The SPICE program has the ability to model both absolute and relative parameter distributions. It can be done by using the *LOT* and *DEV* parameters in the .MODEL statement. For example if *LOT* = 10 percent and *DEV* = 1 percent, then parameters for all devices may vary by ± 10 percent, but relative variation from device to device will be ±1%. This feature makes the SPICE program very suitable for integrated circuit simulation. The Monte Carlo analysis implemented in the PSPICE program makes the integrated circuit design even easier.

55.2 MOSFET Technology Devices

John Choma, Jr.

Introduction

The most widely used monolithic semicoductor, particularly in digital and in hybrid analog–digital circuit applications, is the **silicon metal-oxide-semiconductor field-effect transistor**, or MOSFET. The MOSFET differs from its competitive active element, the **bipolar junction transistor** (BJT), in three fundamental respects. First, BJT's are current-controlled devices in that their output (collector) current is controlled by their base current. Under normal operation, this base current is manifested by hole electron recombination between the background majority charge resident in the base region and the minority charge injected across a forward-biased emitter–base junction. On the other hand, MOSFETs are voltage-controlled elements. Their output (drain) current is controlled by an input voltage that modulates the conductivity of a narrow channel of mobile majority charges whose directed transport comprises the output current. As a result of this different current conduction mechanism, the MOSFET features an input impedance that is significantly larger than that of its bipolar counterpart. Moreover, the MOSFET boasts a linearity between its controlling input and controlled output variables that is better than the I/O linearity of a BJT. The latter feature is exploited in state-of-the-art stereo applications for which the active element of choice in the power output stages is the MOS field-effect transistor.

A second difference between the MOSFET and the BJT is that the MOSFET is a majority carrier device; that is, the mobile charges comprising the output current are majority charges in the channel region in which they are transported. In contrast, bipolar currents materialize principally from minority charge transported across a narrow base region. The immediate consequence of this difference is that the output current in a MOSFET displays a negative temperature coefficient, whereas the output current of a BJT increases with increasing temperature.

Finally, and primarily because of the material structure that achieves voltage-controlled current outputs, the cross section geometry of a MOSFET is simpler than that of a BJT, and its surface area is smaller. These fabrication characteristics, its ability to function at low power levels, and its inherently negative temperature coefficient make the MOSFET ideally suited in digital very large scale integrated (VLSI)

electronic applications for which given signal-processing specifications may require tens or even hundreds of thousands of transistors.

Although the MOS transistor is synonymous with digital signal processing, there is an escalating interest in applying MOS technologies to service a variety of analog operating requirements. Aside from low design, development, and fabrication costs, and the general inability of MOSFETs to compare favorably to bipolar transistors with respect to forward gain and bandwidth, there is at least one other engineering issue that motivates this interest. This issue derives from the burgeoning use of microprocessors and other types of computer–based controllers that are used to optimize the analog responses of automotive, consumer, and industrial electronics. The logic variables produced by these control units require interfacing to their analog inputs and their resultantly processed analog outputs. Until recently, these interface circuits were realized as bipolar cells implemented peripherally to the digital control circuits. But manufacturing costs abate and system reliability improves when peripheral analog interface circuitry is supplanted by monolithic circuits incorporated on the digital circuit chip in the same VLSI device technology that accomplishes requisite digital signal processing.

Four types of MOSFETs are used: the *N-channel* and *P-channel enhancement-mode* MOSFETs and the *N-channel* and *P-channel depletion-mode* MOSFETs. A fifth type of MOSFET is *complementary MOS*, or *CMOS*. Although commonly referred to as a CMOS "device," CMOS is actually a composite connection of N-channel and P-channel enhancement-mode MOSFETs.

This section addresses the circuit level models that emulate the static and dynamic volt–ampere characteristics of the foregoing five types of MOS devices. Additionally, illustrations of the applications of these models to simple circuit applications are provided.

Enhancement-Mode MOSFET

Two types of enhancement-mode MOSFETs are available, which are also known as **insulated gate field-effect transistors** or IGFETs: the *N-channel type* and the *P-channel type*. As shown in the simplified cross section of Fig. 55.15(a) the N-channel enhancement mode MOSFET consists of two heavily doped N-type semiconductor regions that are diffused or implanted into a relatively lightly doped P-type *substrate* or

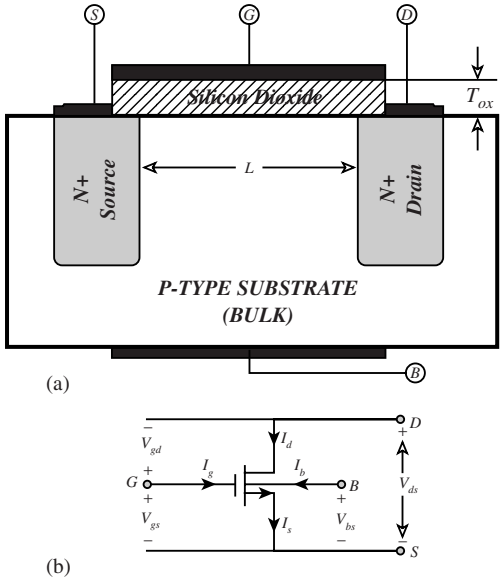

FIGURE 55.15 (a) Simplified cross section of an N-channel enhancement-mode MOSFET. The diagaram is not drawn to scale. (b) Electrical schematic diagram of an N-channel enhancement-mode MOSFET.

© 2003 by CRC Press LLC

bulk. The heavily doped regions, which are indicated in gray shading as the N+ *source* and N+ *drain*, have average concentrations of the order of 10^{19} atoms/cm^3, maximum lateral widths of a few microns, and depths in the range of a micron. In contrast, the P-type substrate is doped to an average concentration of the order of 10^{14} atoms/cm^3, has a vertical thickness that can be hundreds of microns, and a net width that also approaches hundreds of microns. Metallic or polysilicon electrical contacts, shown as black areas in the figure, are made to the source and drain regions on the surface of the device, as well as to the substrate bulk. These contacts are externally accessible on the *source* (S), *drain* (D), and *substrate*, or *bulk*, (B) terminals.

The region between the inner sidewalls of the source and drain diffusions in the immediate neighborhood of the device surface is referred to as the *channel* of the MOSFET. This channel, whose length is indicated as L in Fig. 55.15(a), is typically 2 to 20 microns long. In very high-speed integrated circuit (VHSIC) technology, L can be significantly smaller than 2 μm. *Submicron MOSFET technology* refers to MOSFETs having $L < 1$ μm. A layer of *silicon dioxide* (SiO_2), depicted as the crosshatched area in Fig. 55.15(a) is thermally grown atop this surface channel, and a metallic or *polysilicon* electrical contact is made to the top of the oxide layer. This contact is the external *gate* terminal (G), to which voltage is applied to control the current flowing in the MOSFET drain lead. The thickness T_{ox}, of the oxide layer is in the range of a few hundred to a few thousand angstroms (an angstrom is 10^{-8} cm, or 10^{-4} μm). If W represents the depth of the gate contact (in a direction perpendicular to the face of the page on which the MOSFET cross-sectional diagram appears), LW represents the *gate area*, or *active channel area*, of the divice. The performance of many MOSFET circuits is strongly dependent on this area, as well as on the *gate aspect ratio* W/L, which is a designable parameter whose value can be as small as one to as large as a few hundred.

In Fig. 55.15(a), a small part of the gate oxide, and hence gate metal, interfacial area overlaps both the source and drain regions. These *overlap* areas give rise to *overlap capacitances* between both the gate and source and the gate and drain. Since overlap capacitances degrade the switching speed and frequency response of a MOSFET, a monolithic process known as **self-aligning gate technology** [1] has been developed to minimize these overlapping areas.

The electrical schematic symbol of the N-channel enhancement mode MOSFET is given in Fig. 55.15(b). The four terminals (D), (S), (G), and (B), in the schematic diagram correspond to the drain, source, gate, and substrate bulk contacts delineated in the companion diagram of Fig. 55.15(a). The schematic symbol also defines the positive reference directions of four MOSFET currents. These are the *drain current* I_d, the *source current* I_s, the *gate current* I_g, and the *bulk current* I_b. The drain, gate, and bulk currents are positive when they flow into the N-channel MOSFET, while the source current is positive when it flows out of the transistor. The four indicated MOSFET currents are not independent electrical variables, for by KCL,

$$I_s = I_d + I_g + I_b \tag{55.48}$$

The schematic also defines the positive reference polarities of four MOSFET terminal voltages. In particular, V_{ds} is the *drain to source voltage*, V_{bs} is the *bulk to source voltage*, V_{gs} is the *gate to source voltage*, and finally, V_{gd} is the *gate to drain voltage*. By KVL,

$$V_{ds} = V_{gs} - V_{gd} \tag{55.49}$$

The cross section diagram and corresponding electrical schematic symbol for a P-channel enhancement mode MOSFET and given in Fig. 55.16. The N+ diffusions or implants for the source and drain in the N-channel transistor become P+ regions in the P-channel device. In contrast to the N-channel transistor, the P-channel device uses an N–type substrate. Otherwise, the cross sections for these two transistor types are identical. The only change in the electrical schematic is that the arrow in the source lead of the P-channel transistor is pointed in a direction that is opposite to that shown in the electrical schematic of the N-channel MOSFET.

© 2003 by CRC Press LLC

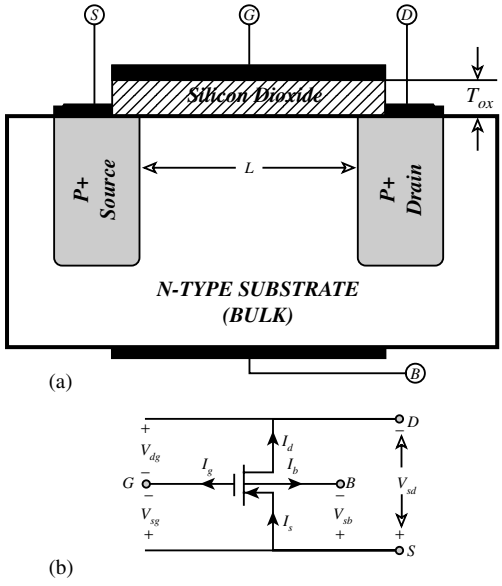

FIGURE 55.16 (a) Simplified cross section of a P-channel enhancement–mode MOSFET. The diagaram is not drawn to scale. (b) Electrical schematic diagram of a P-channel enhancement–mode MOSFET.

The positive reference directions for all P-channel device currents and terminal voltages are reversed with respect to their individual orientations in the N-channel circuit diagram. Specifically, the positive direction of the drain, gate, and substrate bulk currents is out of the P-channel transistor, and positive source current flows in to the device. Likewise, the positive reference polarities of all terminal voltages are reversed; that is, the *source to drain voltage* V_{sd}, the *source to bulk voltage* V_{sb}, the *source to gate voltage* V_{sg}, and the *drain to gate voltage* V_{dg}, are positive electrical variables when their measured polarities mirror those indicated in Fig. 55.16(b). Neither (55.48) nor (55.49) is affected by these polarity reversals.

Static Characteristic Equations

The Ebers–Moll and Gummel–Poon models for a bipolar junction transistor provide a single set of algebraic equations that governs the volt–ampere relationships for each of three BJT currents over all possible regimes of transistor operation. Unfortunately, no single equation set is available to describe the static volt–ampere relationships of a MOSFET. Instead, separate equations are written for the three MOSFET operating regimes: namely, the *cutoff*, the *ohmic* (also known as *triode*), and the *saturation* (also known as *linear*) regimes.

Before discussing these static volt–ampere equations, it should be noted that for low signal frequencies, the current I_g flowing in the gate lead of either an N-channel or a P-channel MOSFET is zero because the silicon dioxide layer lying beneath the gate metal is an almost perfect insulator. Moreover, the substrate current, I_b, is zero because in the majority of MOSFET applications, the PN junctions formed between the substrate bulk and both the drain and source regions are reverse biased. In N-channel devices, this requirement is satisfied by connecting the P-type substrate to the most negative potential afforded by the circuit in which the MOSFET is embedded. For P-channel units, the N-type substrate is connected to the most positive of available circuit node potentials. In either case, since the substrate current, I_b, is the superposition of the bulk–drain junction leakage current, the bulk–source leakage current, and the current flowing between substrate and gate, $I_b \approx 0$. Since I_g and I_b are zero in each of three MOSFET operating regimes, (55.48) shows that the drain current I_d equates to the source current I_s at least at the low signal frequencies for which the capacitive charging currents associated with PN junction depletion layers and oxide capacitances can be ignored.

© 2003 by CRC Press LLC

Cutoff Regime. A MOSFET is said to be cutoff when its drain current I_d is zero. In an N-channel enhancement mode MOSFET, cutoff is realized if the gate-source voltage V_{gs} is at most a positive voltage, say V_{hn}, which is termed the gate to source threshold voltage or simply, the threshold voltage of the MOSFET. The threshold voltage is effectively a turn on voltage for the MOSFET, in the sense that V_{gs} must exceed V_{hn} to cause measurable current conduction through the device. As such, its engineering significance is similar to that of V_γ, the emitter–base junction turn-on voltage for a BJT. But unlike the 700 or so mV that typifies V_γ, V_{hn} is in the range of slightly less than a volt to a few volts. Also unlike V_γ, which is independent of BJT junction voltages and currents, V_{hn} is a function of the bulk-source voltage V_{bs}. However, in the first-order static model presented here, V_{hn} is taken to be a constant, independent of MOSFET terminal voltages and lead currents.

Cutoff in a P-channel transistor is defined analogously. Specifically, cutoff, in the sense of $I_d = 0$ in the schematic representation of Fig. 55.16(b), requires that $V_{sg} \le V_{hp}$ where V_{hp} is the positive *source to gate threshold voltage* of the P-channel device.

Ohmic (Triode) Regime. An N-channel MOSFET operates in its ohmic, or triode, regime if its gate-source voltage satisfies the constraint $V_{gs} \ge V_{hn}$ and simultaneously, its drain-source voltage is such that $V_{ds} < (V_{gs} - V_{hn})$. In this regime, the drain current I_d is given by [2]

$$I_d = K_n\left(\frac{W}{L}\right)V_{ds}\left(V_{gs} - V_{hn} - \frac{V_{ds}}{2}\right) \tag{55.50}$$

Note that for given drain-source and gate-source voltages, the drain current is proportional to the gate aspect ratio, *W*/*L*. In an actual design setting, a desired drain current is achived by altering this ratio through an appropriate choice of the gate depth *W*.

The constant K_n in (55.50) is termed a **transconductance coefficient**. This parameter is in the range of tens to hundreds of micromhos per volt and is given by

$$K_n = \mu_n C_{ox} \tag{55.51}$$

where μ_n is the *surface mobility of electrons* in the channel. Because carrier mobility diminishes with increasing operating temperatures, the transconductance coefficient, and thus the drain current, decreases with increasing temperature. Finally, the parameter C_{ox} is the *density of the gate oxide capacitance*. It has dimensions of farads per square meter and is related to the oxide thickness T_{ox} by the expression

$$C_{ox} = \frac{\varepsilon_{ox}}{T_{ox}} \tag{55.52}$$

where ε_{ox} is the **dielectric constant** of silicon dioxide (345.2 fF/cm).

For P-channel transistors, equations of the form of (55.50) and (55.51) prevail, μ_n in (56.51) is replaced by μ_p, the **surface mobility of holes** in the channel. In particular,

$$I_d = K_p\left(\frac{W}{L}\right)V_{sd}\left(V_{sg} - V_{hp} - \frac{V_{sd}}{2}\right) \tag{55.53}$$

with the understanding that

$$K_p = \mu_p C_{ox} = \mu_p\left(\frac{\in_{ox}}{T_{ox}}\right) \tag{55.54}$$

The triode region of the static MOSFET characteristic curve is more commonly referenced as the ohmic regime because for small drain–source voltages, the MOSFET behaves electrically as a linear,

© 2003 by CRC Press LLC

voltage-controlled, two terminal resistance. This contention is confirmed by (55.50), which produces a differential drain–source conductance ($1/R_{ds}$), of

$$\frac{\partial I_d}{\partial V_{ds}} \triangleq \frac{1}{R_{ds}} = K_n\left(\frac{W}{L}\right)\left(V_{gs} - V_{hn} - V_{ds}\right) = \frac{I_d}{V_{ds}}\left(\frac{V_{gs} - V_{hn} - V_{ds}}{V_{gs} - V_{hm} - \frac{V_{ds}}{2}}\right) \tag{55.55}$$

For $V_{ds} \ll (V_{gs} - V_{hn})$, the drain–source voltage, V_{ds}, and the drain current I_d, conform to the simple Ohm's law relationship

$$V_{ds} \approx R_{ds} I_d \tag{55.56}$$

where R_{ds} is logically viewed as the effective resistance presented between the drain and source terminals of a conducting MOSFET operated at small drain–source voltages. It is interesting to note that the value of this drain–source resistance is controllable by the gate–source voltage, V_{gs}. Specifically, R_{ds} varier inversely with V_{gs}. Accordingly, the possibility of using a MOSFET as a voltage–variable resistance in the design of an electronically controlled attenuator is suggested. It is also interesting to observe that R_{ds} varies directly with the length L of the channel whose resistance is represented by R_{ds} and inversely with W, which is the cross–sectional width of the subject channel. These geometric dependencies mirror the geometric resistance properties of conventional passive resistors.

Saturated (Linear) Regime. An N-channel MOSFET enters the saturation, or linear, region of its static characteristic curves if $V_{gs} > V_{hn}$ and $V_{ds} \geq (V_{gs} - V_{hn})$. The corresponding drain current expression derives from (55.50) by equating V_{ds} to $(V_{gs} - V_{hn})$, with the result that

$$I_d = \frac{K_n}{2}\left(\frac{W}{L}\right)\left(V_{gs} - V_{hn}\right)^2 \tag{55.57}$$

To first order, the saturated value of drain current is independent of the drain-source voltage V_{ds} and is a function of only the gate-source voltage V_{gs}. In short, the saturated MOSFET functions as a voltage-controlled current source, with V_{gs} serving as the controlling electrical variable for the controlled variable, I_d. This voltage-controlled current is the fundamental mechanism allowing for voltage gain from the input (gate–source) port to the output (drain–source) port. Accordingly, MOSFETs earmarked for high gain, nominally linear, signal-processing applications are biased in their saturated regimes. Note that MOSFET saturation has a distinctly different connotation that does saturation in a BJT. In the latter device, the ability to provide forward gain in the saturation regime is sharply degraded by charge injection and charge storage phenomena.

The difference voltage $(V_{gs} - V_{hn})$, is defined as the **drain saturation voltage**, V_{dss}; that is,

$$V_{dss} \triangleq V_{gs} - V_{hn} \tag{55.58}$$

As is highlighted by (55.55), the drain saturation voltage is significant in that for $V_{ds} = V_{dss}$, the static volt-ampere characteristic in the ohmic domain has zero slope and therefore, the ohmic value of drain current is maximized. By (55.50), note that this maximum drain current, say I_{dss}, which is termed the **drain saturation current**, is identical to the saturated drain current given by (55.57). Thus, in the saturated regime of operation, the drain current is alternatively expressible as

$$I_d = \frac{K_n}{2}\left(\frac{W}{L}\right)\left(V_{gs} - V_{hn}\right)^2 \equiv \frac{K_n}{2}\left(\frac{W}{L}\right)V_{dss}^2 \triangleq I_{dss} \tag{55.59}$$

© 2003 by CRC Press LLC

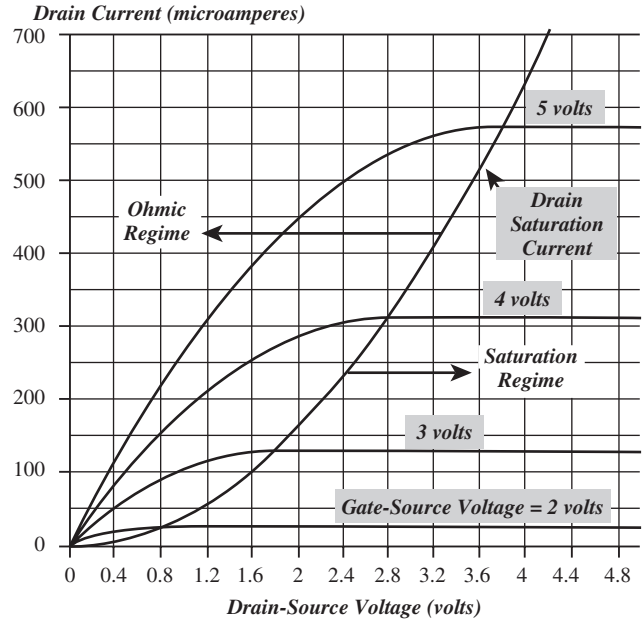

FIGURE 55.17 Static common source volt–ampere characteristic curve for an N-channel enhancement–mode MOSFET having $(K_n W/L) = 80$ μmho/V and a threshold voltage V_{hn} of 1.2 V.

Equations (55.57)–(55.59) remain applicable for P-channel transistors, provided that V_{gs} is replaced by the source–gate voltages, V_{sg} and V_{hn} is supplanted by V_{hp}, the source-gate threshold voltage. In (55.58), the drain-source saturation voltage becomes the souce-drain saturation voltage V_{sds}.

In summary, the simplified static volt-ampere equations for an N-channel enhancement mode MOSFET are

$$I_d = \begin{cases} 0, & V_{gs} \le V_{hn} \\ K_n\left(\dfrac{W}{L}\right)V_{ds}\left(V_{gs} - V_{hn} - \dfrac{V_{ds}}{2}\right), & V_{gs} > V_{hn} \text{ and } V_{ds} < \left(V_{gs} - V_{hn}\right) \\ \dfrac{K_n}{2}\left(\dfrac{W}{L}\right)\left(V_{gs} - V_{hn}\right)^2, & V_{gs} > V_{hn} \text{ and } V_{ds} \ge \left(V_{gs} - V_{hn}\right) \end{cases} \tag{55.60}$$

These equations, which collectively comprise the common drain static characteristic curves, are plotted in Fig. 55.17 for the case an N-channel MOSFET having $V_{hn} = 1.2$ V and $K_n(W/L) = 80$ μmho/V. The superimposed plot of (55.59), which is shown dashed in Fig. 55.17, is a locus of volt–ampere points that separate the ohmic regime on its left from the saturated regime on its right. Observe that for very small drain–source voltages, the ohmic regime curves are nominally linear, as predicted earlier. On the other hand, constant drain currents, whose individual values are determined by gate-source voltages in accordance with (55.60), are evidenced in the saturation regime.

Example 1. The common source inverter is a canonic cell for both analog and digital MOSFET applications. In the enhancement-loaded common source inverter of Fig. 55.18, the N-channel driver transistor *MD* has a gate aspect ratio of (W_d/L) and a threshold voltage of V_{hnd}. On the other hand, the N-channel load transistor *ML* has a gate aspect radio of (W_1/L) and a threshold voltage of V_{hnl}. Both transistors have identical channel properties and accordingly, both devices share the same transconductance coefficient K_n. The input voltage V_i is presumed nonnegative, thereby ensuring that the grounded substrates of both transistors conduct negligible current. Since the gate current flowing into a MOSFET is zero at low signal frequencies, no internal source resistance is included in the input source voltage branch.

© 2003 by CRC Press LLC

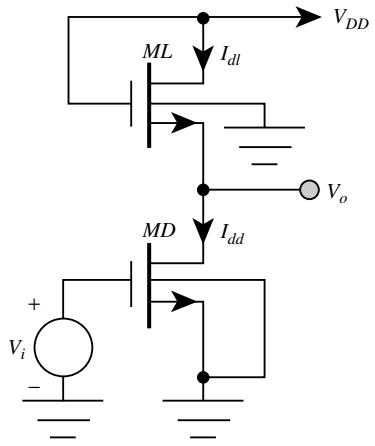

FIGURE 55.18 Schematic diagram of an enhancement-loaded common source inverter.

Use the simple static model of an enhancement-mode MOSFET to determine the relationship of the output voltage V_o to the applied input drive V_i. Investigate this transfer relationship from the viewpoint of setting criteria that allow using the circuit as either a linear amplifier or as a logical inverter.

Solution.

1) The load transistor, *ML*, has a drain–source voltage, say V_{dsl}, that is identical to its gate–source voltage, V_{gsl}, since the drain and gate terminals are electrically incident with one another. Specifically,

$$V_{dsl} \equiv V_{gsl} = V_{DD} - V_o$$

Since MOSFET operation in saturated domains requires a drain-source voltage that exceeds the corresponding gate–source voltage, less a threshold voltage drop, identical drain–source and gate–source voltages ensure volt–ampere operation in the saturation region. Thus, transistor *ML* is always saturated and for $V_{gsl} > V_{hnl}$, the current I_{dl} flowing through the load transistor in Fig. 55.18 is

$$I_{dl} = \frac{K_n}{2}\left(\frac{W_l}{L}\right)\left(V_{DD} - V_o - V_{hnl}\right)^2$$

Observe from the first equation above that since V_{gsl} must exceed V_{hnl} in order for *ML* to conduct, V_o must correspondingly be smaller than $(V_{DD} - V_{hnl})$. This statement is corroborated by the seond of the foregoing two equations, which confirms that $I_{dl} = 0$ when $V_o = (V_{DD} - V_{hnl})$. It follows that the maximum possible output voltage, say $V_{\max}$, is

$$V_{\max} = V_{DD} - V_{hnl}$$

whence

$$I_{dl} = \frac{K_n}{2}\left(\frac{W_l}{L}\right)\left(V_{\max} - V_o\right)^2$$

2) The gate–source voltage V_{gsd} of the driver transistor, *MD*, is the input voltage V_i, while the drain–source voltage, V_{dsd}, of this device is the output voltage, V_o, of the circuit. For $V_i > V_{hnd}$ and $V_o \geq (V_i - V_{hnd}) > 0$, *MD* is saturated, and its drain current I_{dd}, is

© 2003 by CRC Press LLC

$$I_{dd} = \frac{K_n}{2}\left(\frac{W_d}{L}\right)\left(V_i - V_{hnd}\right)^2$$

But since the substrates and gates of either MOSFET conduct zero static current, $I_{dd} \equiv I_{dl}$, which implies that for $V_0 \geq (V_i - V_{hnd})$

$$V_o = V_{\max} - \sqrt{\lambda_{dl}}\left(V_i - V_{hnd}\right)$$

where, subject to the assumptions of identical transconductance coefficients and channel lengths,

$$\lambda_{dl} = \frac{W_d/L}{W_l/L} = \frac{W_d}{W_l}$$

is the ratio of the gate aspect ratio of the driver to the gate aspect ratio of the load transistor.

