, s_2^2\right) \end{aligned}$$

© 2003 by CRC Press LLC

The above is only possible if $P_2(s_1^2, s_2^2) = 0$ and $P_3(s_1^2, s_2^2) = 0$.

Therefore,

$$P(s_1, s_2) = P_1(s_1^2, s_2^2) + s_2 P_4(s_1^2, s_2^2)$$

This can be expressed as:

$$P_6(s_1^2, s_2) \tag{93.60}$$

Corollary of Condition 4

Using (93.23), we can write (93.41) as the following:

$$\begin{aligned} & P_1(s_1^2, s_2^2) + s_1 s_2 P_2(s_1^2, s_2^2) + s_1 P_3(s_1^2, s_2^2) + s_2 P_4(s_1^2, s_2^2) \\ & \qquad = -P_1(s_1^2, s_2^2) + s_1 s_2 P_2(s_1^2, s_2^2) + s_1 P_3(s_1^2, s_2^2) - s_2 P_4(s_1^2, s_2^2) \\ \Leftrightarrow \quad & P_1(s_1^2, s_2^2) + s_2 P_4(s_1^2, s_2^2) = -P_1(s_1^2, s_2^2) - s_2 P_4(s_1^2, s_2^2) \end{aligned}$$

The above is only possible if $P_1(s_1^2, s_2^2) = 0$ and $P_4(s_1^2, s_2^2) = 0$. So,

$$P(s_1, s_2) = s_1 s_2 P_2(s_1^{\,2}, s_2^{\,2}) + s_1 P_3(s_1^{\,2}, s_2^{\,2})$$

This can be expressed as:

$$s_1 \cdot P_6(s_1^{\,2}, s_2) \tag{93.61}$$

Reviewing all the above, we can see that the general polynomial form, $P_5(s_1, s_2^2) \cdot P_6(s_1^2, s_2)$, satisfies (93.58) through (93.61).

Now we can state the polynomials factors that satisfy conditions 1 through 6 of Theorem 1 in the following corollary.

Corollary of Theorem 1

The following polynomial factors possess quadrantal symmetry in their magnitude responses:

a) $P(s_1, s_2^{\,2})$ (93.62)

b) $P(s_1^{\,2}, s_2)$ (93.63)

c) $P(s_1, s_2) \cdot P(s_1, -s_2)$ (93.64)

d) $P(s_1, s_2) \cdot P(-s_1, s_2)$ (93.65)

It is obvious that the product of any of the above polynomial factors satisfies the symmetry as well.

Examples

We now provide examples of 2×2 polynomials satisfying (93.62) and (93.64).

a) $P(s_1, s_2^2) = a_0 + a_1 s_1 + a_2 s_1^2 + a_3 s_2^2 + a_4 s_1 s_2^2 + a_5 s_1^2 s_2^2$

b) $P(s_1, s_2) \cdot P(s_1, -s_2)$

© 2003 by CRC Press LLC

Let $P(s_1, s_2) = b_0 + b_1 s_1 + b_2 s_2 + b_3 s_1 s_2$

Then,

$$P(s_1, s_2) \cdot P(s_1, -s_2) = (b_0 + b_1 s_1 + b_2 s_2 + b_3 s_1 s_2) \cdot (b_0 + b_1 s_1 - b_2 s_2 - b_3 s_1 s_2)$$
$$= b_0^2 + 2b_0 b_1 s_1 + b_1^2 s_1^2 - b_2^2 s_2^2 - 2b_2 b_3 s_1 s_2^2 - b_3^2 s_1^2 s_2^2$$

Using the same derivation procedure outlined above for quadrantal symmetry, we can obtain the conditions and polynomial factors for the other symmetries.