3) Several noteworthy points underscore the foregoing analysis.
   a) Despite the fact that the currents of both saturated transistors are quadratic functions of their respective gate–source voltages, the expression derived for the output voltage, V_o, is a linear function of the circuit input voltage, V_i. This is to say that as long as $V_o \geq (V_i - V_{hnd}) > 0$, the enhancement-loaded common souce inverter functions as a linear signal processor. This observation confirms an original contention that I/O linearity in MOSFET technology circuits requires that all pertinent MOSFETs be biased in the saturation regime of their static volt–ampere characteristic curves.
   b) Since the circuit at hand operates linearly for $V_o \geq (V_i - V_{hnd}) > 0$, a small-signal voltage gain, say A_v, can be meaningfully defined. Returning to the output voltage expression, this gain is seen to be

$$A_v = \frac{dV_0}{dV_i} = -\sqrt{\lambda_{dl}}$$

   where the negative algebraic sign suggests phase inversion between the small-signal input voltage and its corresponding small-signal output response. A laudable attribute of the common source inverter is that its voltage gain depends on only the ratio of gate geometries, which is accurately controlled during processing.
   c) The voltage range, $V_o \geq (V_i - V_{hnd}) > 0$, required for I/O linearity translates to an input voltages requirement of

$$V_{hnd} < V_i \leq V_{hnd} + \frac{V_{\max}}{1 + \sqrt{\lambda_{dl}}}$$

   and a corresponding output voltage range of

$$V_{\max} > V_o \geq \frac{V_{\max}}{1 + \sqrt{\lambda_{dl}}}$$

   The last result suggests that the optimum output bias voltage, say V_{oQ}, in the sense of maximum output signal swing commensurate with linear circuit operation is

$$V_{oQ} = \frac{1}{2}\left(\frac{\sqrt{\lambda_{dl}}}{1 + \sqrt{\lambda_{dl}}}\right)V_{\max}$$

   Using the previously derived output voltage expression, this disclosure corresponds to an input bias, V_{iQ} given by

© 2003 by CRC Press LLC

$$V_{iQ} = V_{hnd} + \frac{1}{2\sqrt{\lambda_{dl}}}\left(\frac{2+\sqrt{\lambda_{dl}}}{1+\sqrt{\lambda_{dl}}}\right)V_{\max}$$

4) While the load transistor is always saturated, the driver *MD* slips into its ohmic regime for $V_o < (V_i - V_{hnd})$ where

$$I_{dd} = K_n\left(\frac{W_d}{L}\right)V_o\left(V_i - V_{hnd} - \frac{V_o}{2}\right)$$

Since $I_{dd} \equiv I_{dl}$, where I_{dl} is given in step 1 above, the output voltage is now prescribed by

$$K_n\left(\frac{W_d}{L}\right)V_o\left(V_i - V_{hnd} - \frac{V_o}{2}\right) = K_n\left(\frac{W_l}{L}\right)\left(V_{\max} - V_o\right)^2$$

which produces the quadratic relationship

$$\left(1+\lambda_{dl}\right)V_o^2 - 2\left[V_{\max} + \lambda_{dl}\left(V_i - V_{hnd}\right)\right]V_o + V_{\max}^2 = 0$$

An approximate solution for the resultantly small output voltage V_o is

$$V_o \approx \frac{V_{\max}}{2\left[1+\lambda_{dl}\left(\dfrac{V_i - V_{hnd}}{V_{\max}}\right)\right]}$$

Unlike the linear output response corresponding to saturation of *MD*, the present result shows that the output voltage decreases nonlinearly with increasing input voltage V_i.

5) When used as a logical inverter, the logic "1" or "high" level for the circuit in Fig. 55.18 is $V_{\max}$, as defined in step 1. It follows that when the input voltage is $V_{\max}$, the logic "0" or "low" voltage $V_{\min}$ is established at the output port. From the output result derived in the preceding step,

$$V_{\min} \approx \frac{V_{\max}}{2\left[1+\lambda_{dl}\left(\dfrac{V_{\max} - V_{hnd}}{V_{\max}}\right)\right]}$$

The proper operation of a digital inverter requires that if a logic high input, $V_i = V_{\max}$, produces a logic low output, $V_o = V_{\min}$, the identical logic low input, $V_i = V_{\min}$, must result in an output response whose value mirrors the defined logic high; that is $V_o = V_{\max}$. Since an output voltage that is numerically equal to $V_{\max}$ is established only if zero current flows through the load transistor, and thus through the driver transistor as well, design care must be exercised to ensure that the logic "0" voltage $V_{\min}$ is smaller than the threshold voltage V_{hnd} of the driver. Using the preceding relationship, $V_{\min} < V_{hnd}$ implies the requirement

$$\lambda_{dl} > \frac{\dfrac{V_{\max}}{2V_{hnd}} - 1}{1 - \dfrac{V_{hnd}}{V_{\max}}}$$

that is, the subject inverter must be capable of sufficient gain. Figure 55.19 summarizes the foregoing disclosures by sketching V_o as a function of V_i.

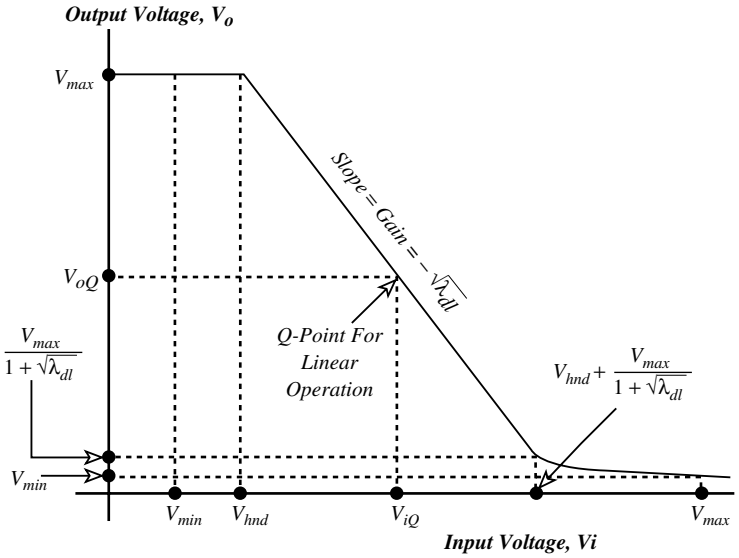

FIGURE 55.19 Static transfer characteristic of an N-channel enhancement-loaded common source inverter.

Engineering Description of Device Operation

A circuit analysis based on the model defined by (55.60) is useful only to the extent that a first–order estimate of MOSFET circuit performance is required. A more accurate estimate of circuit responses demands the use of more sophisticated MOSFET models. Before discussing these refinements, it is instructive to articulate several engineering and physical concepts that underlie the simplified device representation.

To the foregoing end, consider an N-channel enhancement-mode MOSFET operated under the usual case of nonpositive bulk–source biasing V_{bs}, a small drain–source voltage V_{ds}, and a gate–source voltages V_{gs}, that is allowed to vary from zero to a voltage that is larger than the gate–source threshold potential V_{hn}. Figure 55.20 shows the simplified cross section of the device, together with the depletion layers corresponding to the indicated biasing.

For the case of $V_{ds} = V_{bs} = 0$, depletion layers are formed around all bulk–source and bulk–rain junctions. These depletion layers are the zero bias transition regions that establish device equilibrium. For equally doped source and drain diffusions, the depletion layers are uniformly thick, and because the bulk is much more lightly doped than is either the drain or the source diffusion, most of the depletion layer thickness extends into the bulk. If V_{bs} is made negative, the reverse biasing across the bulk–source and bulk–drain junctions increases, and the depletion layer thickness increases uniformly. If V_{ds} is also increased, the depletion region about the drain becomes thicker than the depletion layer about the source, since the net reverse bias at the bulk–drain junction perimeter is $V_{ds} - V_{bs}$, while at the bulk–source junction, the reverse bias is only $-V_{bs}$.

The Depletion Condition. If the gate–source voltage V_{gs}, is allowed to increase to a positive value that is smaller than the gate–source threshold potential, and if the bulk–source voltage V_{bs}, is at most 0 V, no drain current, I_d, can flow even if the drain–source voltage, V_{ds}, is large. In order to understand this fact, it is fruitful to paint a qualitative electrostatic picture corresponding to the biasing, $V_{bs} < 0$, $V_{ds} > 0$, and $0 < V_{gs} < V_{hn}$. This biasing circumstance defines the so-called *depletion condition* in an N-channel enhancement mode MOSFET.

The immediate effect of $V_{gs} > 0$ is to establish a vertical electric field the gate metal (or polysilicon), through the oxide layer, and toward the silicon, as shown by the directed lines in the diagram of Fig. 55.20 Electric field lines must terminate on negative charges. Since the only substantive source of such charges

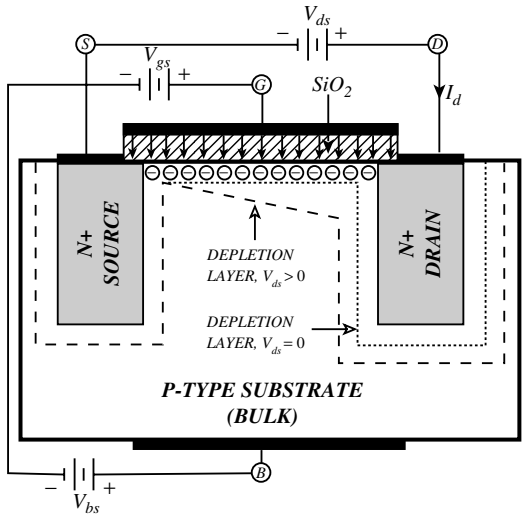

FIGURE 55.20 Cross section of an N-channel enhancement–mode MOSFET showing depletion layers for zero and positive drain–source voltages V_{ds}. The applied bulk source voltage V_{bs} is presumed to be negative or zero, and the voltage V_{gs} applied from gate to source is positive. The encircled negative signs symbolize immobile ionized acceptor atoms. The vertical arrows in the oxide layer represent the electric field induced by applied gate–source potential. The diagram is not drawn to scale.

in an N-channel enhancement–mode MOSFET is ionized acceptor impurities in the bulk, the electric field corresponding to positive V_{gs} induces a depletion region beneath the gate in the MOSFET channel between source and drain. Equivalently, the electrostatic force associated with positive V_{gs} drives the free holes originally present in the interfacial channel region deeper into the bulk, thereby leaving only immobile ionized impurity atoms (depicted as encircled negative signs in the figure) in the channel beneath the gate. The resultant *channel depletion layer*, or *surface depletion layer*, complements the depletion layers already established around the perimeters of the source and drain diffusions. The bulk side boundaries of these transition layers are illustrated in Fig. 55.20 for the cases of $V_{ds} = 0$ and $V_{ds} > 0$.

The reason underlying zero drain current response to even relatively large drain–source voltages is now apparent. In particular, appreciable drain current is realized only if a correspondingly large electron concentration is transported from the source to the drain. Only two paths are conceivable for this charge transport. One is through the channel depletion region, and the other is through the substrate bulk lying beneath the surface depletion layer. But no free electrons are present in the surface depletion region. Furthermore, no free electrons can be injected from the source to the bulk, thence into the drain, because the junction perimeters of both the source and drain regions are reverse biased in the depletion mode of operation. Hence, I_d is essentially zero in the depletion mode of operation.

The Inversion Condition. If the thin interfacial channel region described in the preceding subsection were to contain a large concentration of free electrons, in addition to immobile acceptor ions, a drain current would flow in response to the application of positive drain–source voltage. Positive V_{ds} serves to attract channel electrons in the direction of source to drain, thereby effecting a drain current path from drain, through the channel, to the source. The transport of electrons through the channel in response to a lateral electric field set up in the direction of drain to source by the application of positive V_{ds} is, in fact, the principle mechanism for current flow in an N-channel MOSFET. The problem now is to understand how an appreciable electron concentration is induced in the interfacial channel that is heavily populated by ionized bulk impurities.

Boltzmann statistics and the mass action law provide the answer to the foregoing query. The electric field at the surface of the MOSFET produces a potential, say V_y, at the interface of oxide and silicon. If

© 2003 by CRC Press LLC

an allowance is made for a potential drop, say V_{ox}, from the interface of gate metal (or polysilicon) and gate oxide to the interface of gate oxide and silicon surface, this induced interfacial potential subscribes to the Kirchhoff's voltage law (KVL) relationship

$$V_{gs} = V_{ox} + V_y \tag{55.61}$$

For analytical expedience, the electrical effects of work function differences [3] between gate lead and gate metal (or polysilicon) and between gate metal (or polysilicon) and gate silicon dioxide are presumed to have been incorporated into the voltage V_{ox}. The aforementioned interfacial potential V_y, defines the free-electron concentration is the interfacial channel region in accordance with

$$n = n_o e^{V_{y/V_T}} = \frac{N_{iB}^2}{p_o} e^{V_y/V_T} \tag{55.62}$$

where V_T is the Boltzmann voltage, N_{iB} is the intrinsic carrier concentration in the substrate bulk p_o, the equilibrium concentration of holes in the bulk, is very nearly equal to the average bulk impurity concentraton N_A, and

$$n_o = \frac{N_{iB}^2}{p_o} \approx \frac{N_{iB}^2}{N_A} \tag{55.63}$$

represents the equilibrium concentration of free electrons in the bulk.

Equation (55.62) establishes the mechanism for achieving large-free-electron concentrations in the interfacial channel region. It shown that n rises dramatically with the potential V_y. Suppose that V_y is allowed to increase to a voltage that forces n to equal the intrinsic carrier concentration, N_{iB}. This particular value of V_y is symbolized as V_F and is termed the **Fermi potential** of the substrate bulk. From (55.62) and (55.63)

$$V_F = V_T \ln\left(\frac{N_A}{N_{iB}}\right) \tag{55.64}$$

which is typically of the order of 300 mV. It is crucial to understand that at an interfacial potential of V_F, the channel immediately beneath the oxide–silicon interface is intrinsic; that is, it is neither P-type, as it was prior to the application of the Fermi potential at the interface, nor is it N-type, which is mandated for significant drain currents. Further increases in V_y, which are realized by increasing the gate–source voltage V_{gs}, result in corresponding increases in electron concentration. When V_y is slightly greater than V_F, the interfacial channel is said to experience *weak inversion* in the sense that there are now more electrons than there are holes in the interfacial channel region.

There is a practical limit to the magnitude of V_y. This limit is the interfacial potential corresponding to $n = N_A$, since only one hole can be relinquished by, and hence only one electron can be attracted to, each bulk impurity atom. From (55.62) and (55.63), $n = N_A$ implies $V_y = 2V_F$. This value of interfacial potential is essentially constant, and when it is achieved, the N-channel enhancement mode MOSFET is said to be in *strong inversion*.

Although drain currents can be observed for interfacial potentials in the weak inversion range, $V_F < V_y < 2V_F$, the condition for substantial current flow, in the sense of that predicted by the simplified static model of 55.60), is generally taken to be strong inversion; that is $V_y = 2V_F$. The gate–source voltage V_{gs} corresponding to the strong inversion requirement is the threshold voltage V_{hn}. By (55.61)

$$V_{hn} = V_{ox} + 2V_F \tag{55.65}$$

However, $V_{gs} > V_{hn}$ ensures strong inversion, and hence a substantive supply of free–channel electrons, at only the source end of the channel. In order for strong inversion to prevail throughout the entire

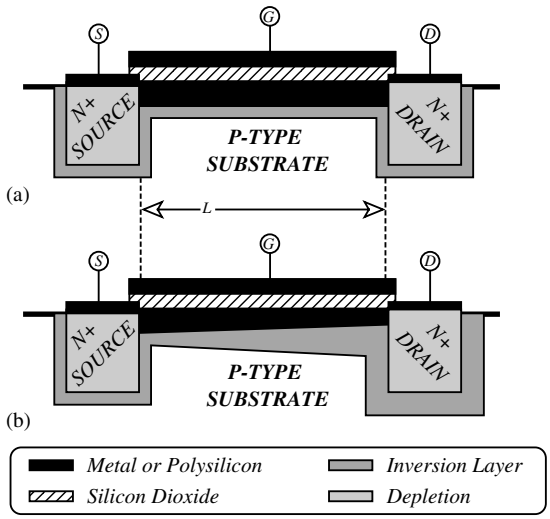

FIGURE 55.21 Simplified cross sections of an N-channel enhancement-mode MOSFET. The substrate contact is now shown, and it is assumed that the bulk–source voltage V_{bs} is zero. (a) The case of $V_{gs} > V_{hn}$ and $V_{ds} = 0$. (b) The case of $V_{gs} > V_{hn}$ and $0 < V_{ds} < V_{dss}$.

source to drain channel, it is also necessary that the gate–drain voltage V_{gd} exceed the threshold potential V_{hn}. Since

$$V_{gd} = V_{gs} - V_{ds} \tag{55.66}$$

$V_{gd} > V_{hn}$ implies

$$V_{ds} < V_{gs} - V_{hn} \equiv V_{dss} \tag{55.67}$$

Thus, the biasing constraints $V_{gs} > V_{hn}$ and $V_{ds} < V_{dss}$, which ensure MOSFET operation in the ohmic regime of its static characteristic curves, are equivalent to establishing the criteria for strong inversion of the entire interfacial channel region.

Figure 55.21 depicts the channel inversion situation for $V_{ds} = 0$ and for $0 < V_{ds} < V_{dss}$, with the bulk–source voltage V_{bs} taken as zero in both cases. For $V_{ds} = 0$, the diagram in Fig. 55.21 (a) shows that the depletion layers around the perimeters of the source, drain, and inverted channel are uniformly thick, as is the channel inversion layer itself. This uniformity reflects identical reverse biases imposed across both the bulk–source and bulk–drain junctions as a result of zero drain–source voltage. The uniformly thick inverted channel volume can be perceived as a resistive semiconductor bar, for which the resistance is R_{ds}, as defined by (55.55). From a physical perspective, it also derives from

$$R_{ds} = \frac{\rho_c L}{A_{\text{eff}}} \tag{55.68}$$

where ρ_c is the average resistivity of the inverted channel, and A_{eff} is the effective cross–sectional area pierced by electrons in transit from the N+ source region to the N+ drain region. This area is the thickness of the inverted channel multiplied by W, the depth of the channel, measured in a direction that is perpendicular to the face of the page in Fig. 55.21(a). Since the free–channel charge concentration, n, is predominantly electrons, the resistivity in (55.68) is

$$\rho_c \approx \frac{1}{q\mu_n n} \tag{55.69}$$

© 2003 by CRC Press LLC

with μ_n representing the mobility of channel electrons. The Ohm's law relationship $I_d = V_{ds}/R_{ds}$ therefore suggests that the ohmic regime drain current, I_d, is proportional to the electron mobility, μ_n, as well as to the geometrical factor, (W/L). The latter contention reinforces the previously discussed direct dependence of drain current on the gate aspect ratio.

The situation corresponding to $V_{ds} > 0$ is depicted in Figure 55.21(b). The thickness of the depletion layer about the perimeter of the bulk–drain junction is now larger than the depletion layer thickness about the bulk–drain junction. This enhanced layer thickness stems from a reverse bias about the bulk–drain junction that is larger than that across the bulk–source junction by an amount V_{ds}. Additionally, the inversion layer nearer the drain end of the channel is thinner than it is near the source end because the gate–drain voltage supporting inversion at the drain site is smaller by the same amount, V_{ds}, than is the gate–source voltage that induces an inversion layer near the source. This nonuniform inversion layer suggests that the resistance R_{ds} associated with the resistive inversion region is no longer independent of the drain–source voltage. It follows that the resultant drain current $I_d = V_{ds}/R_{ds}$, is dependent on V_{ds} as is borne out by the second of the static characteristic equations in (55.60).

There is yet another important aspect of positive V_{ds}. In general, the current flowing through a semiconductor volume is the superposition of drift and diffusion components. When the free-carrier concentration that supports current flow has no charge gradient in the plane of charge transport, the current is exclusively a drift component proportional to the electric field established in the charge transport plane. Such a situation prevails for small V_{ds}, which is to say the drain current arising from the application of small drain–source voltages is approximately proportional to the lateral field established in the direction of drain to source by positive V_{ds}. Further increases in the drain–source voltage incur a more pronounced gradient to the inversion layer charge. Accordingly, the diffusion component of net drain current progressively increases with increasing V_{ds}. Despite inceases in this diffusion current component, the simplified static volt–ampere relationships of (55.60) account for only drift current effects in the interfacial channel of a MOSFET.

Pinchoff and Saturation. As discussed in the preceding section, the thickness of the inversion layer narrows narrows nearer the drain site for increasing values of the drain–source voltage V_{ds}. If V_{ds} is increased to a value that equals the drain saturation voltage V_{dss}, the inversion layer thickness vanishes at the drain end of the channel since the interfacial potential at the end becomes zero. Figure 55.22(a) depicts this so-called channel *pinchoff condition*. Since the inversion layer thickness is zero at the drain end of the channel when $V_{ds} = V_{dss}$, the differential resistance there is infinitely larger, which corroborates the channel resistance conclusions drawn earlier in conjunction with (55.55).

If V_{ds} is increased beyond V_{dss}, the second equation in (55.60) is impertinent to the volt–ampere characteristics of an N-channel enhancement mode MOSFET because the channel inversion region no longer embraces the entire metallurgical channel length L, as depicted in Fig. 55.22(b). Stated in other terms, the gradient of the channel charge profile increases for $V_{ds} > V_{dss}$ to such an extent that drift is no longer the predominant charge transport mechanism supporting the flow of drain current. The diminished channel length contention can be argued as follows. The application of a drain–source voltage V_{ds} establishes a lateral electric field directed through the channel region from the drain to the source. This electric field induces a channel voltage, say V_x, with respect to the source at any position x within the length of the channel. If V_{dss} is the value of drain–source voltage that precisely establishes the inversion charge profile depicted in Fig. 55.22(a), $V_{ds} > V_{dss}$ suggests that the total electron charge embodied by this profile must be contained in a cross–sectional channel area whose length, say L' is smaller than L. In particular, if V_{ds} is written as

$$V_{ds} = V_{dss} + \Delta V_{ds} \tag{55.70}$$

V_{dss} is the potential dropped over the length, L', of the channel, while ΔV_{ds} is the voltage dropped over the channel segment ΔL, as indicated in Fig. 55.22(b).

© 2003 by CRC Press LLC

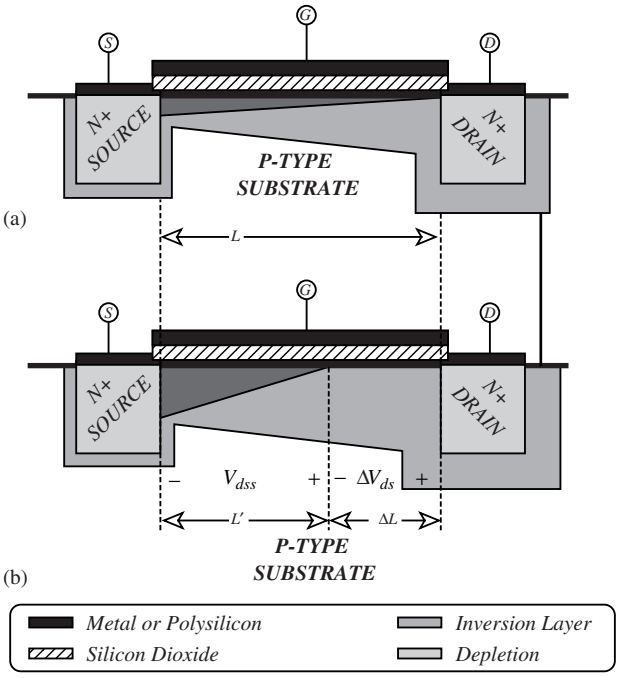

FIGURE 55.22 Simplified cross sections of an N-channel enhancement–mode MOSFET. The substrate contact is not shown, and it is assumed that the bulk–source voltage V_{bs} is zero. (a) The case of $V_{gs} > V_{hn}$ and $V_{ds} \equiv V_{dss}$. (b) The case of $V_{gs} > V_{hn}$ and $V_{ds} = V_{dss} + \Delta V_{ds}$.

Note that the channel region of length ΔL comprises a depletion layer whose intrinsic electric field is a function of the difference voltage, ΔV_{ds}. Intuitively, a drain current dependence on ΔL, and hence on ΔV_{ds}, can be suspected since the large lateral electric field associated with large ΔL (and thus, large V_{ds}) encourages the transport of inversion layer electrons into the drain region. This intuitively deduced dependence of I_d on ΔL is ignored in the third equation of (55.60) for the static model of an N-channel enhancement-mode MOSFET.

Refinements to the Simple MOSFET Model

Several refinements to the simple static model of a MOSFET are typically invoked in either manual or computer-aided analyses of MOS technology circuits. Among these are channel length modulation corrections to the drain saturation current, incorporation of threshold voltage dependence on bulk–source bias, incorporation of series lead resistances, and inclusion of charge storage phenomena in the carrier transport mechanism that underlies MOSFET operation. These refinements are discussed below with respect to only N-channel devices. With appropriate symbolic changes, they apply equally well to P-channel MOSFETs.

Channel Length Modulation. As discussed carlier, the effective channel length of a MOSFET decreases by an amount ΔL when the transistor operates in the saturated regime of its static characteristic curves. Recall from (55.59) that the drain current flowing in an N-channel MOSFET is I_{dss} when the drain–source voltage V_{ds} is V_{dss}. Since I_{dss} is inversely proportional to the channel length L, the drain current I_d for $V_{ds} > V_{dss}$ must be larger than I_{dss} by a factor of $[L/(L - \Delta L)]$; that is,

$$I_d\big|_{V_{ds} \geq V_{dss}} = I_{dss}\left(\frac{L}{L-\Delta L}\right) = \frac{\dfrac{K_n}{2}\left(\dfrac{W}{L}\right)\left(V_{gs} - V_{hn}\right)^2}{1 - \dfrac{\Delta L}{L}} \tag{55.71}$$

© 2003 by CRC Press LLC

In this semiquantitative relationship, the factor $\Delta L/L$ relates empirically to the drain–source voltage as

$$\frac{\Delta L}{L} = \frac{1}{1 + \dfrac{V_\lambda}{V_{ds} - V_{dss}}} \tag{55.72}$$

so that in the saturated domain,

$$I_d\big|_{V_{ds} \geq V_{dss}} = \frac{K_n}{2}\left(\frac{W}{L}\right)\left(V_{gs} - V_{hn}\right)^2\left(1 - \frac{V_{ds} - V_{dss}}{V_\lambda}\right) \tag{55.73}$$

In this expression, V_λ termed the **channel length modulation voltage**, is of the order of tens of volts. Instead of the zero slope in the saturated common drain static volt–ampere characteristics that is indicated in Fig. 55.17, the effect of a finite channel length modulation voltage is to incur a nonzero slope I_{dss}/V_κ in each of these curves.