Diagonal Symmetry for Analog Polynomials

Theorem 2

A polynomial $P(s_1, s_2)$ possesses diagonal symmetry in its magnitude response if its factors either alone or jointly satisfy one of the following conditions:

1. $P(s_1, s_2) = P(s_2, s_1)$ (93.66)
2. $P(s_1, s_2) = -P(s_2, s_1)$ (93.67)
3. $P(s_1, s_2) = P(-s_2, -s_1)$ (93.68)
4. $P(s_1, s_2) = -P(-s_2, -s_1)$ (93.69)
5. $P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(s_2, s_1)$ (93.70)
6. $P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(-s_2, -s_1)$ (93.71)

Corollary of Theorem 2

The following polynomial factors possess diagonal symmetry in their magnitude responses:

a) $P_1(s_1, s_2)$ (93.72)

b) $P_2(s_1^2, s_2^2) + s_1 s_2 P_3(s_1^2, s_2^2) + s_1 P_4(s_1^2, s_2^2) - s_2 P_4(s_2^2, s_1^2)$ (93.73)

c) $P(s_1, s_2) \cdot P(s_2, s_1)$ (93.74)

d) $P(s_1, s_2) \cdot P(-s_2, -s_1)$ (93.75)

where $P_1(s_1, s_2) = P_1(s_2, s_1)$ and $P_k(s_1^2, s_2^2) = P_k(s_2^2, s_1^2)$ for k = 2, 3.

Fourfold (90°) Rotational Symmetry for Analog Polynomials

Theorem 3

A polynomial $P(s_1, s_2)$ possesses fourfold rotational symmetry in its magnitude response if its factors either alone or jointly satisfy one of the following conditions:

1. $P(s_1, s_2) = P(-s_2, s_1)$ (93.76)
2. $P(s_1, s_2) = -P(-s_2, s_1)$ (93.77)

© 2003 by CRC Press LLC

3. $P(s_1, s_2) = P(s_2, -s_1)$ (93.78)

4. $P(s_1, s_2) = -P(s_2, -s_1)$ (93.79)

5. $P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(-s_2, s_1)$ (93.80)

6. $P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(s_2, -s_1)$ (93.81)

7. $P(s_1, s_2) = P_1(s_1, s_2) \cdot P_1(-s_2, s_1) \cdot P_1(-s_1, -s_2) \cdot P_1(s_2, -s_1)$ (93.82)

Corollary of Theorem 3

The following polynomial factors possess fourfold rotational symmetry in their magnitude responses:

a) $P_1(s_1^2, s_2^2) + s_1 s_2 \cdot (s_1^2 - s_2^2) \cdot P_2(s_1^2, s_2^2)$ (93.83)

b) $(s_1^2 - s_2^2) P_1(s_1^2, s_2^2) + s_1 s_2 P_2(s_1^2, s_2^2)$ (93.84)

c) $P(s_1, s_2) \cdot P(-s_2, s_1)$ (93.85)

d) $P(s_1, s_2) \cdot P(s_2, -s_1)$ (93.86)

e) $P(s_1, s_2) \cdot P(-s_2, s_1) \cdot P(-s_1, -s_2) \cdot P(s_2, -s_1)$ (93.87)

where $P_k(s_1^2, s_2^2) = P_k(s_2^2, s_1^2)$ for k = 1, 2.

Octagonal Symmetry for Analog Polynomials

Theorem 4

The following polynomial factors possess octagonal symmetry in their magnitude responses:

a) $(s_1^2 - s_2^2)^{\alpha} \cdot P_1(s_1^2, s_2^2)$, where $\alpha = 0$ or 1. (93.88)

b) $P(s_1^2, s_2) \cdot P(s_2^2, s_1)$ (93.89)

c) $P(s_1^2, s_2) \cdot P(s_2^2, -s_1)$ (93.90)

d) $P(s_1, s_2^2) \cdot P(-s_2, s_1^2)$ (93.91)

e) $P_2(s_1, s_2) \cdot P_2(-s_1, s_2)$ (93.92)

f) $P_2(s_1, s_2) \cdot P_2(s_1, -s_2)$ (93.93)

where $P_1(s_1^2, s_2^2) = P_1(s_2^2, s_1^2)$ and $P_2(s_1, s_2) = P_2(s_2, s_1)$.

Summary of Analog and Digital Polynomial Factors Possessing Symmetry

In Table 93.3, we state the digital polynomial factors that posses the various symmetries, alongside the analog polynomial factors presented earlier. The digital polynomial factors can be derived by assuming the general z-domain polynomial form in (93.24) and following the same derivation steps as the analog case.

© 2003 by CRC Press LLC

[a] $x_i = z_i + z_i^{-1}$ and $y_i = z_i - z_i^{-1}$, for $i = 1, 2$.