Example 2. In the circuit of Fig. 55.23, all transistors have a transconductance coefficient of 200 μmho/V. Transistor $M2$ has a threshold voltage of 2.3 V, a channel length modulation voltage of 25 V, and a gate aspect ratio that is five times larger than that of transistor $M1$. In turn, $M1$ is characterized by a threshold voltage of 2.0 V, and a channel length modulation voltage of 20 V. Transistor $M3$ has a gate aspect ratio of 10, a gate–source threshold voltage of 1.8 V, and a channel length modulation voltage of 45 V. If the power line voltage, V_{DD}, is 5.2 V, calculate the current, I_{d3}, flowing in the drain of transistor $M3$ for V_{CC} = 5.2 V and V_{CC} = 10.4 V.

Solution.

1) Both transistors $M1$ and $M2$ operate in their saturation regions since the gate and drain terminals of each of these devices are electrically tied together. Moreover, since the substrates of all transistors are grounded and no negative voltages are applied to the circuit, the currents conducted by transistors $M1$ and $M2$ are identical. Accordingly, from (55.74)

$$\frac{K_n}{2}\left(\frac{W_2}{L}\right)\left(V_{gs2} - V_{hn2}\right)^2\left(1 + \frac{V_{ds2} - V_{dss2}}{V_{\lambda 2}}\right)$$
$$= \frac{K_n}{2}\left(\frac{W_1}{L}\right)\left(V_{gs1} - V_{hn1}\right)^2\left(1 + \frac{V_{sd1} - V_{dss1}}{V_{\lambda 1}}\right)$$

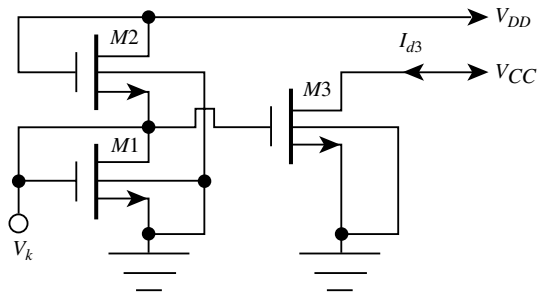

FIGURE 55.23 Schematic diagram of an enhancement-mode N-channel MOSFET constant current sink.

© 2003 by CRC Press LLC

In this expression, the gate–source voltage of $M2$, V_{gs2}, is $(V_{DD} - V_k) \equiv V_{ds2}$, the drain–source voltage of transistor $M2$, and V_{gs1}, the gate–source voltage of transistor $M1$, which is also the drain–source voltage of $M1$, is the voltage V_k, indicated in the schematic diagram. Moreover, from (55.67), the drain–source saturation voltage V_{dss2}, of $M2$ is $(V_{gs2} - V_{hn2}) \equiv (V_{DD} - V_k - V_{hn2})$, while the drain–source saturation voltage V_{dss1} of transistor $M1$ is $(V_{gs1} - V_{hm1}) \equiv (V_k - V_{hn1})$. Using these observations and introducting a parameter h such that

$$h = \sqrt{\frac{1 + \dfrac{V_{hm1}}{V_{\lambda 1}}}{\left(\dfrac{W_2/L}{W_1/L}\right)\left(1 + \dfrac{V_{hn2}}{V_{\lambda 2}}\right)}}$$

the foregoing current relationship yields

$$V_k = \frac{V_{DD}}{h+1} - \frac{V_{hn2} - hV_{hn1}}{h+1}$$

For the stipulated device parameters and circuit variables, V_k is 2.62 V. Note that the $M1$–$M2$ subcircuit functions as a voltage divider that serves to transform the power line voltage V_{DD} into a voltage V_k that is suitable for biasing the current sinking transistor $M3$.

2) For transistor $M3$ in Fig. 55.23, the gate–source voltage is V_k, the drain–source voltage is V_{CC}, and the drain–source saturation voltage is $V_k - V_{hn3}$. Since $V_{CC} > (V_k - V_{hn3})$, at even the smallest value of V_{CC} of interest, $M3$ is always saturated. Thus,

$$I_{d3} = \frac{K_n}{2}\left(\frac{W_3}{L}\right)\left(V_k - V_{hn3}\right)^2\left(1 + \frac{V_{CC} - V_k + V_{hn3}}{V_{\lambda 3}}\right)$$

For $V_{CC} = 5.2$ V, I_{d3} is 740.0 μA, while $V_{CC} = 10.4$ delivers $I_{d3} = 817.9$ μA. It follows that the effect of a finite channel length modulation voltage in transistor $M3$ is to increase the drain current flowing in this device by 10.5% when V_{CC} doubles its original 5.2 V value.

Substrate Bulk Effect on Threshold Voltage. In an N-channel enhancement mode MOSFET, the gate–source threshold voltage V_{hn}, is not a constant, as inferred by (55.65). Instead, V_{hn} is modulated by the applied bulk–source voltage, V_{bs}. This *threshold modulation*, which is commonly called **bulk** or **body effect**, can be understood qualitatively by studying the effect of a strong reverse bias applied from the substrate to the source. In particular, a large negative value of V_{bs} serves to deplete the bottom part of the substrate in the immediate neighborhood of the bulk contact. As a result, free electrons in this neighborhood are displaced toward the oxide-semiconductor interface. Since interfacial depletion precedes the channel inversion caused by a gate–source bias that is at least as large as the threshold potential, these displaced free electrons must be pushed back down into the body of the substrate before channel inversion can occur. The threshold voltage expression given by (55.65) accounts for only equilibrium (zero net reverse bias across the boundary separating the inversion layer from the substrate) concentrations of free substrate electrons. Thus, the actual threshold voltage must be that given by (55.65) plus a correction to allow for the additional energy required to displace substrate electrons that are no longer in equilibrium because of nonzero V_{bs}. This correction is minimal for lightly doped substrates. Substrate bias–induced threshold voltage modulation is also minimized by thin oxides. Thin oxide layers promote strong vertical field intensities for even small gate–source biases, thereby expediting interfacial channel depletion.

© 2003 by CRC Press LLC

A suitable expression for the corrected threshold voltage, say V_{hnc}, is

$$V_{hnc} = V_{hn} + \sqrt{2V_\theta\left(2V_F - 2V_T - V_{bs}\right)} \tag{55.74}$$

where V_F is defined by (55.64). With

$$L_a = \sqrt{\frac{\varepsilon_s V_T}{qN_A}} \tag{55.75}$$

representing the *Debye length* of electrons in a substrate having an average impurity concentration of N_A, the parameter V_θ, which is known as the **body effect voltage**, is

$$V_\theta = \frac{\left(qN_A L_a / C_{ox}\right)^2}{V_T} = \frac{qN_A \in_s}{C_{ox}^2} \tag{55.76}$$

In (55.75) and (55.76), ε_s is the dielectric constant of silicon [1.053 pF/cm], while C_{ox} is the density of gate oxide capacitance given by (55.52).

In (55.74), the effect of a bulk–source reverse bias $V_{bs} < 0$ is to increase the effective threshold voltage V_{hnc}. The amount of such increase depends on the value of the body effect voltage V_θ. Confirming earlier contentions, the amount of requisite threshold correction is small if V_θ is small, which requires small substrate concentration and/or large C_{ox} (corresponding to small oxide thickness T_{ox}).

Equation (55.74) is easily modified to embrace P-channel transistors by replacing V_{hnc} by V_{hpc}, the corrected source to gate threshold voltage of a P-channel enhancement mode MOSFET. Additional changes entail replacing V_{hn} by V_{hp}, substituting V_{sb}, the source to substrate bias, for V_{bs}, and finally, replacing N_A in (55.75) and (55.76) by N_D, the average donor concentration in the N-type substrate of a P-channel device.

It is often convenient to express the effective threshold voltage of an enhancement mode MOSFET in terms of the zero bias threshold voltage; that is, the threshold voltage prevailing with zero bias applied between bulk and source. From (55.74), the zero bias threshold voltage, say V_{hno}, is

$$V_{hno} = V_{hn} + 2\sqrt{V_\theta\left(V_F - V_T\right)} \tag{55.77}$$

It follows that

$$V_{hnc} = V_{hno} + 2\sqrt{V_\theta\left(V_F - V_T\right)}\left[\sqrt{1 - \frac{V_{bs}}{2\left(V_F - V_T\right)}} - 1\right] \tag{55.78}$$

Ohmic Resistances. Although ohmic resistances generally exert negligible effects on the volt–ampere characteristics of MOSFETs, they nonetheless materialize in the bulk, drain, and source regions. The topological significance of these parasitic resistances is abstracted by the symbolic schematic diagram of the N-channel enhancement-mode MOSFET shown in Fig. 55.24.

The resistance of the heavily doped drain region is r_{dd}, and its source region counterpart is r_{ss}. Both of these resistances are of the order of a few ohms. Unfortunately, they are difficult to calculate satisfactorily because their respective net values incorporate the contact resistances formed at the surface of the drain and source. Moreover, they are spreading resistances, since the currents in the drain and source do not flow in one direction. The resistance, r_{bb}, is a spreading resistance associated with the bulk substrate. Because of the relatively light impurity concentration in the bulk, r_{bb} is considerably larger than either r_{dd} or r_{ss}. Under static conditions, however, the voltage dropped across r_{bb} is about the same as, or even less than, the voltages dropped across the internal drain and source resistances, since the substrate–source

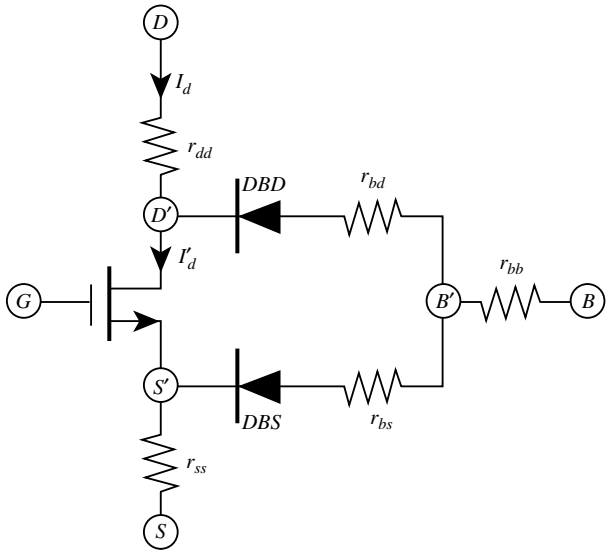

FIGURE 55.24 Schematic diagram of an N-channel enhancement–mode MOSFET with internal ohmic resistances and bulk–drain and bulk–source diodes explicitly delineated. For P-channel devices, the diode connections are reversed, as are the indicated reference directions of the currents, I_d and I'_d.

and substrate–drain junctions are reverse biased. These junctions are represented respectively by the diodes, *DBS* and *DBD*, which have their own internal ohmic resistances, r_{bs} and r_{bd}, respectively.

The immediate effect of incorporating regional ohmic resistances into the MOSFET model is to separate internal drain, source, and bulk nodes from the externally accessible drain, source, and bulk terminals. Thus, the drain–source (V_{ds}), gate–source (V_{gs}), bulk–source (V_{bs}), bulk–drain (V_{bd}), and gate–drain (V_{gd}) voltages exploited previously in all modeling relationships and discussions must now be interpreted as the voltages appearing from internal drain (D′) to internal source (S′), gate to internal source, internal bulk (B′) to internal source, internal bulk to internal drain, and gate to internal drain terminals, respectively. Likewise, the drain current, I_d, in all preceding modeling expressions must be viewed as the channel current I'_d in Fig. 55.24. Note that the channel current differs from the measurable drain current by an amount that equals the small reverse bias current that flows through the drain–bulk PN junction diode.

MOSFET Capacitances. The frequency response of MOS analog circuits and the switching speed of MOS digital circuits are limited by the time required to charge and discharge capacitances that appear between internal device nodes, from interconnecting metallization to the circuit ground plane, and between interconnecting electrical lines. Figure 55.25 illustrates the topological interconnection of intrinsic device capacitances.

The capacitors, C_{bd} and C_{bs}, represent *transition capacitances* associated with the PN bulk–source and bulk–drain junctions. Both of these elements have the voltage function form,

$$C = \frac{C_0}{\left[1 - \dfrac{V}{V_j - 2V_T}\right]^m} \tag{55.79}$$

where m is the *grading coefficient*, C_0 is the *zero-bias value of the transition capacitance*, and V_j is *built-in potential* of the pertinent junction. When computing C_0, care must be taken to include the areas of the drain and source diffusion sidewalls, as well as the areas of the bottoms of these diffused or implanted regions.

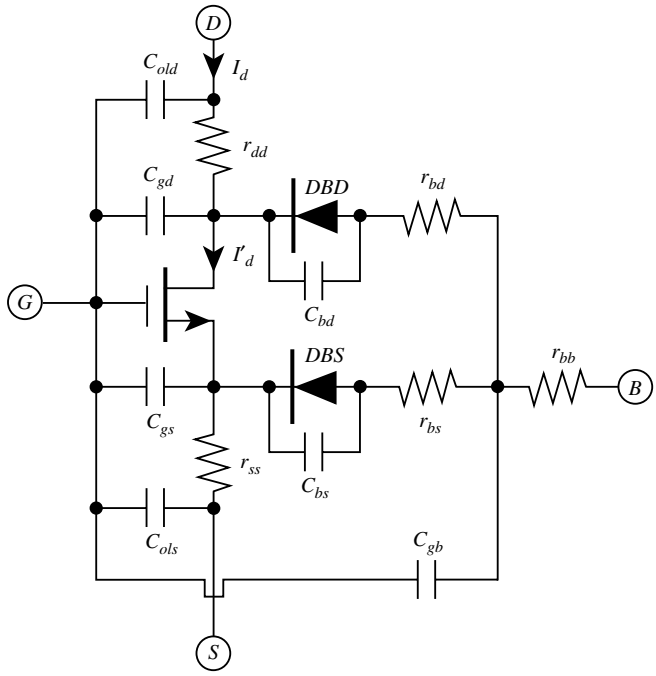

FIGURE 55.25 Schematic diagram of an N-channel enhancement-mode MOSFET with internal ohmic resistances, bulk–drain and bulk–source diodes, and internal device capacitances explicitly delineated. The diodes *DBD* and *DBS* appear as ideal elements in the senses of zero internal capacitances and resistances. For P-channel devices, the diode connections are reversed, as are the indicated reference directions of the currents I_d and I'_d.

The capacitors, C_{old} and C_{ols}, are *overlap capacitances* between the gate and drain and the gate and source, respectively. These capacitances are zero when the subject MOSFET is fabricated in self–aligning gate technology.

To first order, the sum of gate–bulk (C_{gb}), gate–drain (C_{gd}), and gate–source (C_{gs}) capacitances is the net effective capacitance of the gate oxide layer; that is,

$$\mathrm{WLC}_{ox} = C_{gb} + C_{gd} + C_{gs} \tag{55.80}$$

The partitioning of WLC_{ox} into three component capacitances entails a complex calculation. Such partitioning must ensure consistency between capacitive charging currents and the charge storage and transport implications of the static volt–ampere relationships of the MOSFET mode [4]–[6]. For manual analysis purposes, the following approximate relationships have proven to be effective.

1. For linear small-signal operation in the **ohmic region** of the static MOSFET characteristic curves [7],

$$C_{gs} = \frac{\mathrm{WLC}_{ox}}{2}\left(1 + \frac{V_{dsQ}}{3V_{dssQ}}\right) \tag{55.81}$$

and

$$C_{g} = \frac{\mathrm{WLC}_{ox}}{2}\left(1 - \frac{V_{dsQ}}{V_{dssQ}}\right) \tag{55.82}$$

In these two expressions, V_{dsQ} and V_{dssQ}, respectively, symbolize the quiescent values of interal drain–source voltage and drain saturation voltage. Equation (55.80) through (55.82) imply

© 2003 by CRC Press LLC

$$C_{gb} = \mathrm{WLC}_{ox}\left(\frac{V_{dsQ}}{3V_{dssQ}}\right) \tag{55.83}$$

2. For linear small-signal operation in the **saturation region** of the static MOSFET characteristic curves [8]

$$C_{gs} = \frac{2\mathrm{WLC}_{ox}}{3} \tag{55.84}$$

$$C_{gd} \approx 0 \tag{55.85}$$

and

$$C_{gb} = \frac{\mathrm{WLC}_{0x}}{3} \tag{55.86}$$

Note that despite $C_{gd} \approx 0$, the net effective gate–drain capacitance is not zero; rather, it is C_{old}, the gate–drain overlap capacitance.

Other High-Order Effects. At risk of oversimplification, most of the deviations between the observed electrical behavior of MOSFETs and the response predicted by either the simplified model or any of its embellished versions result from processing and manufacturing attempts aimed toward improving the electrical performance of these devices. For example, a continuing design issue is increased switching speed. In MOSFETs, the most commonly invoked mechanism for improved response speed is reduction in channel length. But there are several serious drawbacks to a progressively decreased channel length, most of which stem from the commensurate increase in the strength of the lateral electric field induced by drain–source bias.

One drawback of large channel fields is the possible saturation of the nominal velocity at which majority carriers (electrons in N-channel devices) are transported from the source to the drain [9]. In particular, at low field strengths, the carrier velocity increases almost linearly with the strength of the electric field in which the carrier is immersed. The relevant proportionality constant between carrier velocity and small electric field strengths is, in fact, the carrier mobility. But at high fields, this carrier velocity approaches a constant (known as the **saturated limited velocity**), thereby actually limiting the ability of a MOSFET to respond quickly to applied excitation. Moreover, *carrier velocity saturation* decreases the transconductance coefficient and increases the thermal sensitivity of static drain current [10].

A second ramification of the high electric fields associated with short channel lengths is the production of *hot carriers* [11]. Hot carriers differ from the routine majority carriers that populate the channel in that they absorb an amount of energy from the high lateral channel field that is large enough for them to overcome the potential barrier at the silicon dioxide–silicon interface and thus be injected into the gate oxide layer. This injection alters the voltage drop across the gate oxide and hence, the threshold voltage. The resultant threshold shift causes device turn on voltage perturbations that are especially troublesome in logic cells that are operated in noisy environments or in logic cells for which the logic swing (different between the logical "1" and logical "0" voltages) is small. The trapping of injected charge in the oxide layer also degrades the operational reliability of a MOSFET through a phenomenon known as *oxide wearout* [12], and it increases the vulnerability of the device to electromagnetic and nuclear radiation [13].

Yet another effect of high channel fields is *impact ionization*, or *avalanche multiplication*, in the high-field drain end of the channel [14]. The *secondary carrier emission* associated with this phenomenon can, like hot carrier production, lead to oxide charging. It can also induce substrate currents, thereby significantly modifying the static and dynamic behavior predicted by the simplified model and its first-order refinements [15].

© 2003 by CRC Press LLC

A more insidious problem materializes when impact ionization occurs in the bulk. Secondary carriers emitted in the bulk can diffuse large distances owing to the relatively light doping concentration of the substrate. These diffusing carriers can perturb the electrical operation of proximate devices on the same chip, thereby limiting the packing densities of junction isolated circuits [16]. Yet another substrate problem is *punchthrough*, wherein the depletion layers about the source and drain regions coalesce in the channel [17]. Punchthrough is an extreme condition that results from careless application of excessive drain–source voltage.

Finally, thin gate oxides are desirable from the viewpoint that they diminish the sensitivity of threshold voltage to bulk–source voltage. But the strong vertical electric fields encouraged by thin oxides also decrease the lateral, source to drain, mobility of free channel charges [18], since such fields tend to repel carriers toward the substrate bulk. As a result, the effective mobility of channel charges, which is known as *surface mobility*, can be markedly diminished from the concentration-dependent mobility experienced by current carriers under equilibrium conditions. This decrease in carrier mobility degrades the speed of MOSFET response, as well as reducing the static drain current predicted by the simplified model.

Small-Signal Equivalent Circuit

The development of the small-signal MOSFET model parallels the small-signal modeling of any nonlinear element. In particular, the nonlinear volt–ampere branch relationships of a MOSFET are expanded into a Taylor series about the quiescent operating point, and only the linear terms of these expansions are retained. For the model depicted in Fig. 55.25, the only nonlinearity, assuming that the bulk–drain and bulk–source diodes are reverse biased, is the internal drain current I'_d, which is a function of the internal gate–source, internal drain–source, and internal bulk–source voltages V_{gs}, V_{ds}, and V_{bs}, respectively. Thus,

$$I'_d \approx I'_{dQ} + \left.\frac{\partial I'_d}{\partial V_{gs}}\right|_Q \left(V_{gs} - V_{gsQ}\right) + \left.\frac{\partial I'_d}{\partial V_{ds}}\right|_Q \left(V_{ds} - V_{dsQ}\right) + \left.\frac{\partial I'_d}{\partial V_{bs}}\right|_Q \left(V_{bs} - V_{bsQ}\right) \tag{55.87}$$

If the signal components of drain current, gate–source voltage, drain–source voltage, and bulk–source voltage are denoted by

$$\begin{aligned} i'_{da} &= I'_d - I'_{dQ} \\ v_{ga} &= V_{gs} - V_{gsQ} \\ v_{da} &= V_{gs} - V_{dsQ} \\ v_{ba} &= V_{bs} - V_{bsQ} \end{aligned} \tag{55.88}$$

$$i'_{da} = g_{mf} v_{ga} + g_{mb} v_{ba} + \frac{v_{da}}{r_o} \tag{55.89}$$

Assuming, as is usually the case for linear signal processing applications, that the MOSFET is biased in its saturated domain, (55.73), (55.78), (55.87), and (55.89) yield a *forward transconductance* g_{mf} of

$$g_{mf} \triangleq \left.\frac{\partial I'_d}{\partial V_{gs}}\right|_Q = \sqrt{2K_n\left(\frac{W}{L}\right)I_{dQ}} \times \left[\frac{V_\lambda + V_{dsQ} - \left(\frac{3}{2}\right)V_{dssQ}}{\sqrt{V_\lambda\left(V_\lambda + V_{dsQ} - V_{dssQ}\right)}}\right] \tag{55.90}$$

© 2003 by CRC Press LLC

where I_{dQ}, V_{dsQ}, and V_{dssQ} are the quiescent values of the drain current, drain–source voltage, and drain saturation voltage, respectively. Observe that while the small-signal forward transconductance of a bipolar junction transistor increases linearly with the quiescent collector current, the small-signal forward transconductance of a MOSFET increases with only the square root of the quiescent drain current. Observe further that g_{mf} rises with the square root of gate aspect geometry and that for a large channel length modulation voltage V_λ,

$$g_{mf}\Big|_{V_\lambda \to \infty} \approx \sqrt{2K_n\left(\frac{W}{L}\right)I_{dQ}} \tag{59.91}$$

The equations used to arrive at (55.90) produce a *bulk transconductance* g_{mb} of

$$g_{mb} \triangleq \frac{\partial I'd}{\partial V_{bs}}\Big| q = \lambda_b g_{mf} \tag{55.92}$$

where

$$\lambda_b = \sqrt{\frac{V_\theta/2}{2\left(V_F - V_T\right) - V_{bsQ}}} \tag{55.93}$$

Note that the *threshold modulation factor* λ_b and hence the small-signal bulk transconductance, is small if V_θ, which is a measure of the influence exerted on the threshold voltage by bulk-source biasing, is small. Finally, the small-signal *channel resistance* r_o derives from

$$\frac{1}{r_o} \triangleq \frac{\partial I'_d}{\partial V_{ds}}\Big|_Q = \frac{I_{dQ}}{V_\lambda + V_{dsQ} - V_{dssQ}} \tag{55.94}$$

Equation (55.94) shows that the drain–source channel resistance is infinitely large for an infinitely large channel length modulation voltage V_λ.

Equation (55.89) and Fig. 55.25 give rise to the small-signal equivalent circuit of Fig. 55.26. In this model, the intrinsic drain–bulk and source–bulk diodes are replaced by open circuits on the assumption that the bulk–drain and bulk–source junctions are back biased. The resultant equivalent circuit is applicable to N-channel, as well as to P-channel enhancement-mode MOSFETs.

Example 3. The MOSFET inverter of Fig. 55.27(a) is biased at its input port by a voltage V_{GG} and design care is exercised to ensure that the driver transistor *MD* operates in its saturated regime. Specifically, if V_{oQ} symbolizes the quiescent component of the net output voltage V_o, $V_{oQ} > (V_{GG} - V_{hnd})$, where V_{hnd} is the threshold voltage of the driver. The driver transistor has a gate aspect ratio of (W_D/L), while the gate aspect ratio of the load device *ML* is W_L/L; otherwise, the two transistors in the circuit are identical. Derive expressions for the small-signal, low-frequency voltage gain $A_v = V_{os}/V_s$ of the circuit, and the small-signal driving point output resistance R_{out}, faced by the capacitance C_L. Additionally, give an expression for the 3-dB bandwidth, $B_{3\text{dB}}$, of the circuit, assuming that capacitance C_L is the dominant energy storage element in the neighborhood of the circuit 3-dB bandwidth.

Solution.