93.6 Symmetry and Stability for Polynomials

It has been established [12] that a sufficient condition for the stability of 2-D analog filters is that their transfer functions do not have any poles in the region of the (s_1, s_2) biplane defined by $\mathrm{Re}(s_1) \geq 0$ and $\mathrm{Re}(s_2) \geq 0$, including infinite distant points. Similarly, a sufficient condition for the stability of 2-D digital filters is that their transfer functions do not have any poles in the region of the (z_1, z_2) biplane defined by $|z_1| \geq 1$ and $|z_2| \geq 1$. We will next consider the analog domain and the digital domain stability conditions under the presence of symmetry.

Stability of Analog Domain Polynomials with Symmetric Magnitude Response

The transfer function of an analog 2-D filter can be represented as a rational function in s_1 and s_2 as

$$T(s_1, s_2) = \frac{P(s_1, s_2)}{Q(s_1, s_2)} \tag{93.94}$$

© 2003 by CRC Press LLC

It can be shown that $T(j\omega_1, j\omega_2)$ possesses various magnitude symmetries if $P(j\omega_1, j\omega_2)$ and $Q(j\omega_1, j\omega_2)$ possess the same symmetries individually. Then for $T(s_1, s_2)$ to possess a symmetry and stability, $Q(s_1, s_2)$ should satisfy the conditions for the symmetry as well as the conditions for stability. The type of $Q(s_1, s_2)$ that satisfies these two conditions for quadrantal symmetry is presented in the following theorem.

Quadrantal Symmetry

Theorem 5

For $T(s_1, s_2)$ to be stable and to possess quadrantal magnitude symmetry, $P(s_1, s_2)$ should satisfy the quadrantal symmetry conditions listed in Table 93.3 and the denominator polynomial should be product separable as $Q(s_1, s_2) = Q_1(s_1) \cdot Q_2(s_2)$ where Q_1 and Q_2 are stable 1-D polynomials.

Proof of Theorem 5

As mentioned above for $T(s_1, s_2)$ to possess quadrantal magnitude symmetry in its frequency response, $Q(s_1, s_2)$ should be expressible as

$$Q(s_1, s_2) = Q_A(s_1, s_2^2) \cdot Q_B(s_1^2, s_2) \tag{93.95}$$

Now it can be easily seen that for any s_1, $Q_A(s_1, s_2^2)$ will have zeros in the right half of s_2 plane unless Q_A is a polynomial of s_1 alone. Similarly it can be argued that Q_B should be a polynomial of s_2 alone. In other words, for $Q(s_1, s_2)$ to possess stability and quadrantal magnitude symmetry, it should be expressible as a product of two 1-D polynomials as

$$Q(s_1, s_2) = Q_1(s_1) \cdot Q_2(s_2) \tag{93.96}$$

such that Q_1 and Q_2 are stable analog polynomials. Q.E.D

Octagonal Symmetry

As quadrantal symmetry is an integral part of octagonal symmetry, for $T(s_1, s_2)$ to possess octagonal symmetry it should first satisfy the conditions for quadrantal symmetry, i.e., the denominator polynomial should be separable. Then it can be shown that as octagonal symmetry also implies diagonal symmetry, $Q(s_1, s_2)$ should be expressible as

$$Q(s_1, s_2) = Q_1(s_1) \cdot Q_1(s_2) \tag{93.97}$$

Rotational Symmetry

In a similar manner examining the various factors that can be present in the polynomials possessing rotational symmetry, it can be shown that the denominator polynomial of a stable 2-D analog filter possessing rotational magnitude symmetry should be expressible as

$$Q(s_1, s_2) = Q_1(s_1) \cdot Q_1(s_2) \tag{93.98}$$

Diagonal Symmetry

It can be shown that the denominator of a stable 2-D analog filter possessing diagonal magnitude symmetry should satisfy the stability conditions and satisfy the symmetry condition:

$$Q(s_1, s_2) = Q(s_2, s_1) \tag{93.99}$$

Stability of Digital Domain Polynomials with Symmetric Magnitude Response

Now applying the stability conditions on the polynomial factors that possess the various magnitude symmetries, the following conditions on the denominator polynomials of 2-D digital filters are obtained.

© 2003 by CRC Press LLC

Quadrantal Symmetry

The denominator polynomial of a stable 2-D digital filter possessing quadrantal symmetry in its magnitude response can be expressed as

$$Q(z_1, z_2) = Q_1(z_1) \cdot Q_2(z_2) \tag{93.100}$$

where Q_1 and Q_2 are 1-D stable polynomials.