1) The first step toward solving this problem is to recognize that at low signal frequencies, the load transistor *ML* functions as a two terminal linear resistance, say R_{Leff}, as is suggested by the AC schematic diagram in Fig. 55.27(b). This resistance is the ratio V_x/I_x in the load transistor AC

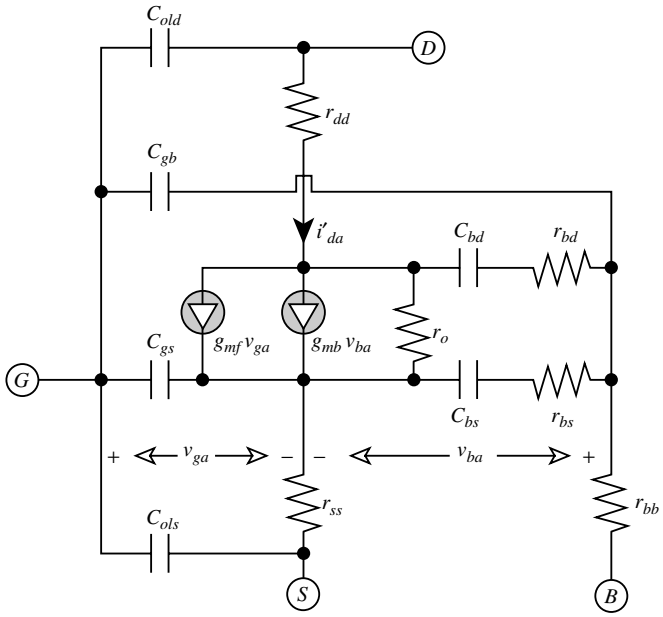

FIGURE 55.26 Small-signal, high-frequency equivalent circuit for N-channel and P-channel enhancement-mode MOSFETs. All indicated capacitances are evaluated at the quiescent operating point of the subject MOSFET.

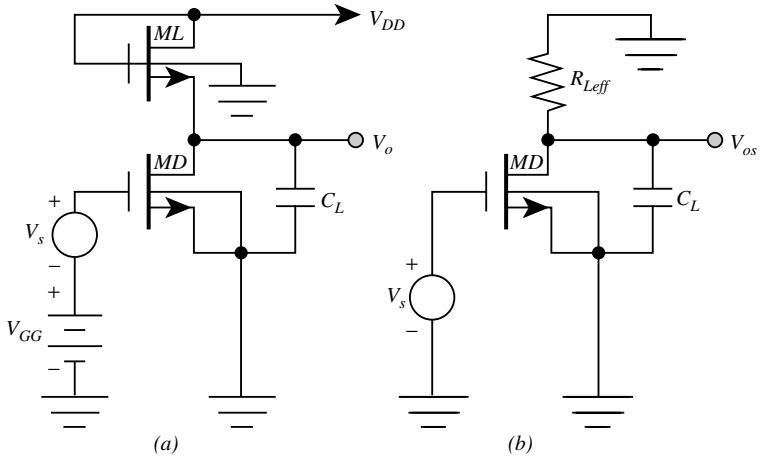

FIGURE 55.27 (a) A capacitively loaded N-channel enhancement-mode common source inverter. (b) AC schematic diagram of the circuit in (a). The battery voltages, V_{GG} and V_{DD}, are replaced by short circuits (or by their internal impedances, which are presumed to be zero here), the load transistor *ML* is replaced by an effective load resistance R_{Leff}, and the net output voltage V_o, is represented by its small-signal component V_{os}.

schematic diagram drawn in Fig. 55.28(a), for which the low-frequency small-signal equivalent circuit is the structure depicted in Fig. 55.28(b). An inspection of the latter diagram reveals

$$v_{ga} = v_{ba} = -V_x + r_{ssl} I_x$$

and

$$V_x = \left(r_{ssl} + r_{ddl}\right) I_x + r_{ol}\left[I_x + g_{mfl} v_{ga} + g_{mbl} v_{ba}\right]$$

© 2003 by CRC Press LLC

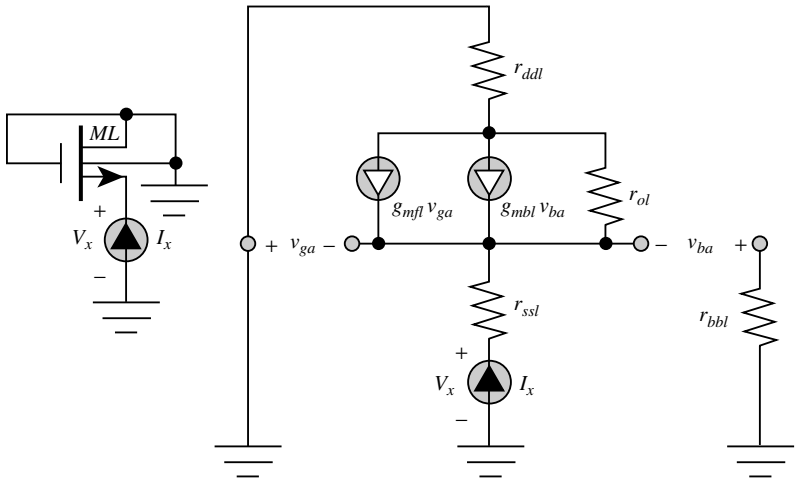

FIGURE 55.28 (a) AC schematic diagram of the load transistor in the amplifier of Fig. 55.27(a). (b) Small-signal, low-frequency equivalent model of the circuit in (a). The subscript "*l*," appended to the symbology for the conventional small-signal parameters of a MOSFET, signifies that the subject parameter corresponds to the load transistor.

Combining these two relationships and recalling (55.92), the effective resistance R_{Leff} presented to the drain of the driver transistor *MD* by the load transistor *ML* is

$$R_{Leff} \triangleq \frac{V_x}{I_x} = r_{ssl} + \frac{r_{ddl} + r_{ol}}{1 + (1 + \lambda_{bl}) g_{mfl} r_{ol}}$$

where λ_{bl} is the threshold modulation factor of the load transistor. Since the source and drain ohmic resistances, r_{ssl} and r_{ddl}, respectively, are very small and since the drain–source channel resistance, r_{ol}, is typically at least in the mid-tens of thousands of ohms, R_{Leff} can be approximated as

$$R_{Leff} \approx \frac{1}{(1 + \lambda_{bl}) g_{mfl}}$$

2) With the load transistor modeled as a two terminal load resistance, the AC schematic diagram of the inverting amplifier in Fig. 55.27(a) becomes the structure in Fig. 55.27(b), for which the small-signal model in the diagram is drawn in Fig. 55.29(a). Noting in the latter diagram that

$$v_{ga} = V_s + \left(\frac{r_{ssl}}{R_{\text{Leff}}} \right) V_{os}$$

and

$$v_{ba} = \left(\frac{r_{ssl}}{R_{\text{Leff}}} \right) V_{os}$$

a straightforward low-frequency circuit analysis produces a small-signal voltage gain A_v of

$$A_v = \frac{V_{os}}{V_s} = -\frac{g_{mfd} R_{\text{Leff}}}{1 + (1 + \lambda_{bd}) g_{mfd} r_{ssd} + \dfrac{R_{\text{Leff}} + r_{ddd} + r_{ssd}}{r_{od}}}$$

© 2003 by CRC Press LLC

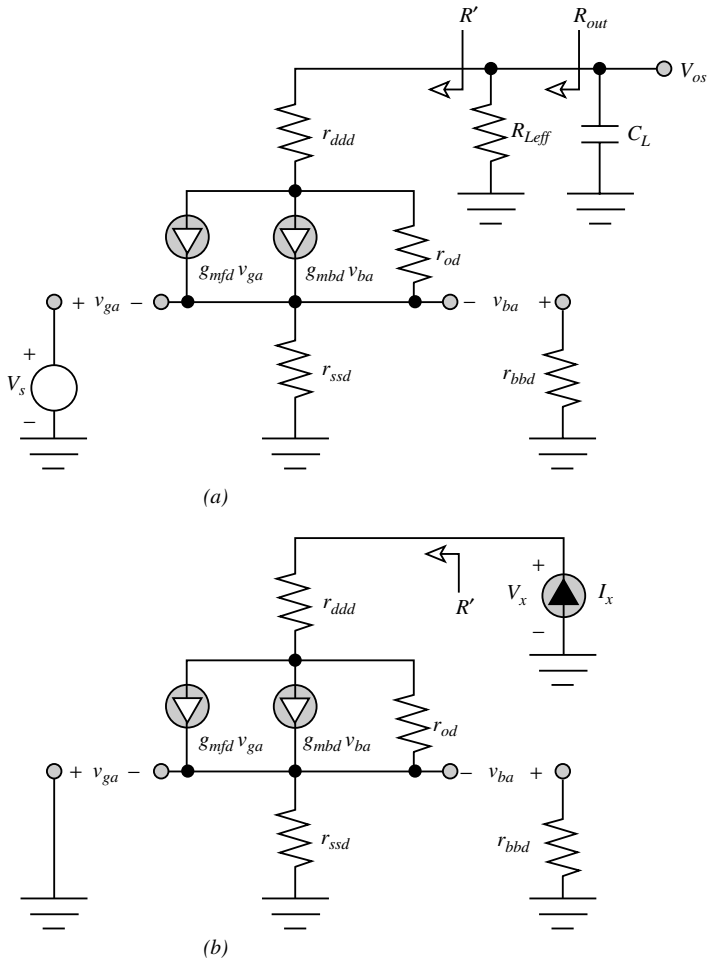

FIGURE 55.29 (a) Small-signal equivalent circuit of the amplifier represented by the AC schematic diagram in Fig. 55.27(b). (b) Small-signal model for calculating the resistance R′ presented to the output port of the amplifier in Fig. 55.27(a) by the driver transistor.

Observe a 180° phase inversion, as expected, between the source excitation and resultant output voltage response. Note further that for a large drain–source channel resistance, r_{od}, and small ohmic resistance, r_{ddd} and r_{ssd}, in the drain and source leads, respectively, the voltage gain relationship collapses to the simple expression

$$A_v \approx -g_{mfd}R_{Leff}$$

3) It is instructive to substitute the simplified expression for the effective load resistance into the foregoing approximate gain equation. The result is

$$A_v \approx -\frac{g_{mfd}}{\left(1+\lambda_{bl}\right)g_{mfl}}$$

The approximate gain relationship exploits the assumption of infinitely large drain-source channel resistance, and hence infinitely large channel length modulation voltage. Thus, (55.91) can be used for the transconductances that appear in the preceding gain equation. But since the load and driver

© 2003 by CRC Press LLC

transistors conduct the same quiescent drain current and since the two transistors are identical except for differing gate aspect ratios,

$$A_v \approx -\left(\frac{1}{1+\lambda_{bl}}\right)\sqrt{\frac{W_d/L}{W_1/L}}$$

The last result agrees well with the results of the voltage gain analysis performed in conjunction with Example 1. In that example, an analogous inverter was addressed analytically by applying a simple MOSFET model that inherently ignores both channel length and threshold modulation phenomena. In fact, the present result agrees exactly with the relevant results of Example 1 if in the present case, threshold modulation is ignored to constrain λ_{bl} to zero.

4) Since the load capacitance, C_L, in the inverting amplifer of Fig. 55.27(a) is assumed to be the dominant energy storage element at signal frequencies lying in the immediate neighborhood of the circuit 3-dB bandwidth, C_L is the only capacitive element that appears in the corresponding small-signal model of Fig. 55.29(a). With only one capacitance embedded in a low-pass network, the 3-dB bandwidth (in units of radians per second) is simply the inverse of the time constant established by the capacitance. Thus,

$$B_3 dB = \frac{1}{R_{\text{out}}C_L} = \frac{1}{\left(R' \| R_{L\text{eff}}\right)C_L}$$

where R_{out} is the driving point resistance facing C_L, and R' in Fig. 55.29(a) is the resistance seen to the left of the effective load resistance $R_{L\text{eff}}$. The resistance R' is the V_x/I_x ratio in the model of Fig. 55.29(b), which can be shown to be

$$R' = r_{ddd} + r_{ssd} + \left[1 + \left(1+\lambda_{bl}\right)g_{mfd}r_{ssd}\right]r_{od}$$

Clearly, the resistance R′ is larger than the relatively large drain–source channel resistance, r_{od}. It follows that R′ is significantly larger than $R_{L\text{eff}}$, whence the approximate 3-dB bandwidth is

$$B_{3\text{ dB}} \approx \frac{1}{R_{L\text{eff}}C_L} \approx \frac{\left(1+\lambda_{bl}\right)g_{mfl}}{C_L}$$

Complementary MOS (CMOS)

Complementary MOS, or *CMOS*, is an actively loaded enhancement-driven MOSFET network. Its topology, which is depicted in Fig. 55.30, consists of an N-Channel enhancement mode MOSFET (*MN*) whose drain terminal is connected to the drain terminal of a P-channel enhancement mode MOSFET (*MP*). Because the gate terminals of both the N-channel and the P-channel devices are indicated as electrically tied together, the response of a CMOS cell coalesces the response afforded by an N-channel amplifier driving a P-channel enhancement load with the response delivered by a P-channel amplifier driving an N-channel enhancement load. Many of the advantages of CMOS technology in digital logic applications are made transparent by an analysis of the static transfer characteristic of the CMOS cell.

Static Transfer Characteristic

The P-channel transistor *MP* in Fig. 55.30 is saturated when its source–drain voltage $V_{sdp} = (V_{DD} - V_o)$ is at least as large as its source–gate voltage $V_{sgp} = (V_{DD} + V_i)$, less one source–gate threshold voltage, say V_{hp}. Thus, *MP* is saturated for output voltages that satisfy

$$V_o \le V_i = V_{hp} \tag{55.95}$$

© 2003 by CRC Press LLC

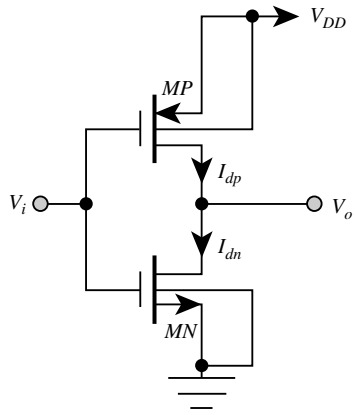

FIGURE 55.30 The circuit schematic diagram of a simple CMOS cell.

Analogous reasoning leads to

$$V_o \geq V_i - V_{hn} \tag{55.96}$$

as the saturation requirement for the N-channel device, *MN*.

Consider first the case of $V_i < V_{hn}$, which corresponds to cutoff of transistor *MN*, or $I_{dn} = 0$ in Fig. 55.30. Since V_i is small, (55.95) is not satisfied, and transistor *MP* operates in its ohmic regime. Using the simplified model for the static volt–ampere characteristics of an enhancement mode P-channel MOSFET, it follows that

$$I_{dp} = K_p\left(\frac{W_p}{L_p}\right)(V_{DD} - V_0)\left[(V_{DD} - V_i) - V_{hp} - \frac{(V_{DD} - V_0)}{2}\right] \tag{55.97a}$$

where K_p is the transconductance coefficient of *MP* (W_p/L_p) is the gate aspect ratio of *MP*. Since $I_{dp} = I_{dn} = 0$, $V_o = V_{DD}$ for all $V_i < V_{hn}$. As diagrammed in the static transfer characteristic of Fig. 55.31, the logic "1" level is the full power supply voltage V_{DD}. This logic result contrasts with that of the enhancement-loaded enhancement-driven inverter, for which the logic "1" level is one load threshold voltage below the power line voltage.

For output voltages in the neighborhood of V_{DD}, (55.95) is violated, while (55.96) is satisfied; that is, *MP* remains in its ohmic regime, but *MN* is saturated. Accordingly, with K_n and (W_n/L_n) denoting the transconductance coefficient and gate aspect ratio, respectively, of the N-channel MOSFET, respectively, $I_{dp} = I_{dn}$ implies

$$\begin{aligned} I_{dp} &= K_p\left(\frac{W_p}{L_p}\right)\left(V_{DD} - V_o\right)\left[\left(V_{DD} - V_i\right) - V_{hp} - \frac{\left(V_{DD} - V_o\right)}{2}\right] \\ &= \left(\frac{K_n}{2}\right)\left(\frac{W_n}{L_n}\right)\left(V_i - V_{hn}\right)^2 = I_{dn} \end{aligned} \tag{55.97b}$$

If V_{ic} is the input voltage at which V_o falls from V_{DD} to the level $V_i + V_{hp} = V_{ic} + V_{hp}$, the last result delivers

$$V_{ic} = \frac{V_{DD} - V_{hp} + \sqrt{\eta_{np}}V_{hn}}{1 + \sqrt{\eta_{np}}} \tag{55.98}$$

© 2003 by CRC Press LLC

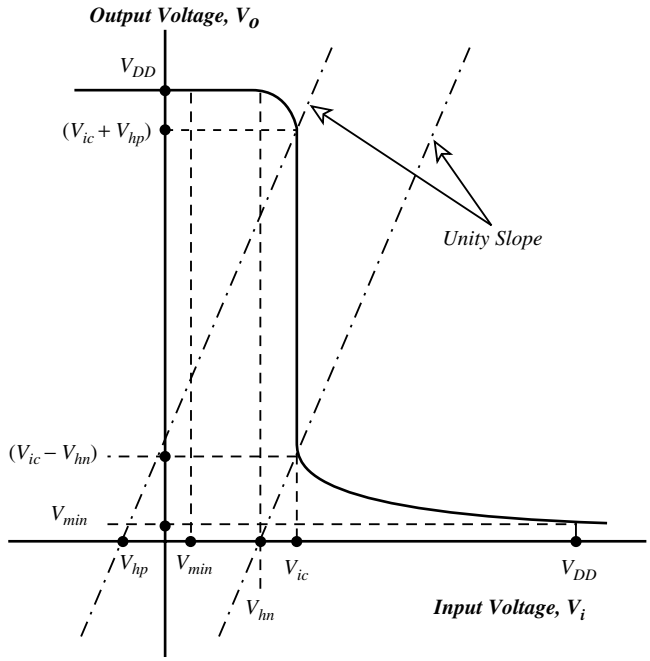

FIGURE 55.31 Approximate static forward transfer characteristic of the CMOS cell in Fig. 55.30.

where

$$\eta_{np} = \left(\frac{K_n}{K_p}\right)\left(\frac{W_n / L_n}{W_p / L_p}\right) \tag{55.99}$$

Thus, for $V_i < V_{ic}$, *MP* operates in its ohmic regime, *MN* is in saturation, and the static transfer characteristic is derived implicity from (55.97b).

When the output voltage V_o simultaneously satisfies (55.95) and (55.96) both *MP* and *MN* are saturated. It follows that since $I_{dp} = I_{dn}$,

$$\left(\frac{K_p}{2}\right)\left(\frac{W_p}{L_p}\right)(V_{DD} - V_i - V_{hp})^2 = \left(\frac{K_n}{2}\right)\left(\frac{W_n}{L_n}\right)(V_i - V_{hn})^2 \tag{55.100}$$

which is independent of V_o. Moreover, this relationship is satisfied for $V_i = V_{ic}$. Thus, for $(V_i - V_{hn}) < V_o < (V_i + V_{hp})$, $V_i \equiv V_{ic}$, implying, as shown in Fig. 55.31, an infinitely large incremental slope in the static transfer characteristic at $V_i = V_{ic}$. In practice, the magnitude of this slope is large, but not infinitely large, owing to channel length modulation and body effects.

For $V_i > V_{ic}$, which corresponds to $V_o < (V_i - V_{hn})$, transistor *MN* operates in its ohmic regime, while transistor *MP* is saturated. The resultant static characteristic derives from

$$\left(\frac{K_p}{2}\right)\left(\frac{W_p}{L_p}\right)(V_{DD} - V_i - V_{hp})^2 = \left(\frac{K_n}{2}\right)\left(\frac{W_n}{L_n}\right)V_o\left(V_i - V_{hn} - \frac{V_o}{2}\right) \tag{55.101}$$

If $V_{\min}$ denotes the logic "0" output voltage corresponding to a logic "1" input voltage of $V_i = V_{DD}$ (55.101) produces

© 2003 by CRC Press LLC

$$V_{\min} = (V_{DD} - V_{hn})\sqrt{1 - \frac{1}{\eta_{np}}\left(\frac{V_{hp}}{V_{DD} - V_{hn}}\right)^2} \tag{55.102}$$

which can be approximated as

$$V_{\min} \approx \frac{1}{2\eta_{np}}\left[\frac{V_{hp}^2}{V_{DD} - V_{hn}}\right] \tag{55.103}$$

Since $V_{\min}$ must be smaller than V_{hn} in order to ensure that a logic "1" output results from an application of a logic "0" input, (55.103) shows that

$$\eta_{np} > \frac{V_{hp}^2}{2V_{hn}(V_{DD} - V_{hn})} \tag{55.104}$$

is a design requirement in logic applications of CMOS.

Small-Signal Analysis

Although the foregoing static analysis suggests that abrupt switching between logic states takes place at an input voltage of V_{ic}, the slope of the transfer characteristics when both transistors are saturated is finite in an actual CMOS cell. The slope, which represents the small-signal voltage gain of the circuit, is best estimated by performing a small signal analysis. To this end, let the input voltage V_i in Fig. 55.30 be the superposition of an input Q-point voltage, say V_{iQ}, and an applied small-signal voltage, say V_s. The resultant output voltage V_o is a Q-point component V_{oQ}, and a small-signal voltage V_{os}, where the ratio V_{os}/V_s is the small-signal voltage gain A_v.

The low-frequency small-signal model for evaluating A_v for the CMOS cell in Fig. 55.30 is offered in Fig. 55.32. In this equivalent circuit, which is derived from the model given in Fig. 55.26

$$V_{sn} = V_{sp} = V_s \tag{55.105}$$

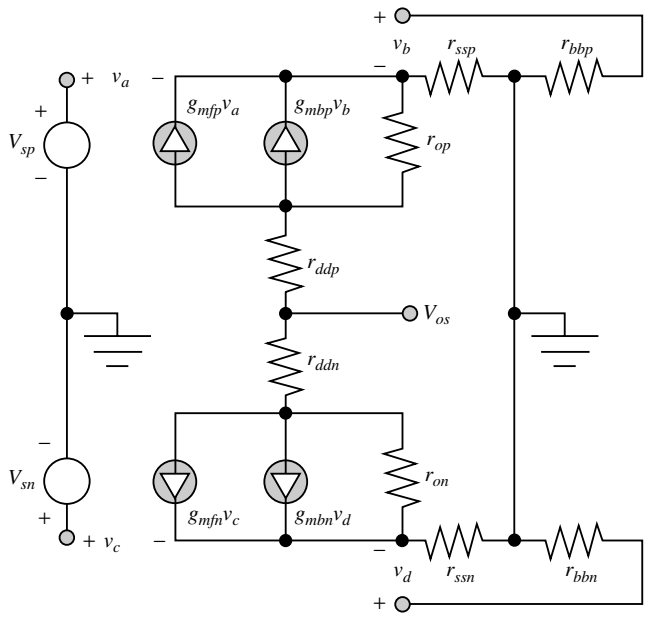

FIGURE 55.32 Small-signal, low-frequency equivalent circuit of the CMOS cell in Fig. 55.30.

© 2003 by CRC Press LLC

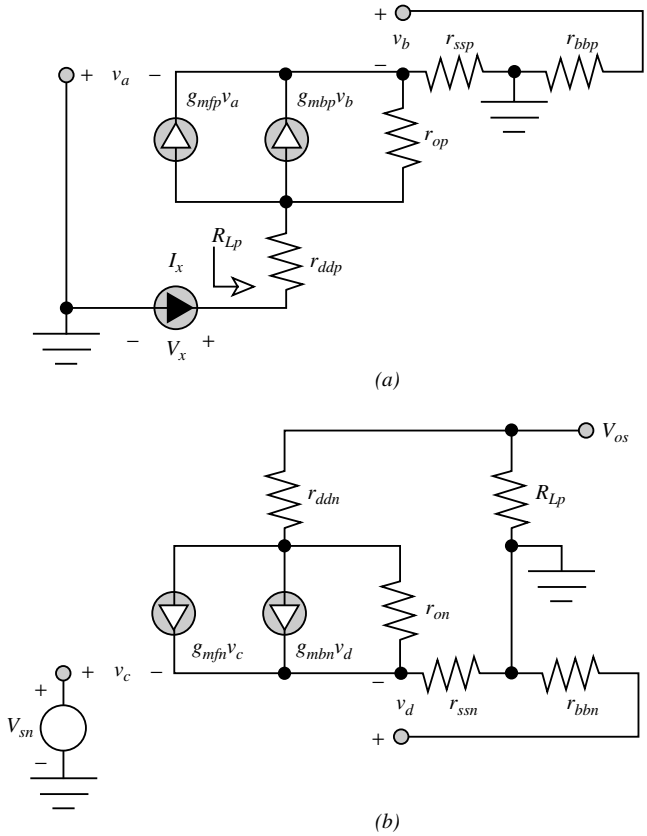

FIGURE 55.33 (a) Small-signal, low-frequency equivalent circuit used to evaluate the effective resistance R_{Lp} that loads the drain of the N-channel transistor MN in the CMOS amplifier of Fig. 55.30. (b) Equivalent circuit for evaluating the voltage gain due solely to the N-channel transistor in the CMOS cell.

The partitioning of the input signal voltage into two identical components V_{sn} and V_{sp} reflects the simultaneous application of the input signal V_s to the gates of both the N-channel and the P-channel transistors. Since the small-signal equivalent circuit is linear, this voltage decomposition allows superposition theory to be applied in the evaluation of the voltage gain. In particular,

$$V_{os} = A_{vn}V_{sn} + A_{vp}V_{sp} = (A_{vn} + A_{vp})V_s \tag{55.106}$$

where A_{vn} is the circuit voltage gain due solely to the application of V_{sn} to the N-channel transistor. Similarly, A_{vp} is the voltage gain attributed exclusively to the application of V_{sp} to the gate of the P-channel device.

The N-channel transistor gain, A_{vn}, can be computed by setting the signal source, V_{sp}, to zero. With $V_{sp} = 0$, the P-channel transistor acts as an effective load on the drain terminal of the N-channel transistor. The effective resistance of this P-channel load, say R_{LP}, derives from an analysis of the circuit given in Fig. 55.33. In this model,

$$V_a = V_b = -I_x r_{ssp} \tag{55.107}$$

whence

$$R_{LP} = \frac{V_x}{I_x} = r_{ddp} + r_{ssp} + [1 + (1 + \lambda_{bp})g_{mfp}r_{ssp}]r_{op} \tag{55.108}$$

© 2003 by CRC Press LLC

Given R_{LP} as the effective resistance terminating the drain of the N-channel transistor, the voltage gain, A_{vn}, follows from a consideration of the equivalent circuit provided in Fig. 55.33(b). It can be shown that

$$A_{vn} = -\frac{g_{mfn}R_{LP}}{1+(1+\lambda_{bn})g_{mfn}r_{ssn}+\dfrac{R_{LP}+r_{ddn}+r_{ssn}}{r_{on}}} \tag{55.109}$$

The gain, A_{vp}, attributed to the P-channel transistor can be found by repeating the foregoing calculations for the case of $V_{sn}=0$. In this case, the N-channel transistor loads the drain of the P-channel device by a resistance, say R_{Ln}. By symmetry, R_{Ln} is given by (55.108) with the subscript "p," replaced by the subscript, "n," to connote N-channel device parameters. Similarly, A_{vp} is derived from (55.109), with the subscript "n" supplanted by subscript "p." The result is

$$A_{vp} = -\frac{g_{mfp}R_{Ln}}{1+(1+\lambda_{bp})g_{mfp}r_{ssp}+\dfrac{R_{Ln}+r_{ddp}+r_{ssp}}{r_{op}}} \tag{55.110}$$

where

$$R_{Ln} = r_{ddn}+r_{ssn}+[1+(1+\lambda_{bn})g_{mfn}r_{ssn}]r_{on} \tag{55.111}$$

The substitution of (55.109) and (55.110) into (55.106) leads directly to an expression for the desired small-signal voltage gain. This gain is the slope of the static transfer characteristics curve at a quiescent operating point that constrains the operation of both transistors in the CMOS cell to their saturated regimes.

The CMOS cell voltage gain expression can be simplified by assuming that the internal series drain and source resistances are negligible and the channel length modulation voltages are large in both the P-channel and the N-channel transistors. Accordingly,

$$R_{Ln} \approx r_{on} \approx \frac{V_{\lambda n}}{I_{dQ}}$$

and (55.112)

$$R_{Lp} \approx r_{op} \approx \frac{V_{\lambda p}}{I_{dQ}}$$

where I_{dQ} is the quiescent drain current flowing through both transistors and $V_{\lambda n}$ and $V_{\lambda p}$ represent the channel length modulation voltages of the N-channel and P-channel transistors, respectively. Thus,

$$A_v = \frac{V_{os}}{V_s} \approx -\left(g_{mfn}+g_{mfp}\right)\left(r_{on}\middle\|r_{op}\right) \tag{55.113}$$

and using (55.112),

$$A_v = -\sqrt{\frac{2K_n\left(W_n/L_n\right)}{I_{dQ}}}\left[\frac{1+\sqrt{\dfrac{K_p\left(W_p/L_p\right)}{K_n\left(W_n/L_n\right)}}}{\dfrac{1}{V_{\lambda n}}+\dfrac{1}{V_{\lambda p}}}\right] \tag{55.114}$$

Interestingly, (55.114) shows that the voltage gain magnitude is inversely proportional to the square root of the quiescent drain current flowing on both devices of the CMOS cell.

Cross Section of Monolithic CMOS

In principle, the CMOS cell shown in Fig. 55.30 can be realized by interconnecting an individual N-channel (NMOS) enhancement-mode MOSFET and an individual P-channel (PMOS) enhancement-mode transistor. But both MOSFETs can be fabricated monolithically on the same chip, thereby explaining why a CMOS cell is often referred to as CMOS "device."

The simplified cross section of a monolithic CMOS transistor is shown in Fig. 55.34. The left-hand side of this structure comprises the N-channel component of the CMOS cell. This half structure consists of gate oxide, surface metallization for the source, drain, gate, and bulk electrical contacts for the NMOS transistor, and a P-type substrate into which a P^+ and two N^+ regions are diffused or implanted. The two N^+ diffusions form the source and drain regions of the NMOS transistor, while the P^+ diffusion establishes a low resistance contact to the substrate bulk. The right-hand side of the structure is the PMOS transistor. It has a lightly doped N-type well that is diffused into the P-type bulk. Into this N-type region, which forms the substrate of the PMOS transistor, two P^+ regions are diffused for the PMOS source and drain. An N^+ diffusion or implant into the lightly doped N-type region ensures a low resistance electrical contact to the PMOS bulk.

The ability to synthesize CMOS as a monolithic interconnection of its NMOS and PMOS components is advantageous from both fabrication and circuit design perspectives. However, potentially serious problems plague the resultant structure [19]. The source of most of these problems is the unavoidable appearance of bipolar transistors and semiconductor resistors beneath the surface of the CMOS cell. To crude first order, these bulk parasitic elements are formed topologically as shown in Fig. 55.35. The emitter of the PNP bipolar junction transistor in this diagram is the P^+ drain/source diffusion of the P-channel MOSFET, its base is the N-type PMOS well, and its collector is the P-type tub that serves as the substrate for the NMOS device. The NPN transistor has an emitter which is the N^+ drain/source diffusion of the NMOS transistor, its base is the P-type tub, and its collector is formed of the N-type well that is used as the PMOS substrate.

The electrical equivalent of the circuit topology abstracted in Fig. 55.35 is the schematic offered in Fig. 55.36. Under most operational circumstances, the surface current, I_d, flowing through the CMOS device is significantly larger than the bulk current, I_{bulk}, flowing through the bulk parasitic elements. One way of ensuring $I_d \gg I_{\text{bulk}}$ is to preclude the bipolar devices from turning on, which requires that resistors

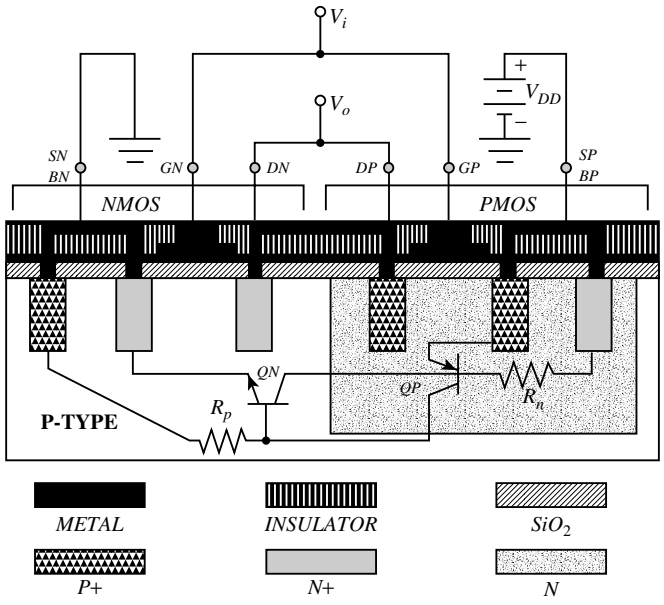

FIGURE 55.35 Simplified topological representation of parasitic bulk transistors and resistors in the cross section of monolithic CMOS. Also shown is the biasing and the I/O terminals for normal inverter operation of the CMOS cell.

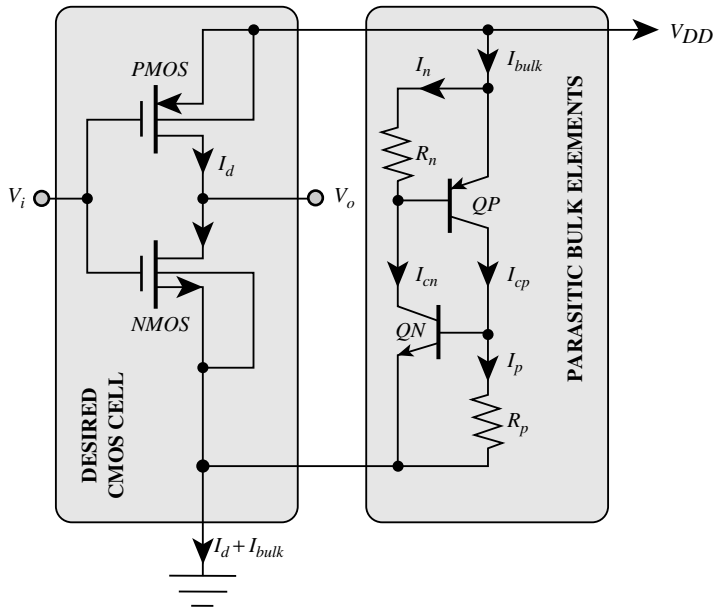

FIGURE 55.36 Equivalent circuit of electrical cross section depicted in Fig. 55.35.

R_n and R_p be so small as to disallow the development of an appreciable forward bias across the emitter-base junctions of either BJT. Small R_n and R_p require large doping concentrations in the P-type substrate and in the N-type well, respectively. Unfortunately, these large substrate concentrations have the undesirable effect of increasing the threshold voltages of, and exacerbating the body effect in, both MOS transistors.

© 2003 by CRC Press LLC

Short of achieving an ideal goal of $R_n = R_p = 0$, there is no practical way of precluding turn on of both the parasitic bipolar devices, because the bipolar subcircuit on the right-hand side of Fig. 55.36 is a positive feedback network. The instability mechanism can be illustrated qualitatively as follows. Assume that both of the parasitic bipolar units conduct slightly. Let the collector current of transistor *QN* be I_{cn} and that of *QP* be I_{cp}. The collector current, I_{cn}, produces a base current, I_{cn}/β_n, in the base of *QN*, where β_n is the static forward current transfer ratio, or static beta of *QN*. Similarly, the base current flowing in transistor *QP* is I_{cp}/β_p, with β_p symbolizing the static beta of *QP*. The resultant current, I_n, flowing in the resistance, R_n, is

$$I_n = I_{cn} - \frac{I_{cp}}{\beta_p} \tag{55.115}$$

Likewise, R_p conducts a current I_p of

$$I_p = I_{cp} - \frac{I_{cn}}{\beta_n} \tag{55.116}$$

Let the original collector current I_{cn} increase be a small amount, say ΔI_{cn}. This perturbation is arguably the result of a change in circuit operating temperature, impacting electromagnetic radiation, or a spurious signal that superimposes with the power line voltage V_{DD}. Then, I_n can be expected to change by an amount ΔI_n such that

$$\Delta I_n = \Delta I_{cn} - \frac{\Delta I_{cp}}{\beta_p} > 0 \tag{55.117}$$

The current change ΔI_{cp} in the *QP* collector current is positive, since positive ΔI_n increases the forward bias across the emitter–base junction of transistor *QP*. But an increase, ΔI_{cp}, in the *QP* collector current, I_{cp}, results in a change, say ΔI_p, in the current flowing through the resistance R_p. If, in addition to satisfying (55.117),

$$\Delta I_p = \Delta I_{cp} - \frac{\Delta I_{cn}}{\beta_n} > 0 \tag{55.118}$$

a further increase in the collector current of *QN* materializes, owing to the fact that an enhanced current through R_p increases the forward bias across the emitter–base junction of the NPN transistor, *QN*. This additional increase, which superimposes with the originally incurred increase in the collector current of *QN*, propagates through the bulk bipolar subcircuit in a fashion that is similar to the foregoing scenario. It therefore causes further increases in the *QN* (and in the *QP*) collector current.

The process described previously continues until both bipolar transistors saturate, which is the so-called **latchup** condition. Since saturated bipolar transistors develop only small voltages across their collector–emitter terminals, the latchup condition in monolithic CMOS is tantamount to a very low resistance path between the power supply line and circuit ground. The resultantly large power supply current, most of which is the saturation current supplied to the bulk parasitic elements, causes significant self heating of the bulk. Aside from the fact that this self heating supports still further increases in bulk bipolar collector currents, it can damage the semiconductor bulk, thereby leading to catastrophic failure of the entire CMOS structure.

It is important to note that two conditions must be satisfied if latchup is to occur. These two conditions, which are defined by (55.117) and (55.118), can be combined into the single latchup condition,

$$\beta_n \beta_p > 1 \tag{55.119}$$

© 2003 by CRC Press LLC

Recalling that the beta of bipolar devices is inversely proportional to base width, the likelihood of latchup can be minimized by designing the CMOS cell so that its N-type substrate well is sufficiently wide and/or its P-type substrate is also wide. Unfortunately, these width guidelines do not complement ongoing demands to downsize integrated devices. This observation explains why latchup is an especially perplexing problem in many state of the art VLSI architectures that feature minimal geometry devices. Another way to reduce bipolar beta is to increase base region doping. This increased doping decreases the resistances R_n and R_p, but only at the expense of increasing NMOS and PMOS threshold voltages and increasing the MOSFET threshold voltage dependence on bulk–source biasing.

The foregoing difficulties with respect to minimizing the risk of CMOS latchup compel creative engineering solutions to the latchup problem. One of these solutions involves selective light doping of the P^+ and/or N^+ drain/source regions with gold or other inert impurities. Such doping has the effect of reducing the minority carrier diffusion lengths to which bipolar transistor betas are dependent. Another solution places a lightly doped trench of semiconductor material around the PMOS transistor. This *guard ring* inserts a large resistance in series with the collectors of both transistors *QN* and *QP* in the bulk parasitic subcircuit. The resultantly high net collector resistances inhibit collector current increases, thereby reducing the chance of latchup. In some applications, the guard ring is an oxide trench that serves to open circuit the collectors of *QN* and *QP*.

Depletion-Mode MOSFET

As is the case with enhancement-mode transistors, there are two types of *depletion mode* MOSFETs: the **N-channel device** and the **P-channel transistor**. Figure 55.37(a) displays the cross section of the N-channel depletion mode MOSFET, and Fig. 55.37(b) is the corresponding circuit schematic symbol. The P-channel counterparts to the N-channel depletion-mode transistor are offered in Fig. 55.38. A comparison of these two figures to the device cross sections offered in Figs. 55.15(a) and 55.16(a) reveals that the cross sections of depletion-mode MOSFETs differ from those of enhancement-mode transistors only in that depletion-mode transistors have a semiconductor impurity layer diffused or implanted in the source to drain spacing

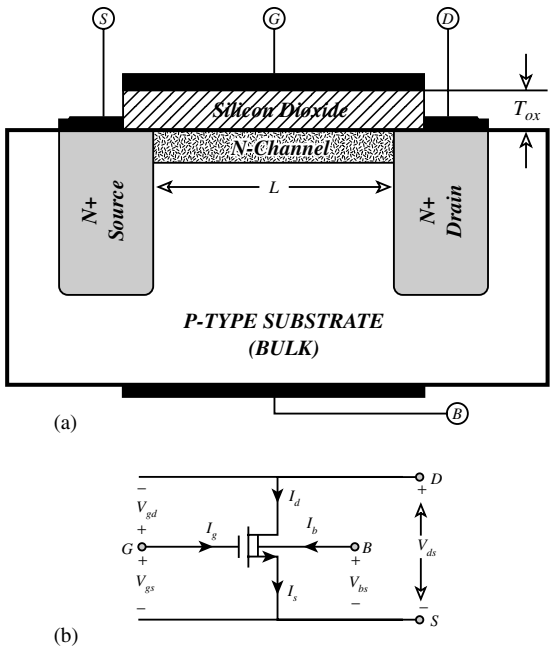

FIGURE 55.37 (a) Simplified cross section of an N-channel depletion-mode MOSFET. The diagram is not drawn to scale. (b) Electrical schematic symbol of an N-channel depletion-mode MOSFET.

immediately beneath the gate oxide. This thin channel region has an impurity concentration that is greater than the substrate dopant concentration and is typically of the order of 10^{16} atoms/cm^3.

Static Volt–Ampere Curves

The cross section of the N-channel depletion mode MOSFET differs from that of the N-channel enhancement mode MOSFET by a thin N-type layer, which is diffused or implanted in the source–drain channel of the depletion mode device. An understanding of the electrical effect of this channel is facilitated by recalling that in N-channel enhancement mode transistors, a concentration of free electrons must be induced in the source–drain channel in order for a drain current to flow. The vehicle for inducing such a channel of free electrons is the gate–source voltage, V_{gs}. In particular, V_{gs} must exceed the gate–source threshold voltage, V_{hnc}, to allow an enhancement MOSFET to operate in either the ohmic or saturated regimes of its static characteristic curves. Thus, V_{hnc} is the minimum gate–source voltage commensurate with establishing the supply of free-channel region electrons whose source to drain transport comprises the transistor drain current. Moreover, the amount by which V_{gs} exceeds V_{hnc} determines the amount of drain current that flows for given V_{ds}. This means that for fixed V_{ds}, the dran current is controlled by V_{gs} or, more correctly, by the excess voltage $V_{gs} - V_{hnc}$.

In contrast, the diffused or implanted N-type channel renders a copious supply of free electrons available in the source–drain channel of an N-channel depletion mode MOSFET. Consequently, this device does not require elevation of the gate-source voltage to a threshold level. In fact, the free electrons made available by ionized N-type impurity atoms in the diffused or implanted channel allows for the flow of drain current in response to positive drain-source voltage for $V_{gs} = 0$ and even for $V_{gs} < 0$. This contention can be understood by studying the N-channel depletion-mode device cross section of Fig. 55.39, which is drawn to illustrate the electrical effects of nonpositive gate-source voltage $V_{gs} < 0$, positive drain-source voltage $V_{ds} > 0$, and negative bulk–source voltage $V_{bs} < 0$. The effect $V_{bs} < 0$ is a depletion layer about the bulk–source, bulk–drain, and bulk–channel PN junctions. Since the source and drain regions are much more heavily doped than is the P-type substrate, most of the bulk–source and bulk–drain depletion layers extend into the substrate. On the other hand, the fact that the channel dopant

© 2003 by CRC Press LLC

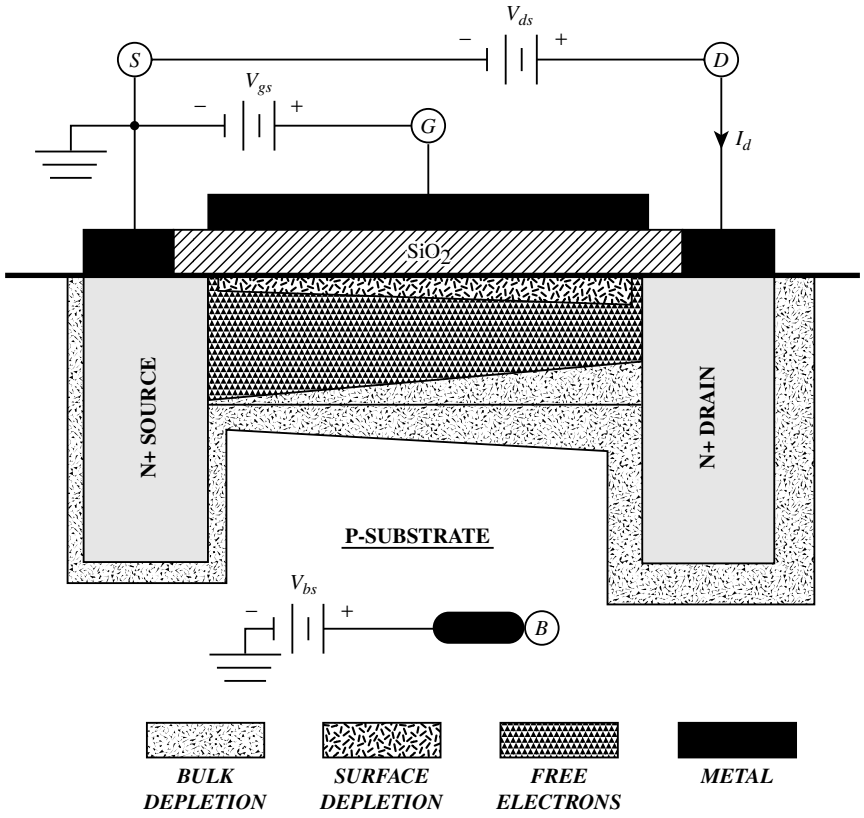

FIGURE 55.39 Cross section of an N-channel depletion mode transistor. The indicated depletion layers correspond to $V_{ds} > 0$, $V_{gs} < 0$, and $V_{bs} < 0$. The diagram is not drawn to scale.

concentration is only slightly larger than that of the substrate means that the bulk-channel depletion layer extends significantly into the channel region. The net bulk-channel depletion layer is thicker at the source end of the channel than at the drain end, because the reverse bulk-channel bias at the drain end is $(V_{ds} - V_{bs})$, while at the source end, it is only $-V_{bs}$.

A depletion layer is also formed beneath the oxide-surface interface, since negative gate-source voltage serves to repel free-channel electrons away from the interface and deeper into the channel. This interfacial depletion region is thicker at the drain site, where the net interface-channel reverse bias is the gate-drain voltage, $V_{gd} = (V_{gs} - V_{ds})$, than at the source end, where the interface-channel reverse bias is only the gate-source voltage, V_{gs}. As a result, free-channel electrons are confined to the trapezoidal region shown as the darkened area in Fig. 55.39. These free electrons are available for source to drain transport, and thus, they give rise to a drain current, I_d, in respect to an applied positive drain-source bias, V_{ds}.

Several points in regard to the cross section picture of the depletion layers formed in an N-channel depletion-mode transistor warrant attention. First, an interface-channel depletion layer is established at the source end of the N-type channel even if $V_{gs} \equiv 0$ because of metal-oxide contact potential, stray charges trapped in the gate oxide region, and interfacial oxide-surface imperfections. This zero-bias depletion layer, which corresponds to a zero-bias interfacial potential at the source end of the channel, is analogous to the zero-bias transition layer and corresponding built-in potential that prevail across the PN junction of a conventional semiconductor diode. Second, the available volume of free-channel electrons is controllable by the gate-source bias. A decreasing (more negative) V_{gs} produces a surface depletion region that extends deeper into the substrate. This extended depletion layer reduces the channel

© 2003 by CRC Press LLC

cross section area through which available free electrons are transported, thereby increasing the effective channel resistance and decreasing the drain current that flows as a result of applied drain–source bias. On the other hand, an increased (more positive) V_{gs} narrows the depth of the surface–channel depletion layer, which increases the drain current, I_d, for a given value of drain–source bias, V_{ds}. Thus, just as an increasing V_{gs} increases the drain current flowing for fixed V_{ds} in NMOS, the drain current that flows in an N-channel depletion-mode MOSFET (DNMOS) biased at a fixed positive drain–source voltage is a monotonically increasing function of gate–source bias.

A third important point is that the bulk–source bias, V_{bs}, like the gate–source bias, V_{gs}, modulates the drain current. An increasingly negative V_{bs} makes the bulk–channel depletion layer protrude further into the channel, thereby diminishing the cross section channel area pierced by transported free electrons and thus, the drain current that flows for a given V_{ds}. Accordingly, a body effect induced by substrate reverse bias, not unlike the body effect in enhancement-mode transistors, materializes in depletion-mode devices.

A fourth point is that for the depletion condition illustrated in Fig. 55.39, the free electrons available for transport in the source–drain channel are isolated from the oxide-semiconductor interface by the surface depletion region induced by $V_{gs} < 0$. These electrons are not as affected by the vertical electric fields arising from gate–source bias as are those free electrons that prevail in enhancement mode devices. Thus, even if the doping concentration in the N-type channel of a DNMOS device is identical to the P-type substrate doping concentration in an NMOS transistor, the average mobility of free electrons in a depletion-mode MOSFET is larger than that of free electrons in an enhancement-mode unit. Since the transit time, which is the average time required for the transport of electrons from the source to the drain, is inversely related to electron mobility, the electrical responses of DNMOS circuits are potentially faster than those of comparable NMOS circuits.

For given V_{ds} and V_{bs}, it is clear that there exists a negative value of gate–drain voltage, say $V_{gd} = (-V_{pnc})$, such that the surface depletion layer coalesces with the channel side of the bulk-channel depletion layer at the drain end of the N-type channel. This condition, which is diagrammed in Fig. 55.40(a), is referred to as **channel pinchoff** and corresponds to a gate–source voltage of

$$V_{gs} = V_{gs} + V_{ds} = -V_{pnc} + V_{dss} \tag{55.120}$$

where V_{pnc}, a positive number, is termed the **channel pinchoff voltage**. The parameter V_{ds} is the drain saturation voltage; it is the particular drain–source voltage commensurate with channel pinchoff at the drain site. For $V_{gd} < (-V_{pnc})$, which corresponds to $V_{ds} > (V_{gs} + V_{pnc}) \equiv V_{dss}$, the point of channel pinchoff moves closer to the source end of the channel, as indicated in Fig. 55.40(b). Channel length modulation is therefore observed in an N-channel depletion mode transistor, just as it is in enhancement-mode technology. A first-order static model of the drain current increase arising from channel length modulation is identical to the model invoked for channel length modulation in NMOS. This is to say that the effect of channel length modulation is given by (55.73), subject to replacing V_{hn} by $(-V_{pmc})$ and interpreting V_{dss} as $(V_{gs} + V_{pnc})$.

Progressive increases in V_{ds} above V_{dss} move the channel pinchoff point closer to the source end of the channel. When the gate–source bias V_{gs} decreases to $(-V_{pnc})$, the pinchoff point is at the source, and the entire channel is said to be pinched off. Under this operating condition, no drain current can flow, since the entire source to drain channel is depleted of free electrons. It follows that a necessary condition for nonzero drain current, I_d, in DNMOS technology is $V_{gs} > (-V_{pnc})$, which suggests viewing $(-V_{pnc})$ as an effective threshold voltage for DNMOS. To first order, the dependence of pinchoff voltage V_{pnc} on the bulk–source bias is the threshold voltage function given by (55.78), provided V_{hno} in (55.78) is replaced by V_{pno}, the pinchoff voltage of zero bulk–source bias. Moreover, the substrate Debye length implicit to the variable V_θ is taken to be the average Debye length in the N-type channel of DNMOS.