Octagonal Symmetry

The denominator polynomial of a stable 2-D digital filter possessing octagonal symmetry in its magnitude response can be expressed as

$$Q(z_1, z_2) = Q_1(z_1) \cdot Q_1(z_2) \tag{93.101}$$

Rotational Symmetry

The denominator polynomial of a stable 2-D digital filter possessing rotational symmetry in its magnitude response can be expressed as

$$Q(z_1, z_2) = Q_1(z_1) \cdot Q_1(z_2) \tag{93.102}$$

Diagonal Symmetry

The denominator polynomial of a stable 2-D digital filter possessing diagonal symmetry in its magnitude response should satisfy the stability condition and satisfy the symmetry condition:

$$Q(z_1, z_2) = Q(z_2, z_1) \tag{93.103}$$

93.7 Filter Design Procedure

We now present the design steps for 2-D z-domain IIR filters with symmetry in the magnitude response. Computer optimization is used in this procedure to obtain the filter coefficients such that the filter specifications are satisfied.

Steps:

1. Identify the type of symmetry in the magnitude response specifications for the filter.
2. Assume a transfer function of the form:

$$H(z_1, z_2) = \frac{N(z_1, z_2)}{D(z_1) \cdot D(z_2)} \tag{93.104}$$

   Select the numerator from the list of polynomials in Table 93.3, such that it satisfies the required symmetry identified in Step 1. The denominator is chosen to be separable so that its stability can be easily assured. This denominator possesses all four types of symmetries.
3. Select a suitable order for the filter such that the specifications can be met.
4. Choose a region in the (θ_1, θ_2) frequency plane to specify the desired magnitude response. (Note that $\theta_i = \omega_i \cdot T$.) For quadrantal, diagonal, and rotational symmetries, the region need only be a 90° sector in the frequency plane. For octagonal symmetry, it need only be a 45° sector. Specify the frequency sample points in this region using concentric circles or rectangular grids.
5. Form an objective function to be minimized. This will be based on the difference between the magnitude response of the transfer function and the desired magnitude response, at the selected frequency points. One such objective function is:

$$J = \sum_k \sum_l \left[F(\theta_{1k}, \theta_{2l}) - F_d(\theta_{1k}, \theta_{2l}) \right]^2 \tag{93.105}$$

© 2003 by CRC Press LLC

where F is the magnitude squared response and θ_{1k}, θ_{2l} are the sample frequency points where the desired response is specified. In this function, the variables to be optimized are the coefficients of the transfer function.

6. Use any minimization algorithm, such as those provided in Matlab®, to minimize the objective function J and obtain the optimal values for the filter coefficients. Verify that the filter specifications can be met with this set of filter coefficients. If not, make adjustment to the minimization algorithm and repeat the process.
7. Check the stability of the filter by finding the poles. Any unstable pole can be stabilized by replacing it with its inverse pole.

93.8 Various Filter Designs

Bandpass Filter

Using the procedure discussed in the previous section, we now design a bandpass filter with the ideal filter specification shown in Fig. 93.7.

It can be seen that the filter possesses diagonal symmetry. So we select the numerator to be $N(z_1, z_2) = N(z_2, z_1)$, which is case (a) in the list of polynomials with diagonal symmetry in Table 93.3. We pick the order of the filter to be 4×4. Because of the diagonal symmetry constraints, the number of variables to optimize is reduced from 33 to 19. The following are the forms for the numerator and denominator:

$$N(z_1, z_2) = \begin{array}{c} \\ z_2^0 \\ z_2^1 \\ z_2^2 \\ z_2^3 \\ z_2^4 \end{array} \begin{array}{c} \begin{array}{ccccc} z_1^0 & z_1^1 & z_1^2 & z_1^3 & z_1^4 \end{array} \\ \begin{bmatrix} a_{00} & a_{10} & a_{20} & a_{30} & a_{40} \\ \boxed{a_{10}} & a_{11} & a_{21} & a_{31} & a_{41} \\ \boxed{a_{20}} & \boxed{a_{21}} & a_{22} & a_{32} & a_{42} \\ \boxed{a_{30}} & \boxed{a_{31}} & \boxed{a_{32}} & a_{33} & a_{43} \\ \boxed{a_{40}} & \boxed{a_{41}} & \boxed{a_{42}} & \boxed{a_{43}} & a_{44} \end{bmatrix} \end{array} \tag{93.106}$$