The static volt–ampere characteristic of an N-channel depletion-mode MOSFET derives approximately from the static equations for enhancement-mode transistors [20]. In particular,

© 2003 by CRC Press LLC

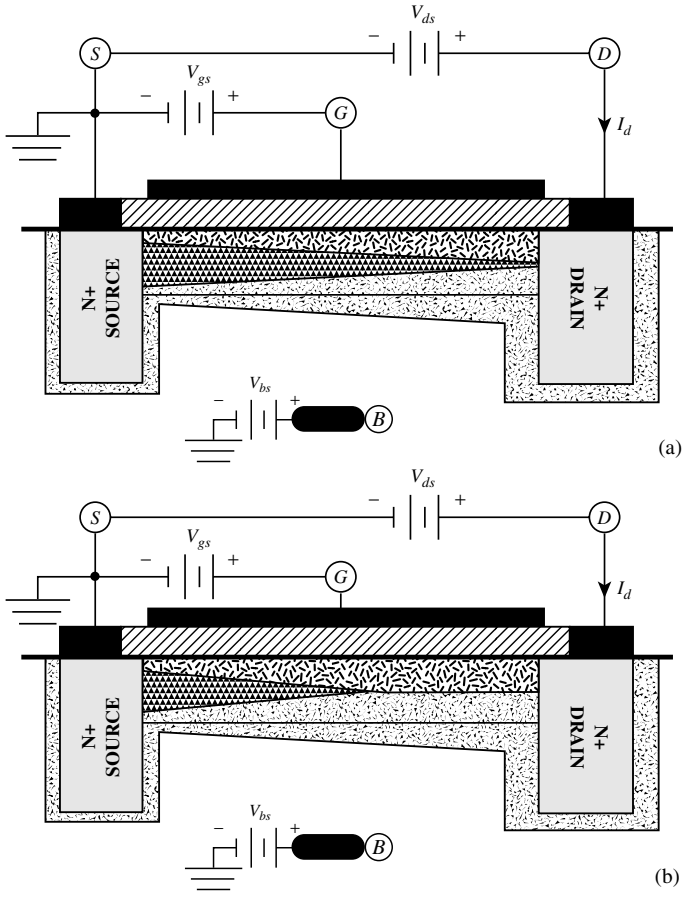

FIGURE 55.40 Cross section of N-channel depletion-mode MOSFET. The diagram is not drawn to scale. (a) Pinchoff at drain end of channel, $V_{gd} = -V_{pnc}$. (b) Operation beyond pinchoff, $V_{gd} \le -V_{pnc}$.

$$I_d = \begin{cases} 0, & V_{gs} \le -V_{pnc} \\ K_n\left(\dfrac{W}{L}\right)V_{ds}\left(V_{gs} + V_{pnc} - \dfrac{V_{ds}}{2}\right), & V_{gs} > -V_{pnc} \text{ and } V_{ds} < \left(V_{gs} + V_{pnc}\right) \\ \dfrac{K_n}{2}\left(\dfrac{W}{L}\right)\left(V_{gs} + V_{pnc}\right)^2\left(1 + \dfrac{V_{ds} - V_{dss}}{V_\lambda}\right), & V_{gs} > -V_{pnc} \text{ and } V_{ds} \ge \left(V_{gs} + V_{pnc}\right) \end{cases} \tag{55.121}$$

where I_d is taken as a current flowing into the drain terminal of an N-channel transistor. Because of internal drain, source, and substrate resistances, V_{gs}, V_{ds}, and V_{bs} (on which V_{pnc} is dependent), respectively, are internal gate–source, internal drain-source, and internal bulk–source voltages, respectively. For P-channel depletion-mode MOSFETs, (55.121) remains applicable provided I_d is interpreted as a current flowing out of the drain terminal, V_{gs} is replaced by the source–gate voltage V_{sg}, V_{ds} is supplanted by the source–drain voltage V_{sd}, and V_{bs} is replaced by the bulk–source voltage V_{sb}. The commentary offered earlier in regard to second-order effects in enhancement-mode technology apply to depletion-mode technology as well.

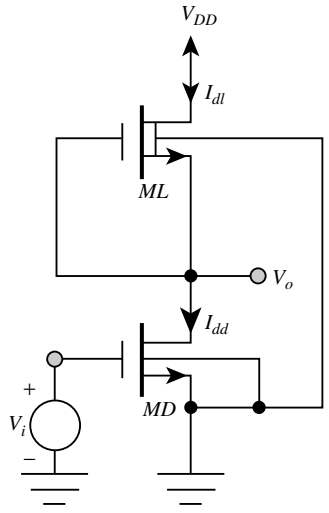

FIGURE 55.41 Schematic diagram of an enhancement-driven, depletion-loaded N-channel MOSFET inverter.

Depletion-Loaded Inverter

Depletion-mode transistors, like enhancement-mode MOSFETs, can be used as load devices in inverters designed for either digital or analog signal-processing applications. The simplified schematic diagram of a typical enhancement-driven depletion-loaded inverter is given in Fig. 55.41. As the following analyses confirm, the inverter offers a logic swing capability that extends to the power supply voltage, V_{DD}. In linear signal processors, the inverter in Fig. 55.41 also delivers a small-signal voltage gain that is larger than the gain afforded by an enhancement-driven enhancement-loaded inverter.

Static Transfer Analysis. The static transfer characteristic of the depletion loaded, enhancement driver inverter is depicted in Fig. 55.42. Its derivation commences with the observation that the gate–source voltage of *ML* is zero. Accordingly, *ML* in the circuit of Fig. 55.41 is saturated if $(V_{DD} - V_o) > V_{pnl}$, where V_o is the indicated output voltage and V_{pnl} is the pinchoff voltage of *ML*. (For simplicity, body effect, as well as channel length modulation, series internal device resistances, and other second-order effects are ignored.) With *ML* saturated, the simplified static model of a MOSFET gives for its drain current I_{dl}

$$I_{dl} = \frac{K_{nl}}{2}\left(\frac{W_l}{L_l}\right)V_{pnl}^2, \quad \text{for} \quad V_o \le \left(V_{DD} - V_{pnl}\right) \tag{55.122}$$

where K_{nl} is the transconductance coefficient and (W_l/L_l) is the gate aspect ratio of *ML*. On the other hand, $V_o > (V_{DD} - V_{pnl})$ constrains *ML* to its ohmic regime, where

$$I_{dl} = \frac{K_{nl}}{2}\left(\frac{W_l}{L_l}\right)\left(V_{DD} - V_o\right)\left[V_{pnl} - \frac{V_{DD} - V_o}{2}\right] \quad \text{for} \quad V_o > \left(V_{DD} - V_{pnl}\right) \tag{55.123}$$

If the input voltage V_i is smaller than the threshold voltage V_{hnd} of the driver transistor *MD*, I_{dd} in Fig. 55.41 is zero. Moreover, since the circuit operates as an inverter, V_o is large when V_i is small. Thus, $V_i < V_{hnd}$ forces *ML* to conduct in its ohmic regime where (55.123) is applicable. Since I_{dl} is identical to I_{dd},

$$V_o = V_{DD}, \quad \text{for} \quad V_i < V_{hnd} \tag{55.124}$$

© 2003 by CRC Press LLC

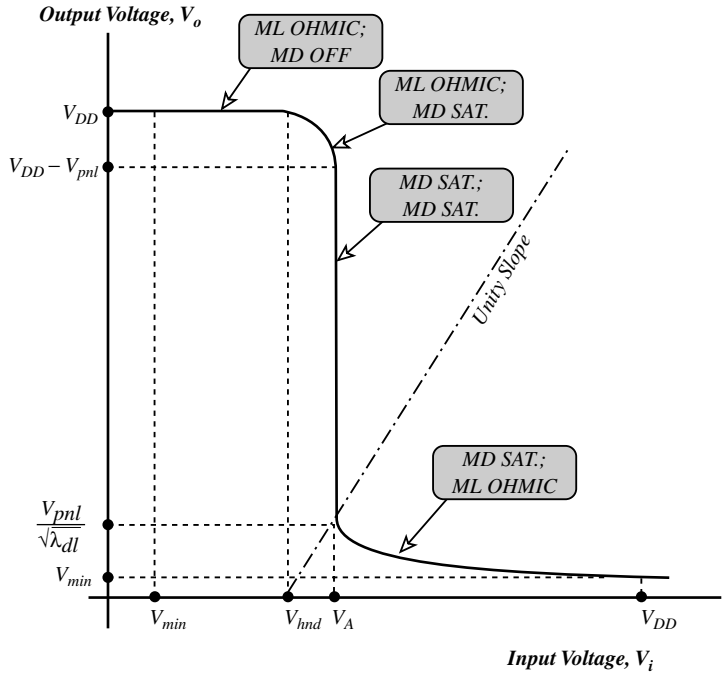

FIGURE 55.42 Static transfer characteristic of an enhancement-driven, depletion-loaded, common-source MOSFET inverter. The characteristic exploits the simplified MOSFET model equations.

Within the context of simplified MOSFET modeling, the logical "one" voltage of the depletion-loaded enhancement-driven inverter is seen to be the power supply voltage, V_{DD}. Recall that in the enhancement-loaded enhancement-driven inverter considered earlier, the logical "one" voltage is one load threshold voltage below the supply voltage.

As V_i rises above the threshold voltage, V_{hnd}, the driver begins to conduct a drain current, I_{dd}. If V_i is such that V_o, which is the drain–source voltage developed across *MD*, is larger than $(V_i - V_{hn})$, *MD* is saturated, whence

$$I_{dd} = \frac{K_{nd}}{2}\left(\frac{W_d}{L_d}\right)\left(V_i - V_{hnd}\right)^2 \quad \text{for} \quad V_o \geq V_i - V_{hnd} \tag{55.125}$$

with K_{nd} denoting the transconductance coefficient of the driver, and W_d/L_d its gate aspect ratio. As long as V_o, in addition to exceeding $V_i - V_{hnd}$, remains above $V_{DD} - V_{pnl}$, *ML* continues operating in its ohmic domain. Since $I_{dd} = I_{dl}$, (55.123) and (55.125) provide

$$\begin{aligned} &\left(V_{DD} - V_o\right)\left[V_{pnl} - \frac{V_{DD} - V_o}{2}\right] = \frac{\lambda_{dl}}{2}\left(V_i - V_{hnd}\right)^2 \\ &\text{for} \quad V_o \geq \left(V_i - V_{hnd}\right) \quad \text{and} \quad V_o > \left(V_{DD} - V_{pnl}\right) \end{aligned} \tag{55.126}$$

where

$$\lambda_{dl} \triangleq \frac{K_{nd}}{K_{nl}}\left(\frac{W_d/L_d}{W_l/L_l}\right) \tag{55.127}$$

Equation (55.126) implicitly defines the static forward transfer characteristic for the indicated range of output voltages. The subject relationship shows that V_o reduces to $V_{DD} - V_{pnl}$ when V_i rises to a value, say V_A, give by

© 2003 by CRC Press LLC

$$V_A = V_{hnd} + \frac{V_{pnl}}{\sqrt{\lambda_{dl}}} \tag{55.128}$$

When V_o falls below $V_{DD} - V_{pnl}$, *ML* becomes saturated. But as long as V_o remains above $V_i - V_{hnd}$, *MD* remains saturated. The pertinent transfer characteristic derives from equating (55.122) and (55.125), so that

$$\begin{gathered} V_{pnl}^2 = \lambda_{dl}\left(V_i - V_{hnd}\right)^2 \\ \text{for } V_o > \left(V_i - V_{hnd}\right) \text{ and } V_o \le \left(V_{DD} - V_{pnl}\right) \end{gathered} \tag{55.129}$$

This relationship is independent of the output voltage V_o and additionally, it is satisfied for only one value of the input voltage; namely, $V_i = V_A$, as defined by (55.128). It follows that the circuit at hand, biased at $V_i = V_A$, delivers a theoretically infinitely large magnitude of small-signal gain, subject to the assumption that channel length and threshold voltage modulation phenomena can be ignored.

When V_o falls below $V_i - V_{hnd}$, the load transistor remains saturated, while the driver enters its saturation regime. Under this condition, the pertinent device volt–ampere equations deliver a static transfer characteristic that derives from the solution of the quadratic expression,

$$\lambda_{dl} V_o^2 - 2\lambda_{dl}\left(V_i - V_{hnd}\right)V_o + V_{pnl}^2 = 0 \tag{55.130}$$

The logical "0" output, say $V_{\min}$, corresponding to a logical "1" input of $V_i = V_{DD}$ can be determined by applying the quadratic formula to this relationship. To first order,

$$V_{\min} = \frac{V_{pnl}^2}{2\lambda_{dl}\left(V_{DD} - V_{hnd}\right)} \tag{55.131}$$

Because a logical "0" input must produce a logical "1" output, and recalling that the logical "1" output of V_{DD} is produced whenever $V_i < V_{hnd}$, (55.131) implies the design requirement,

$$V_{DD} > V_{hnd} + \frac{V_{pnl}^2}{2\lambda_{dl} V_{hnd}} \tag{55.132}$$

Small-Signal Analysis. Recall that the static volt–ampere equations of a depletion-mode MOSFET differ from those of its enhancement-mode counterpart only in that the threshold voltage V_{hnc} of the enhancement-mode transistor is replaced by $(-V_{pnc})$, where V_{pnc} symbolizes the pinchoff voltage, corrected for body effect, of the depletion-mode device. It follows that the topology of the low-frequency model for a depletion-mode MOSFET is identical to that of the enhancement-mode transistor. Indeed, the high-frequency model depicted in Fig. 55.26 remains applicable to depletion-mode units, provided V_{hnc} is replaced by $(-V_{pnc})$ in (55.90) – (55.94), which analytically define the small-signal model parameters g_{mf}, g_{mb}, and r_o. The discussion in regard to capacitances and various high-order effects submitted in the section on refinements to the simple MOSFET model remain generally applicable as well.

Example 4. The input voltage, V_i, in the enhancement-driven depletion-loaded MOSFET inverter of Fig. 55.41 is of the form $V_i = (V_{iQ} + V_s)$, where V_{iQ} is a constant voltage that biases both transistors in their saturated domains. The voltage V_s is a small amplitude, low-frequency sinusoidal signal. Derive a general expression for the low-frequency small-signal voltage gain $A_v = V_{os}/V_s$, and compare the results to those obtained earlier in conjunction with the enhancement-driven enhancement-loaded MOSFET inverter. Do not ignore the electrical effects of internal series resistances, bulk-induced threshold and pinchoff voltage modulation, and channel length modulation.

Solution.

1) The schematic diagram in Fig. 55.41) indicates that, at low frequencies, transistor *ML* imposes a resistive load on the drain of the driver transistor, *MD*. This contention follows from the observations that V_{DD} is grounded for small-signal considerations and that the only signal exciting transistor *ML* is applied simultaneously to its gate and source terminals by the drain of *MD*. Thus, for small input signals, *ML* behaves as a two terminal linear resistor of resistance, say R_{Leff}. Accordingly, the pertinent small-signal equivalent circuit is identical to the equivalent circuit shown in Fig. 55.29, save for the fact that no load capacitor is currently considered. From the results of Example 3, the voltage gain is of the form

$$A_v = \frac{V_{os}}{V_s} = -\frac{g_{mfd}R_{Leff}}{1+(1+\lambda_{bd})g_{mfd}r_{ssd}+\dfrac{R_{Leff}+r_{ddd}+r_{ssd}}{r_{od}}}$$

The only remaining task is the determination of an expression for the resistance R_{leff}.

2) The equivalent circuit pertinent to finding R_{Leff} is offered in Fig. 55.43, in which the drain, to which V_{DD} is applied in the original circuit schematic diagram, is grounded, and the gate is connected directly to the source. Let a signal current, I_x, be applied as indicated from ground to the source–gate terminal. The desired resistance, which is the ratio of the indicated voltage, V_x, to the applied current, I_x, is

$$R_{Leff} = \frac{(r_{ssl}+r_{ddl})+\left[1+(1+\lambda_{bl})g_{mfl}r_{ssl}\right]r_{ol}}{1+\lambda_{bl}g_{mfl}r_{ol}}$$

3) Several important aspects of the foregoing analysis warrant attention.
   a. If all model parameters in both the gain and the effective resistance expressions are evaluated for MOSFET operation in the saturated regime, the voltage gain obtained is the slope at $V_i = V_A$ of the static transfer characteristic curve plotted in Fig. 55.42. Although the voltage gain is not infinitely large, as is implied by the aforementioned transfer characteristic, its magnitude

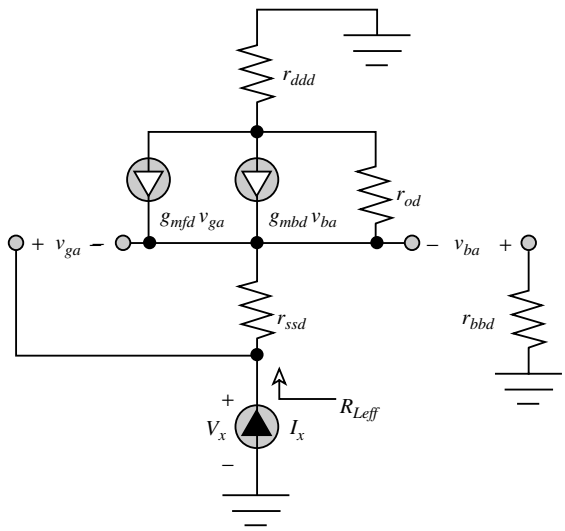

FIGURE 55.43 Equivalent circuit used to determine the effective load resistance R_{Leff} presented to the enhancement-mode driver by the depletion-mode load in the inverter of Fig. 55.41.

© 2003 by CRC Press LLC

approaches infinity if $r_{ol} \to \infty$ and if $\lambda_{bl} \to 0$. But $r_{ol} \to \infty$ implies negligible channel length modulation, while $\lambda_{bl} \to 0$ corresponds to the neglect of threshold body phenomena. These simplifying approximations are implicit to the plot of Fig. 55.42.

b. If the internal series resistances are very small, and if the channel length modulation resistance is very large in both the load and driver transistors,

$$R_{Leff} \approx \frac{1}{\lambda_{bl} g_{mfl}}$$

and

$$A_v \approx -g_{mfä} R_{Leff}$$

The resultant voltage gain collapses to

$$A_v \approx -\frac{g_{mfd}}{\lambda_{bl} g_{mfl}}$$

c. A comparison of the approximate gain expression found above to the corresponding gain approximation for the enhancement-loaded inverter considered in Example 3 indicates that the gain afforded by the depletion-loaded inverter is slightly larger. In particular, if A_{ve} and A_{vd}, respectively, denote the approximate voltage gains of the enhancement-driven enhancement-loaded inverter and the enhancement-driven depletion-loaded inverter,

$$A_{vd} \approx \left(\frac{1+\lambda_{bl}}{\lambda_{bl}} \right) A_{ve}$$

Note once again that a tacit neglect of body effect yields infinitely large voltage gain magnitude in the depletion-loaded inverter.

55.3 JFET Technology Transistors

Stephen I. Long

Both the MOSFET and the junction FET or JFET are used in analog IC design, usually in conjunction with bipolar transistors. In this section, the mechanisms responsible for the operation of the JFET will be described, models presented, and fabrication technologies discussed. Performance of integrated and discrete silicon JFETs are compared with each other and with compound semiconductor FET devices.

Introduction

The JFET consists of a conductive channel with source and drain contacts whose conductance is controlled by a gate electrode. The channel can be fabricated in either conductivity type, n or p, and both normally on (depletion-mode-type devices) and normally off (enhancement-mode-type) devices are possible. The circuit symbols typically used for JFETs are shown in Fig. 55.44 along with the bias polarities of active region operation for these four device possibilities. For analog circuit applications, the depletion mode is almost exclusively utilized because it provides a larger range of input voltage and therefore greater dynamic range. In silicon, both p- and n-channel JFETs are used, but when compound semiconductor materials such as GaAs or InGaAs are used to build the FET, n-channel devices are used almost exclusively.

When fabricated with silicon, the JFET is used in analog IC processes for its high input impedance, limited by the depletion capacitance and leakage current of a reverse-based pn junction. When the JFETs are used at the input stage, an op-amp with low input bias current, at least at room temperature, can be built. Fortunately, a p-channel JFET can be fabricated with a standard bipolar process with few additional process steps. This enables inexpensive BiFET processes to be employed for such applications. Unfortunately, the simple process modifications required for integrating JFETs and BJTs are not consistent with the requirements for high-performance devices. Short gate lengths and high channel doping levels are generally not possible. So the transconductance per channel width and the gain–bandwidth product of

© 2003 by CRC Press LLC

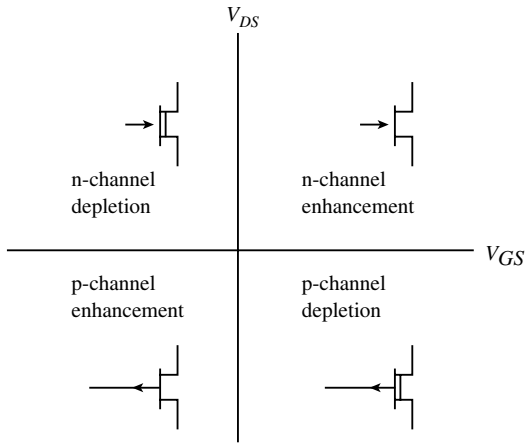

FIGURE 55.44 The circuit symbols typically used for JFETs are shown with the bias polarities for active region operation.

JFETs integrated with a traditional analog BJT process are not very good. The short-circuit current gain–bandwidth product (f_T) is about 50 MHz for an integrated p-channel JFET. The MOSFETs in a BiCMOS process are much better devices, however a BiCMOS process does not often include both NPN and PNP BJTs needed for high-performance analog circuits.

Discrete silicon JFET's are available with much better performance because they can be fabricated with a process optimized for the JFET. Typical applications are for low-noise amplifiers up to the VHF/UHF range. Noise figures less than 0.1 dB can be obtained at low frequencies with high source impedances and 2 dB at high frequencies at the noise matching input condition with high-performance discrete silicon JFETs. The low input gate current I_G, which can be in the picoamp range, causes the shot noise (proportional to $\sqrt{1_G}$) component to be very low. The input equivalent noise current of the JFET is mainly due to input referred channel (Johnson) noise. This property gives very low noise performance when presented with a high source impedance. In this case, the JFET is often superior to a BJT for noise. For low source impedances, the BJT is generally better.

Compound semiconductor materials such as GaAs and InGaAs are used to fabricate JFET-like devices called MESFETs (metal-semiconductor FET) and HEMTs (high electron mobility transistor). The reason for using these materials is superior performance at high frequencies. These devices are unequaled for gain — bandwidth, ultralow noise, and power amplification at frequencies above 10 GHz and up to 200 GHz. Integrated analog microwave circuits are fabricated with these devices and are commercially available for use in low noise receiver and power amplifier applications. Some representative results will be summarized in the section on GaAs MESFET and HEMT technologies.

JFET Static I–V Characteristics

The JFET differs in structure and in the details of its operation from the MOSFET discussed in the previous section. Figure 55.45 shows an idealized cross section of a JFET. The channel consists of a doped region, which can be either p or n type, with source and drain contacts at each end. The channel is generally isolated from its surrounding substrate material by a reverse biased pn junction. The depletion regions are bounded in Fig. 55.45 by dashed lines and are unshaded. The thin, doped channel region forms a resistor of width W into the page and height d. A gate electrode is located at the center of the channel, defined by a semiconductor region of opposite conductivity type of length L. An n-channel structure is shown here for purposes of illustration. The p-type gate constricts the channel, both through the depth of the diffusion or implant used to produce the gate and through the depletion layer formed at the p–n junction. The height of the channel can be varied by biasing the gate relative to the source

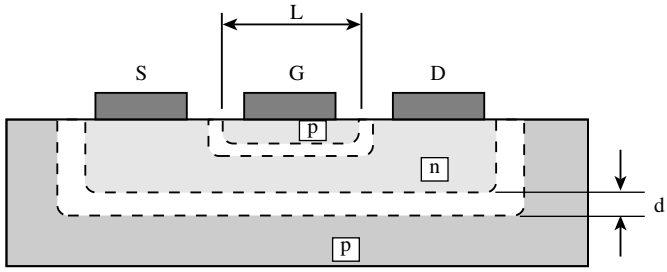

FIGURE 55.45 Idealized cross section of a JFET. The depletion regions are bounded with dashed lines and are unshaded.

(V_{GS}). A reverse bias increases the depletion layer thickness, reducing the channel height and the drain current. If V_{GS} is large enough that the channel is completely depleted, the drain current will become very small. This condition corresponds to the *cutoff* and *subthreshold* current regions of operation, and the V_{GS} required to cutoff the channel is called V_P, the *pinchoff voltage*. V_P corresponds to the threshold voltage that was defined for the MOSFET. Similarly, a forward bias between gate and channel can be used to increase drain current, up to the point where the gate junction begins to conduct. Most JFETs are designed to be *depletion mode* (normally on); drain current can flow when $V_{GS} = 0$ *and* they are normally operated with a reverse-biased gate junction. It is also possible, however, to fabricate *enhancement-mode* JFETs by use of a thinner or more lightly doped channel.

The pinchoff voltage is a sensitive function of the doping and thickness of the channel region. It can be found through Poisson's equation if the channel doping profile $N(x)$ is known. For a nonuniform profile,

$$V_P = V_{BI} - \frac{q}{\varepsilon}\int_0^d xN(x)dx \tag{55.133}$$

For uniform doping, $N(x) = N_D$ and the familiar result in (55.134) shows that the pinchoff voltage depends on the square of the thickness. This result shows that very precise control of profile depth is needed if good matching and reproductibility of pinchoff voltage is to be obtained [11].

$$V_P = V_{BI} - \frac{qN_D d^2}{2\varepsilon} \tag{55.134}$$

JFET Operating Regions

The static current–voltage characteristics of the JFET can be categorized by the five regions of operation shown in Fig. 55.46 for an n-channel device. The mechanisms that produce these regions can be qualitatively understood by referring to the channel cross sections in Fig. 55.47. In these figures, the doped channel region is shaded, and the depletion region is white. First, consider the JFET in Fig. 55.47(a) with small V_{DS} ($\ll V_{GS} - V_P$). This condition corresponds to the ohmic region (sometimes called linear or triode region) where current and voltage are linearly related. At small drain voltages, the depletion layer height is nearly uniform, the electric fields in the channel are too small to saturate the carrier velocity, and thus the channel behaves like a linear resistor. The resistance can be varied by changing V_{GS}. The channel height is reduced by increasing the reverse bias on the gate leading to an increased resistance.

As V_{DS} increases, the depletion layer thickness grows down the length of the channel, as shown in Fig. 55.47(b). This occurs because the drain current causes a voltage increase along the channel as it flows through the channel resistance. Since the depletion layer thickness is governed by the gate-to-channel voltage (V_{GC}), there is an increasing reverse bias that leads to constriction of the channel at the drain end of the gate. Ideally, when $V_{DS} = V_{GS} - V_P$, then $V_{GC} = V_P$, and the channel height will approach zero (pinchoff). The constricted channel will cause the drain current to saturate as shown. Further increases

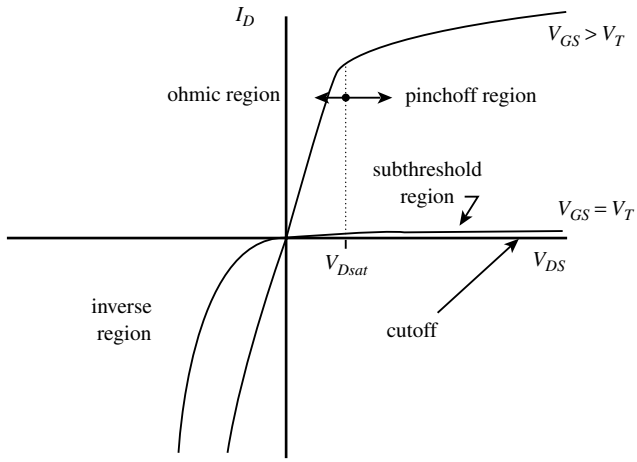

FIGURE 55.46 The static current–voltage characteristic of the JFET can be categorized by five regions of operation. An n-channel device is shown in this illustration with grounded source.

in V_{DS} do not cause the drain current to increase since the channel has already constricted to a minimum height and the additional potential is accommodated by lateral extension of the depletion region at the drain end of the gate. This region of operation is generally described as the **pinchoff region** (rather than the saturation region in order to avoid confusion with BJT saturation). The height of the channel is not actually zero but is limited by the mobile channel charge, which travels at saturated drift velocity in this high field region.

If $V_{GS} < 0$, then the initial channel height at the source is reduced, I_D is less, and the pinchoff region occurs at a smaller drain voltage $V_{DS} = V_{GS} - V_P$. The saturation of drain current can also occur at smaller V_{DS} if the gate length is very small. In this case, the electric field in the channel is large, and the carrier velocity will saturate before the channel can reach pinchoff. Velocity saturation will also limit drain current.

The *subthreshold* region of operation, shown in Fig. 55.47(c) is defined when small drain currents continue to flow even though $V_{GS} \leq V_P$. While technically this gate bias should produce cutoff, some small fraction of the electrons from the source region will have sufficient energy to overcome the potential barrier caused by the gate depletion region and will drift into the drain region and produce a current. Since the energy distribution is exponential with potential, the current flow in this region varies exponentially with V_{GS}.

The *inverse* region occurs when the polarity of the drain bias is reversed. This region is of little interest for the JFET since gate-to-drain conduction of the gate diode limits the operation to the linear region only.

Channel Length Modulation Effect

A close look at the I–V characteristic in the pinchoff region shows that the incremental conductivity or slope of this region is not equal to zero. There is some finite slope that is not expected from the simple velocity saturation or pinchoff models. Channel length modulation is one explanation for this increase; the position under the gate where pinchoff or velocity-saturation first occurs moves toward the source as V_{DS} increases. This is due to the expansion of the drain side depletion region at large V_{DS}. Figure 55.48 illustrates this point. Here, a channel cross section is shown for $V_{DS} = V_{GS} - V_P$ in Fig. 55.48(a) and for $V_{DS} \gg V_{GS} - V_P$ in Fig. 55.48(b). While pinchoff always occurs when the gate-to-channel voltage is V_P, the higher drain voltage causes the location of this point (L) to move closer to the source end of the channel (L'). Since the electric field in this region E is roughly proportional to $(V_{GS} - V_P)/\mathrm{L}$ where L is now a function of V_{DS} and V_{GS}, then the current must increase as the channel length decreases due to increasing carrier velocity ($v = \mu E$). If the channel length is short, velocity saturation may cause the drain current to saturate. In this case, the velocity saturation point moves closer to the source as drain voltage

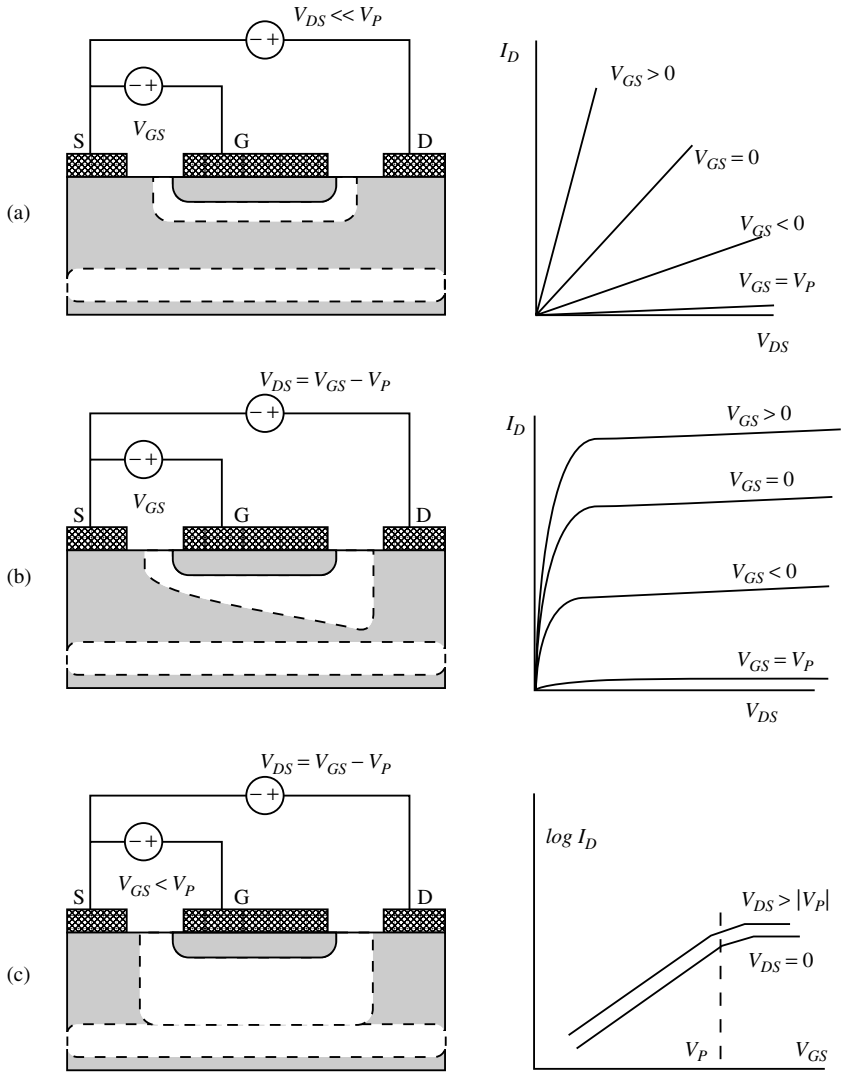

FIGURE 55.47 (a) Ohmic region with small $V_{DS}(\ll V_{GS} - V_P)$. (b) When $V_{DS} = V_{GS} - V_P$, the channel height will become narrow at the drain end of the gate. The device enters pinchoff. The constricted channel will cause the drain current to saturate as shown. (c) Cutoff and subthreshold current regions occur when the depletion region extends through the channel.

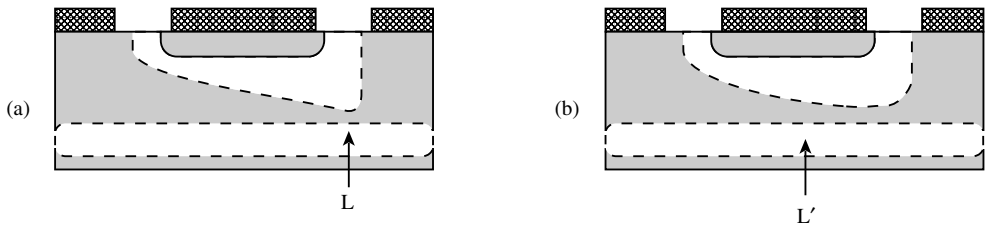

FIGURE 55.48 A channel cross section is shown for $V_{DS} = V_{GS} - V_P$ in (a) and for $V_{DS} \gg V_{GS} - V_P$ in (b). While pinchoff always occurs when the gate-to-channel voltage is V_P, the higher drain voltage causes the location of this point (L) to move closer to the source end of the channel (L').

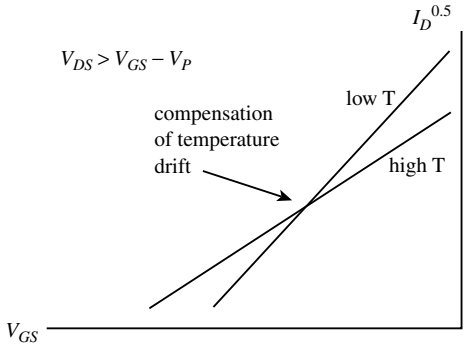

FIGURE 55.49 Effect of temperature on the drain current in the pinchoff region.

is increased. Since the length has decreased, less gate-to-channel voltage is needed to produce the critical field for velocity saturation. Less voltage implies a wider channel opening, hence more current.

Temperature Effects

Two mechanisms influence the drain current of the JFET when temperature is changed [4], [12]. First, the pinchoff voltage becomes more negative (for n-channel) with increase in temperature, therefore requiring lower V_{GS} to cut off the channel or to enter the pinchoff region. Therefore, when the device is operating in the pinchoff region, and $V_{GS} - V_P$ is small, the drain current will increase with temperature. This effect is caused by the decrease in the built-in voltage of the gate-to-channel junction with increasing temperature. Second, the carrier mobility and saturated drift velocity decreases with temperature. This causes a reduction in drain current that is in opposition to the first effect. This effect dominates for large $V_{GS} - V_P$. Therefore, there is a V_{GS} value for which the drain current is exactly compensated by the two effects. This is illustrated qualitatively in Fig. 55.49.

The gate current is also affected by temperature, as it is the reverse current of a pn junction. The current increases roughly by a factor of 2 for each 10°C increase in temperature. At high temperatures, the input current of a JFET input stage may become comparable to that of a well-designed BJT input stage of an op-amp, thus losing some of the benefit of the mixed BJT–JFET circuit design.

JFET Models

Most applications of the JFET in Analog ICs employ the pinchoff region of operation. It is this region, that provides power gain and buffer (source follower) capability for the device, so the models for the JFET presented next will concentrate on this region. It will also be assumed that the gate–source junction will not be biased into forward conduction. Although forward conduction is simple to model using the ideal diode equation within the FET equivalent circuit models, this bias condition is not useful for the principal analog circuit applications of the JFET and will also be avoided in the discussion that follows.

Large-Signal Model: Drain Current Equations

Equations modeling the large signal JFET $I_D - V_{GS}$ characteristic can be derived for the two extreme cases of FET operation in the pinchoff region. A gradually decreasing channel height and mobility limited drift velocity in the channel are appropriate assumptions for very long gate length FETs. A fixed channel height at pinchoff with velocity saturation limited drift velocity are more suitable for short gate lengths.

The square-law transfer characteristic [2] given by (55.135) provides a good

$$I_D = I_{DSS}\left(1 - \frac{V_{GS}}{V_P}\right)^2 \left(1 + \lambda V_{DS}\right) \tag{55.135}$$

approximation to measured device characteristics in the case of long gate length (>5 μm) or very low electrical fields in the channel ($V_{GS} - V_P)/L < E_{sat}$. In both cases, the channel height varies slowly and the

© 2003 by CRC Press LLC

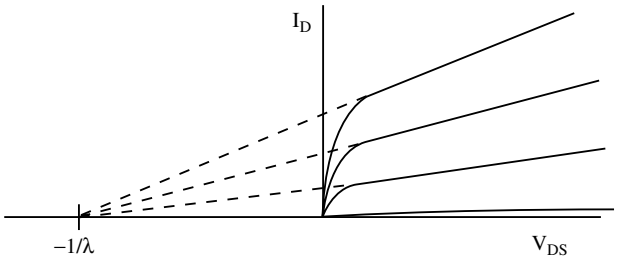

FIGURE 55.50 The channel length modulation parameter λ is defined by the extrapolation of the drain current in saturation to $I_D = 0$.

velocity remains proportional to mobility. E_{sat} is the critical field for saturation of drift velocity, about 3.5 kV/cm for GaAs and 20 kV/cm for Si. I_{DSS} is defined as the drain current in the pinchoff region when $V_{GS} = 0$. The first two terms of the equation are useful for approximate calculation of dc biasing. The third term models the finite drain conductance caused by the channel length modulation effect. The parameter λ in this term is derived from the intercept of the drain current when extrapolated back to zero as shown in Fig. 55.50.

Equation (55.135) is also used to represent the pinchoff region in the SPICE JFET model. It is parameterized in a slightly different form as shown below in (55.136).

$$I_D = \beta\left(V_{GS,i} - V_{T0}\right)^2\left(1 + \lambda V_{DS}\right) \tag{55.136}$$

These equations are the same if $V_{T0} = V_P$, and

$$\beta = \frac{I_{DSS}}{V_P^2}$$

$$V_{GS,i} = V_{GS} - I_D R_S \tag{55.137}$$

$$V_{DS,i} = V_{DS} - I_D R_S - I_D R_D$$

The pinchoff region is defined for $V_{DS,i} \geq V_{GS,i} - V_{T0}$ as is usual for the gradual channel approximation. R_S and R_D are the parasitic source and drain resistances associated with the contacts and the part of the channel that is outside of the gate junction. These resistances will reduce the internal device voltages below the applied terminal voltages as shown in (55.137).

For shorter gate length devices, improved models have been proposed and implemented in SPICE3 and some of the many commercial SPICE products, often in the MESFET model. The Raytheon or Statz model [10] is frequently used for this purpose. This model modifies the drain current dependence on V_{GS} by adding a velocity saturation model parameter b in the denominator as shown in (55.138).

$$I_D = \left[\frac{\beta\left(V_{GS,i} - V_{T0}\right)^2}{1 + b\left(V_{GS,i} - V_{T0}\right)}\right]\left(1 + \lambda V_{DS,i}\right) \tag{55.138}$$

This added term allows the drain current to be nearly square law in V_{GS} for small $V_{GS} - V_{T0}$, but it becomes almost linear when V_{GS} is large, effectively emulating the rapid rise in transconductance followed by saturation that is typical in short channel devices. Although the specific behavior of the drain current is sensitive to the vertical doping profile in the channel [15], (55.138) is flexible enough to accommodate most short channel device characteristics with uniform or nonuniform channel doping. Another feature of short gate length FET's that this model predicts adequately is a saturation of I_D at $V_{DS,i} < V_{GS,i} - V_{T0}$.

© 2003 by CRC Press LLC

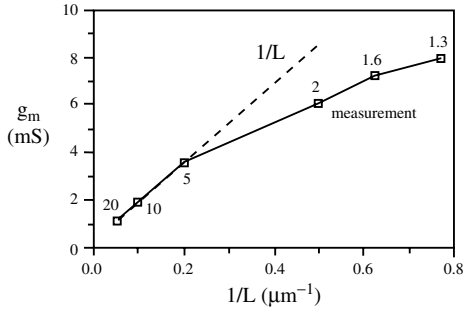

FIGURE 55.51 Plot of transconductance vs. $1/L$. The gate length L is varied over the range of 1.3 to 20 μm (lengths shown next to data points). $1/L$ scaling is observed for gate lengths greater than 5 μm.

This early transition into the pinchoff region is also a consequence of velocity saturation and is widely observed.

Width and Length Scaling

Classical FET theory suggests that the drain current should scale linearly with channel width W and inversely with gate length L. In practice, this applies adequately for JFETs with long gate lengths ($L \geq 5$ μm) and wide channels ($W \geq 5$ μm) but breaks down below these approximate dimensions. In the case of the width, the drain current of a narrow channel JFET will be larger than expected by a linear scaling due to the lateral diffusion that occurs during implantation or diffusion. The channel may be wider than the mask dimension by possibly 0.5 μm for this reason. If the process design rules allow use of very narrow channels, experimental data should be used to determine the effective channel width.

Scaling of drain current with gate length is less straightforward. For very short gate lengths, at the limit of velocity saturation, no increase in drain current is predicted by (55.139) unless the channel depth d is also scaled. An increase in channel doping is required to reduce d. Since channel doping in a given process is constant, the drain current will scale less sensitively than $1/L$ if gate lengths below 5 μm are used. This effect is illustrated in Fig. 55.51 for a GaAs MESFET, a type of JFET to be described in the section on JFET technologies, where the transconductance is plotted against $1/L$. The gate length L is varied over the range of 1.3–20 μm (lengths shown next to data points). $1/L$ scaling is observed for gate lengths greater than 5 μm.

$$\beta = \frac{\varepsilon v_{sat} W}{d} \tag{55.139}$$

In practice, data measured on devices covering a range of L is needed in order to predict length scaling accurately. Note that the SPICE2 or SPICE3 JFET and MESFET models do not attempt to scale device parameters for gate length, so the length scaling must be accomplished manually through use of parameter sets optimized for each length.

Device Capacitances

There will be capacitances associated with the pn junctions comprising the JFET. Figure 55.45 shows that are junctions between the gate and channel and between the channel and substrate. In addition, for some silicon JFET devices as discussed in the section on JFET technologies, there will also be a junction between the gate and substrate. Each of these capacitances are voltage dependent and should be considered in a device model if it is to be accurate at high frequencies.

The gate-to-channel capacitance is split into two components, a gate-to-source capacitance C_{gs} and a gate-to-drain capacitance C_{gd}. The V_{GS} and V_{GD} dependence of these capacitances is often approximated by the depletion capacitance of a pn junction; eqs. (55.140) and (55.141) are typically used to predict variation of capacitance in the indicated bias range. For $V_{GS} < V_P$ the capacitance rapidly drops to a small

© 2003 by CRC Press LLC

value limited by parasitic capacitances and is insensitive to either V_{GS} or V_{DS}. V_{BI} is the apparent built-in voltage of the junction. In some models, the parameter m is made adjustable to accommodate nonuniform doping profile effects. Typically, $m = 0.5$ is used to represent a uniformly doped channel.

$$C_{gs} = \frac{C_{gso}}{\left(1 - V_{GS}/V_{BI}\right)^{m}} \tag{55.140}$$

$$C_{gd} = \frac{C_{gdo}}{\left(1 - V_{GD}/V_{BI}\right)^{m}} \tag{55.141}$$

While this model is severely in error in the linear region [6], if operation of the device is limited to the pinchoff region it can provide an adequate prediction. For the GaAs MESFET, C_{gd} will be of the order of 15 percnt of the total gate capacitance; C_{gs} about 85 percent. For the SI JFET, C_{gd} is about 25 percent; C_{gs} is about 75 percent. This formulation is found in both the SPICE JFET and MESFET models; however, the MESFET model implementation [10] includes the pinchoff effects and is considerably more accurate in the linear region.

The parasitic gate-to-substrate capacitance C_{gss} found certain Si JFET technologies can also be modeled by functions like (55.140) or (55.141). However, it is not included explicitly as part of the SPICE JFET model. If it is necessary, the diode model can be used to simulate C_{gss} by connecting an external diode from gate-to-substrate.

Small-Signal Model

The small-signal model for the JFET in the pinchoff region is shown in Fig. 55.52. The voltage-dependent current source models the transconductance g_m as a constant that can be derived from the drain current equations above from

$$g_m = \frac{\partial I_D}{\partial V_{GS}} \tag{55.142}$$

The square-law current model (55.135) predicts a linearly increasing g_m with V_{GS}

$$g_m = -\frac{2I_{DSS}}{V_P}\left(1 - \frac{V_{GS}}{V_P}\right) \tag{55.143}$$

whereas a model that includes some velocity saturation effects such as (55.138) would predict a saturation in g_m.

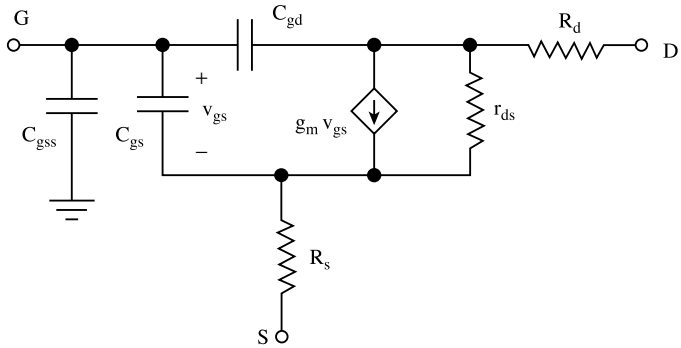

FIGURE 55.52 The small-signal model for the JFET in the pinchoff region.

© 2003 by CRC Press LLC

The small-signal output resistance r_0 models the channel length modulation effect. This is also derived from the drain current equations through

$$r_0^{-1} = \frac{\partial I_D}{\partial V_{DS}} \tag{55.144}$$

For both models, r_0 is determined by

$$r_0 = \frac{1}{I_D \lambda} \tag{55.145}$$

The small-signal values of the nonlinear, voltage dependent C_{gs}, C_{gd}, and C_{gss} are also shown in Fig. 55.52. Parasitic source and drain resistances R_S and R_D can also be included, as shown. If they are not included in the small-signal model, the effect of these parasitics can sometimes be produced in the intrinsic FET model by reducing the intrinsic g_m of the device.

The short-circuit current gain–bandwidth product f_T defined in (55.146) is a high-frequency figure of merit for transistors. It is inversely proportional to the transit time τ of the channel charge, and it is increased by reducing the gate length. Reduced L also reduces the gate capacitance and increases transconductance. The FET channel material also affects f_T as higher drift velocity leads to higher g_m.

$$f_T = \frac{g_m}{2\pi\left(C_{gss} + C_{gs} + C_{gd}\right)} = \frac{1}{\tau} \tag{55.146}$$

SPICE Model Parameter Summary

In Tables 55.3 and 55.4, a brief summary of the basic set of parameters used in all SPICE JFET and MESFET models is provided. These parameters were defined in the section on the large-signal model. Note that some SPICE versions will include other parameters designed to improve the accuracy or versatility of the model. These parameters scale directly or inversely in channel width W for most implementations. If the gate length is changed, generally a new set of parameters extracted for the new gate length will be required. The parameters β, C_{gso}, C_{gdo}, and I_S scale directly with W and R_S, R_D inversely. Other parameters are not affected by width to the first order.

JFET Technologies

The IC fabrication technology used to make JFETs depends primarily on the material. Discrete Si JFETs are available that provide f_T above 500 MHz and very low input rms noise currents through optimizing the channel design and minimizing parasitic capacitances, resistances, and gate diode leakage currents. However, a silicon IC process is rarely designed to optimize the performance of the JFET; rather, the JFET is made to accommodate an existing bipolar process with as few modifications as possible [2]. Then, the extra circuit design flexibility and performance benefits of a relatively inexpensive mixed FET/BJT process (often called BiFET) can be obtained with small incremental cost. On the other hand, gallium arsenide IC processes exist only for the improved performance that is possible with these devices. Thus, the process technology is carefully designed to optimize device performance for bandwidth, noise, or power and to minimize the parasitic capacitances and inductances associated with passive components [9].

Silicon JFET Technologies

In principle, it would be possible to build p-channel Si JFETs in a standard analog BJT process without additional mask steps if the base diffusion has suitable doping and thickness to give a useful pinchoff voltage when overlaid with the emitter diffusion. Unfortunately, this is usually not the case, since the emitter diffusion is too shallow, and the pinchoff voltage resulting from this approach would be too high (positive

in the case of the p-channel device). Therefore, the channel of the JFET must be made thinner either through the use of an additional diffusion or by providing the channel and gate with ion implantations.

The double diffused JFET process was the earliest approach to be used, since the channel depth could be reduced through the use of only one additional diffusion step. A cross-sectional view is shown in Fig. 55.53. Here, the depth of the gate diffusion is extended by an extra predeposition and drive-in diffusion step carried out prior to the emitter diffusion steps. Therefore, a narrower base region is obtained allowing the pinchoff voltage of the JFET to be independent of the requirements of the BJT. While this

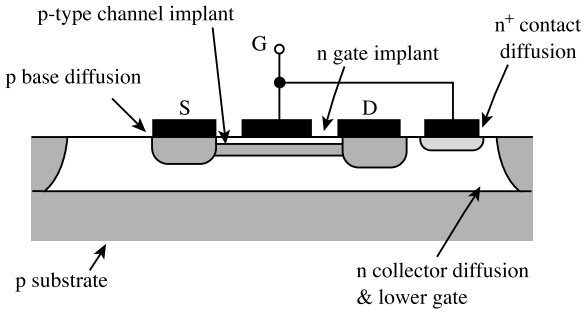

FIGURE 55.54 Cross section of an ion implanted silicon JFET (not to scale).

simple process modification is inexpensive to implement, the absolute control and matching of pinchoff voltage is not accurate enough for low input offset voltage in JFET differential amplifier pairs. In addition, the forced compatibility with the BJT process requires use of the collector layer under the channel. This forms a lower gate electrode that is by necessity less heavily doped than the channel. Therefore, the depletion region at this interface extends primarily into the gate, and the lower gate is rather ineffective in contributing to the total transconductance of the JFET. It does add the parasitic capacitance C_{gss} to the device at the collector to substrate junction, limiting frequency response. Finally, due to the relatively high base doping level, the drain breakdown voltage is low.

Because of the performance compromises inherent in this approach, it has been largely superceded by the ion implantation method. Figure 55.54 illustrates the cross section of an ion-implanted JFET. In order to gain better control of the pinchoff voltage and transconductance, both the channel and the gate are formed by ion implantation. This allows use of a channel that is more lightly doped than the base diffusion enabling the collector "gate" layer to more effectively contribute to the transconductance of the device. In addition, the predeposition of channel and gate charge is much more repeatable with ion implantation, so device matching and reproducibility of pinchoff voltage is greatly improved. The f_T will be improved by the larger g_m per unit width and the slightly reduced gate capacitances, and the drain breakdown voltage will be increased as is often needed for an analog IC process. However, low channel doping is not a good recipe for a high-frequency transistor with short gate length, so the f_T of these devices is still only 50 MHz or so.