and $$D(z_i) = b_0 + b_1 z_i + b_2 z_i^2 + b_3 z_i^3 + z_i^4, \qquad i = 1, 2$$

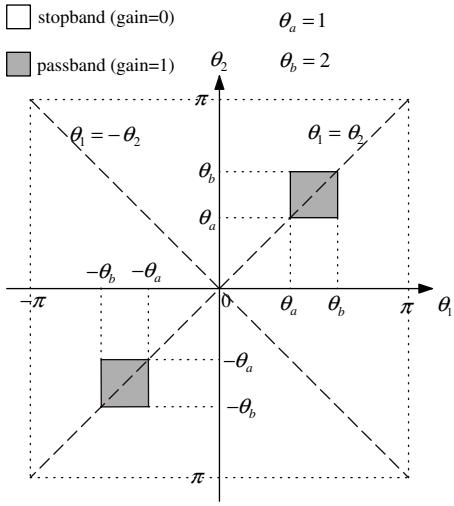

FIGURE 93.7 Specification for a bandpass filter with diagonal symmetry.

© 2003 by CRC Press LLC

Also, because of symmetry, we need only specify the desired response in a reduced region (90° sector) in the frequency plane. In this case, we use the sector from 45° to 135°, and specify the sample points using rectangular grids.

We use the "lsqnonlin" routine in Matlab® 5.3 Optimization Toolbox to minimize the objective function. The Matlab M-files used to optimize the filter are listed at the end of the chapter. Optimize.m is the main program. Z2diir1.m calculates the objective and gradient functions. Diasym.m, Diasym1.m, and Diasym2.m are supporting M-files that impose the diagonal symmetry constraints on the objective and gradient functions. The coefficients to be optimized are arranged in vector form: xzo = [a_{00} a_{10} a_{20} a_{30} a_{40} a_{11} a_{21} a_{31} a_{41} a_{22} a_{32} a_{42} a_{33} a_{43} a_{44} b_0 b_1 b_2 b_3].

The transfer function coefficients of the optimized filter are listed below, together with the contour and 3-D magnitude plots. We verified that the filter is stable and meets the specifications.

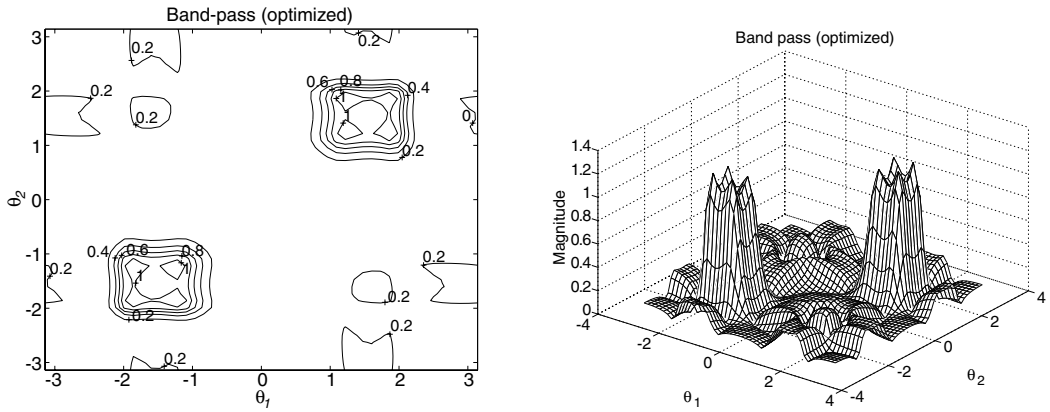

FIGURE 93.8 Contour and 3-D magnitude plots of the optimized bandpass filter.

Other types of filters can be designed using the same procedure. In the following, we provide examples of lowpass, highpass, and bandstop filters with diagonal symmetry. We assume the same forms for the numerator and denominator as in (93.106), and the same 4×4 filter order. Only minor modification to optimize.m is needed to accommodate the different filter specifications. For each example, the initial filter specification, together with the final optimized filter coefficients and magnitude plots are shown.