GaAs MESFET and HEMT Technologies

High-performance GaAs MESFET devices are constructed with a metal-semiconductor junction gate instead of a diffused or implanted pn junction gate. The metal gate forms a Schottky barrier diode directly on an n-type channel as shown in Fig. 55.55 and allows the channel height to be varied in the same manner as the JFET. No gate dielectric or diffusion is necessary. The channel is formed either by ion implantation of an n-type dopant into a high resistivity (semiinsulating) GaAs substrate or a lightly

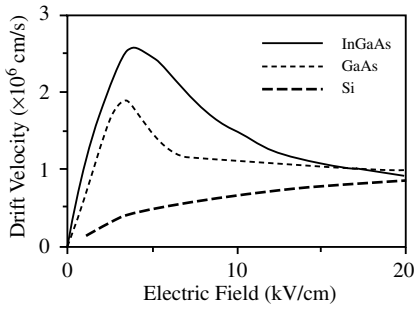

FIGURE 55.56 Electron velocity vs. electric field for InGaAs (53% In) [5], GaAs [8], and Si [3].

p-type substrate or by growth of the channel region with molecular beam epitaxy. These MESFETs are used as the primary active device in analog microwave and mm-wave monolithic integrated circuits (sometimes called MMICs). Since analog MESFET circuits are used for low noise, wide bandwidth, or high power amplification up to 50 GHz, gate lengths are often quite small; 0.25 μm is not unusual. The high performance of these devices comes through a combination of factors. First, the mobility and saturated drift velocity of n-GaAs are five times and two times larger than n-Si, respectively. In addition, the peak drift velocity is reached at much lower electric field for GaAs [8] as illustrated in Fig. 55.56. The parasitic substrate capacitance is quite small due to the high resistivity provided by semiinsulating GaAs. These factors lead to a much higher f_T (20–50 GHz) and lower parasitic resistances (f_{max}) at lower operating voltages for the GaAs MESFET than the Si JFET. These are desirable qualities for high performance microwave circuits, and the high electron velocity at low bias voltage can lead to reduced power as well. Also, patterning submicrometer gate lengths with metal or silicide gate materials is relatively straightforward, and gate resistance can be reduced through plating thick gate stripes with mushroom cross sections. Passive interconnections can have low losses through the use of plated air bridge interconnections suspended over the surface of the MMIC, and plated-through substrate vias can be fabricated when needed to reduce parasitic inductances.

MESFET MMICs are available commercially from several sources. Custom MMIC design and fabrication can also be supported by several GaAs IC foundries.

Further reduction in noise figure and increase in bandwidth has been demonstrated by the use of heterojunction MESFETs, sometimes called HEMT's (high electron mobility transistors) or P-HEMTs (pseudomorphic HEMTs). This device achieves its improved performance mainly through the high mobility, undoped InGaAs channel material. The electron velocity versus electric field of $In_{0.53}Ga_{0.47}As$ is compared with GaAs and Si in Fig. 55.56, where it can be seen that higher drift velocity is obtained in $In_{0.53}Ga_{0.47}As$ [5] than either GaAs [8] or Si [3]. The higher the In concentration in the InGaAs, the higher the mobility and velocity and the lower the noise. InGaAs cannot be lattice matched to GaAs substrates, but about 20 percent In can be tolerated if the InGaAs channel is very thin. In this case, the mismatch is accommodated by elastic strain rather than by the formation of lattice defects. This strained condition is called pseudomorphic: a forced lattice match due to elastic strain. When grown on InP semiinsulating substrates, much higher In concentration can be used in the channel (53%) under lattice-matched conditions, and even more In is possible when pseudomorphic growth conditions are used.

In addition, the channel layer is confined between higher bandgap regions (InAlAs) as illustrated in Fig. 55.57. The confinement provided by these energy barriers provides large channel electron sheet concentrations, also improving g_m.

Finally, the gate barrier heterojunction also enables good Schottky gate characteristics to be obtained even though the channel material itself has a low bandgap and would otherwise provide a poor barrier height if the metal were in direct contact.

Excellent performance of HEMT or P-HEMT devices and MMICs at microwave and millimeter wave frequencies has been reported. Table 55.5 summarizes some representative results.

Resistors

Resistors available in monolithic form are classified in general as semiconductor resitors and thin-film resistors. Semiconductor structures include diffused, pinched, epitaxial, and ion-implanted resistors. Commonly used thin-film resistors include tantalum, nickel–chromium (Ni–Cr), cermet (Cr–SiO), and tin oxide (SnO_2). Diffused, pinched, and epitaxial resistors can be fabricated along with other circuit elements without any additional processing steps. Ion-implanted and thin-film resistors require additional processing steps for monolithic integration but offer lower temperature coefficient, smaller absolute value variation, and superior high-frequency performance.

Resistor Calculation. The simplified structure of a uniformly doped resistor of length L, width W, and thickness T is shown in Fig. 55.58. The resistance is

$$R = \frac{1}{\sigma}\frac{L}{WT} = \left(\frac{\rho}{T}\right)\frac{L}{W} = R_{\square}\frac{L}{W} \tag{55.147}$$

where σ and ρ are conductivity and resistivity of the sample, respectively, and $R_{\square}$ is referred to as the *sheet resistance*. From the theory of semiconductor physics, the conductivity of a semiconductor sample is

$$\sigma = q\left(\mu_n n + \mu_p p\right) \tag{55.148}$$

where q is the electron charge (1.6×10^{-19} Coulomb), μ_n (cm^2/V · s) is the electron mobility, μ_p (cm^2/V · s) is the hole mobility, n (cm^{-3}) is the electron concentration, p (cm^{-3}) is the hole concentration, and σ (Ω/cm)$^{-1}$ is the electrical conductivity. For an n-type doped sample with a concentration N_D (cm^{-3}) of donor impurity atoms, the electron concentration n is approximately equal to N_D. Given the *mass-action law* $np = n_i^2$, the conductivity of an n-type doped sample is approximated by

$$\sigma = q\left(\mu_n N_D + \mu_p \frac{n_i^2}{N_D}\right) \approx q\mu_n N_D \tag{55.149}$$

where n_i (cm^{-3}) is the *intrinsic* concentration. For a p-type doped sample, the conductivity is

$$\sigma = q\left(\mu_n \frac{n_i^2}{N_A} + \mu_p N_A\right) \approx q\mu_p N_A \tag{55.150}$$

where N_A (cm^{-3}) is the concentration of p-type donor impurity atoms. The sheet resistance of an n-type uniformly doped resistor is thus

© 2003 by CRC Press LLC

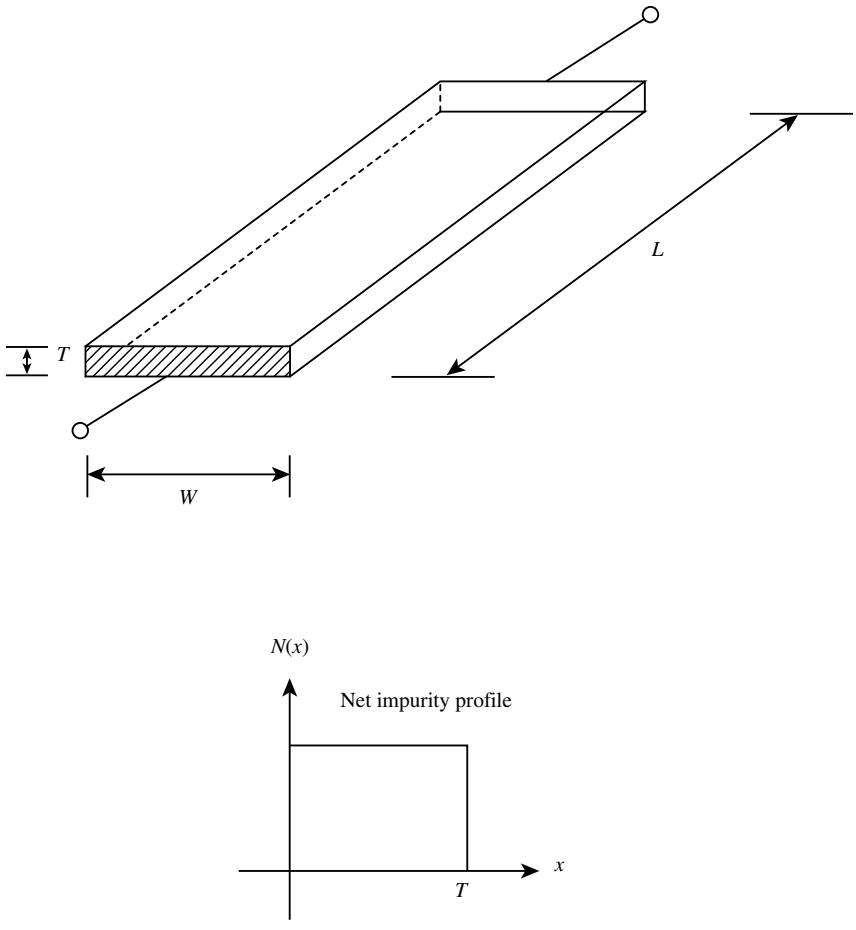

FIGURE 55.58 Simplified structure of a uniformly doped resistor.

$$R_{\square} = \left(\frac{1}{q\mu_n N_D T} \right) \tag{55.151}$$

For an n-type nonuniformly doped resistor as shown in Fig. 55.59, where n-type impurity atoms are introduced into the p-type region by means of a high-temperature diffusion process, the sheet resistance [7] is

$$R_{\square} = \left[\int_0^{x_j} q\mu_n N_D(x) dx \right]^{-1} \tag{55.152}$$

where x_j is the distance from the surface to the edge of the junction depletion layer.

Measured values of electron mobility and hole mobility in silicon material as a function of impurity concentration are shown in Fig. 55.60 [4]. The resistivity ρ (Ω-cm) of n-type and p-type silicon as a function of impurity concentration is shown in Fig. 55.61 [12].

The sheet resistance depends also on temperature since both electron mobility and hole mobility vary with temperature [17]. This effect is accounted for by utilizing *a temperature coefficient* quantity that measures the sheet resistance variation as a function of temperature. A mathematical model of the temperature effect is

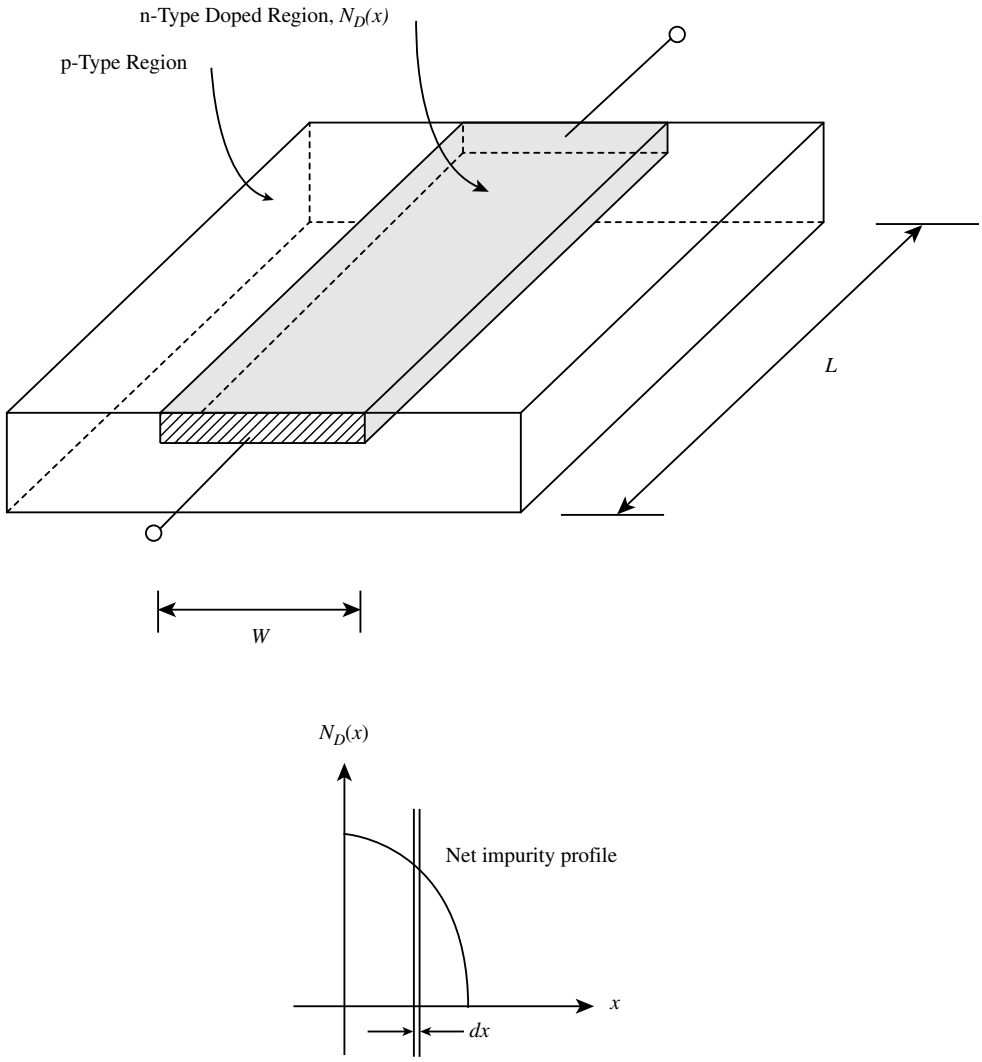

FIGURE 55.59 Simplified structure of an n-type nonuniformly doped resistor.

$$R_{\square}(T) = R_{\square}(T_o)\left[(T - T_o)TC\right] \tag{55.153}$$

where T_o is the room temperature and TC is the temperature coefficient.

Diffused Resistors

In MOS (metal-oxide-semiconductor) technology, the diffused layer forming the source and drain of the MOS transistors can be used to form a diffused resistor. In silicon bipolar technology, the available diffused layers are base diffusion, emitter diffusion, active base region, and epitaxial layer.

Base Diffused Resistors. The structure of a typical base diffused resistor is shown in Fig. 55.62, where the substrate material is assumed of p-type silicon material. The diffused resistor is formed by using the p-type base diffusion of the npn transistors. The resistor contacts are formed by etching selected windows of the SiO_2 passivation layer and depositing thin films of conductive metallic material. The isolation region can be formed with either a p-type doped junction or a trench filled with SiO_2 dielectric material.

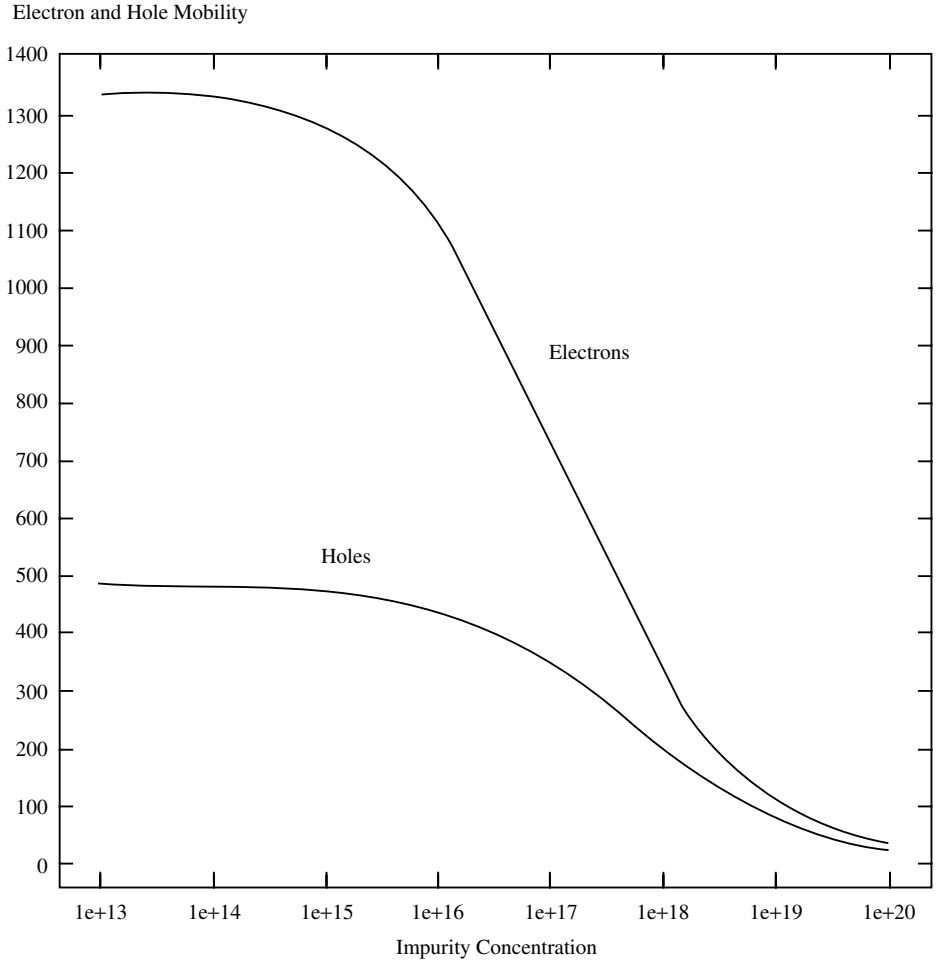

FIGURE 55.60 Electron and hole mobility vs. impurity concentration in silicon.

The pn junction formed by the p-type resistor and the n-type epitaxial (epi) layer must be reverse biased in order to eliminate the undesired dc current path through the pn junction. The impedance associated with a forward-biased pn junction is low and thus would also cause signficant ac signal loss. To ensure this reverse bias constraint the epi region must be connected to a potential that is more positive than either end of the resistor contacts. Connecting the epi region to a relatively higher potential also eliminates the conductive action due to the parasitic pnp transistor formed by the p-type resistor, the n-type epi region, and the p-type substrate. When the base diffused resistor is fabricated along with other circuit elements to form an integrated circuit, the epitaxial contact is normally connected to the most positive supply of the circuit.

The resistance of a diffused resistor is given by (55.147), where the diffused sheet resistance is between 100 and 200 Ω/□. Due to the lateral diffusion of impurity atoms, the effective cross-sectional area of the resistor is larger than the width determined by photomasking. This lateral or side diffusion effect can be accounted for by replacing the resistor width W by an effective width W_{eff}, where $W_{\text{eff}} \geq W$. The resistance from the two resistor contacts must also be accounted for, especially for small values of L/W [3]. Base-diffused resistors have a typical temperature coefficient between +1500 and +2000 ppm/°C.

The maximum allowable voltage for the base-diffused resistor of Fig. 55.62 is limited by the breakdown voltage between the p-type base diffusion and the n-type epi. This voltage equals the breakdown voltage BV_{CBO} of the collector-base junction of the npn transistor and typically causes an *avalanche breakdown*

© 2003 by CRC Press LLC

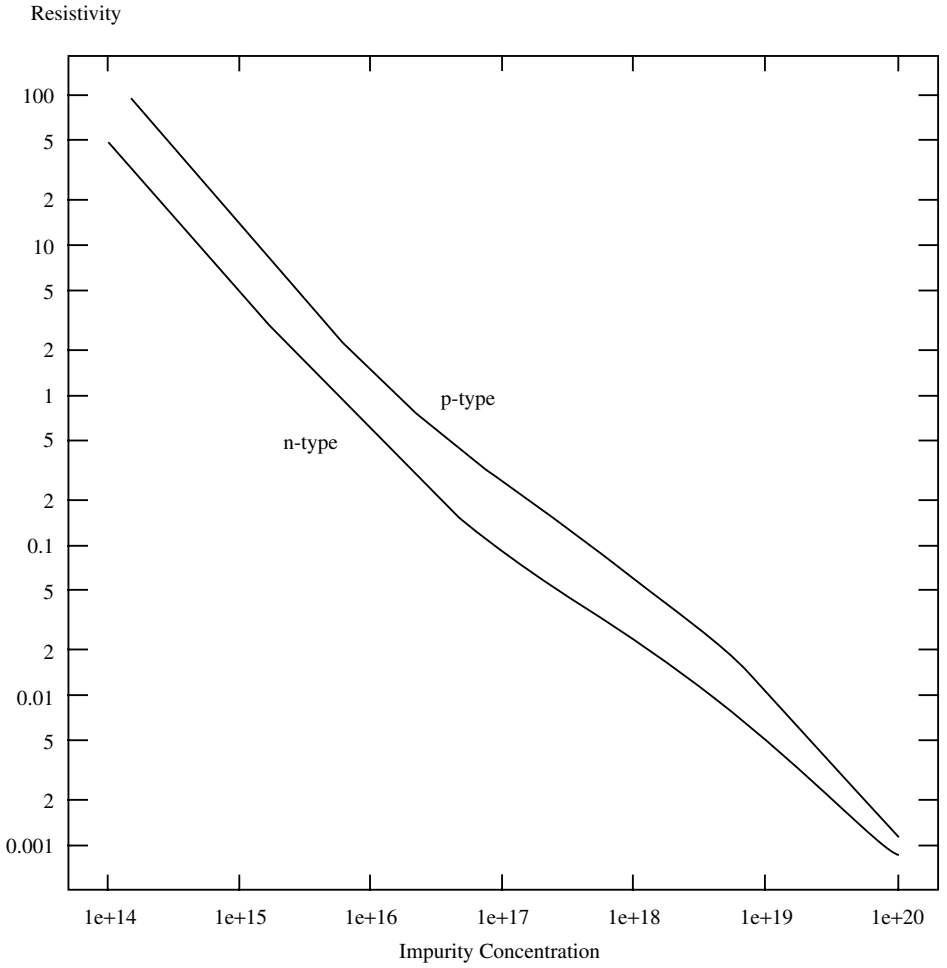

FIGURE 55.61 Resistivity of p-type and n-type silicon vs. impurity concentration.

mechanism across the base–epi junction. As the applied voltage approaches the breakdown voltage, a large leakage current flows from the epi region to the base region and can cause excessive heat dissipation.

For analog integrated circuit applications where good matching tolerance between adjacent resistors is required, the resistor width should be made as large as possible. Base-diffused resistors with 50-μm resistor widths can achieve a matching tolerance of ± 0.2 percent. The minimum resistor width is limited by photolithographic consideration with typical values between 3 and 5 μm. Also, in order to avoid the self-heating problem of the resistor it is important to ensure a minimum resistor width for a given dc current level, with a typical value of about 3 μm for every 1 mA of current.

With respect to high-frequency performance, the reverse-biased pn junction between the p-type base diffusion and the n-type epi contributes a distributed depletion capacitance which in turn causes an impedance roll-off at 20 dB/decade. This capacitance depends on the voltage applied across the junction and the junction impurity-atom dopings. For most applications the electrical lumped model as shown in Fig. 55.62 is adequate for characterizing this capacitive effect where the effective pn junction area is divided equally between the two diodes. Figure 55.63 shows a normalized impedance response as a function of the *RC* distributed stage. The frequency at which impedance value is reduced by 3 dB is given by

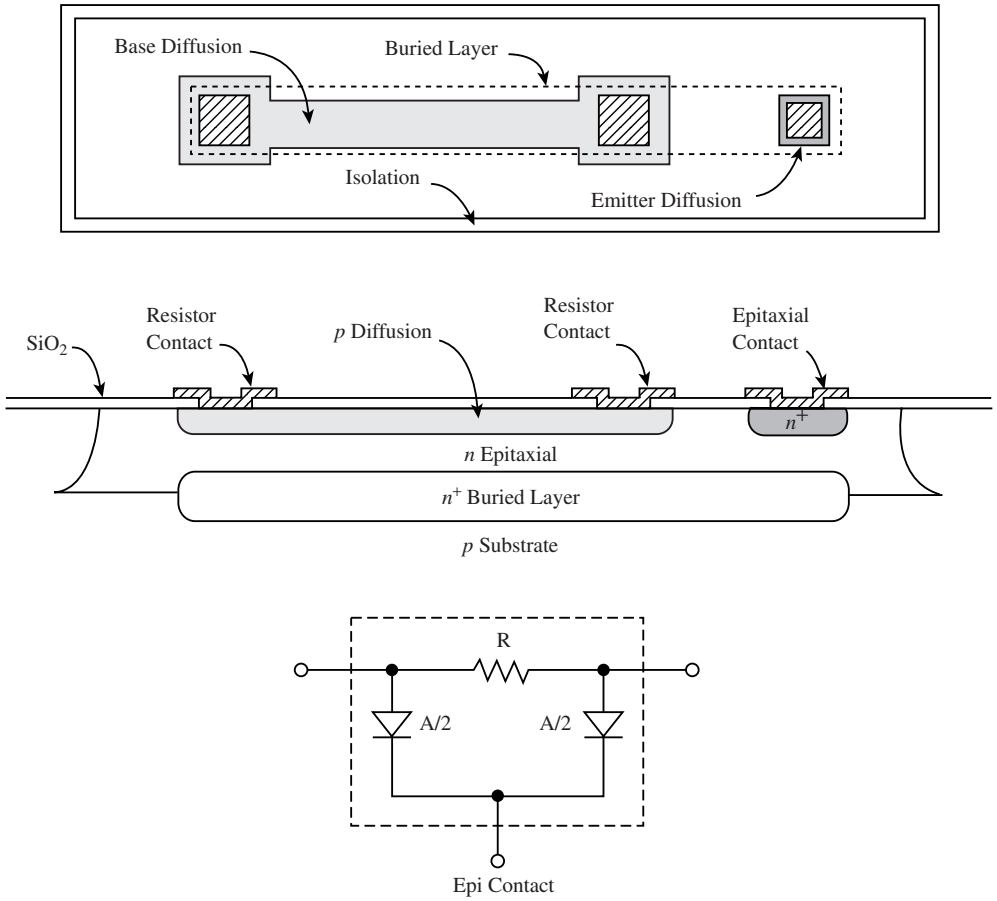

FIGURE 55.62 p-type base-diffused resistor.

$$f_{-3\text{ dB}} = \begin{cases} \left(\frac{1}{2\pi}\right)\frac{2.0}{RC} & N = 1 \quad \text{(Circuit model of Fig. 55.62)} \\ \left(\frac{1}{2\pi}\right)\frac{2.32}{RC} & N = 2 \\ \left(\frac{1}{2\pi}\right)\frac{2.42}{RC} & N = 3 \\ \left(\frac{1}{2\pi}\right)\frac{2.48}{RC} & N = 4 \end{cases} \tag{55.154}$$

Emitter Diffused Resistors. Emitter-diffused resistors are formed by using the heavily doped n^+ emitter diffusion layer of the npn transistors. Due to the high doping concentration, the sheet resistance can be as low as 2 to 10 Ω/□ with a typical absolute value tolerance of ± 20 percent.

Figure 55.64 shows an emitter-diffused resistor structure where an n^+ diffusion layer is formed directly on top of the n-type epitaxial region and the ohmic contacts are composed of conductive metal thin films. Since the resistor body and the epi layer are both n-type doped, they are electrically connected in

© 2003 by CRC Press LLC

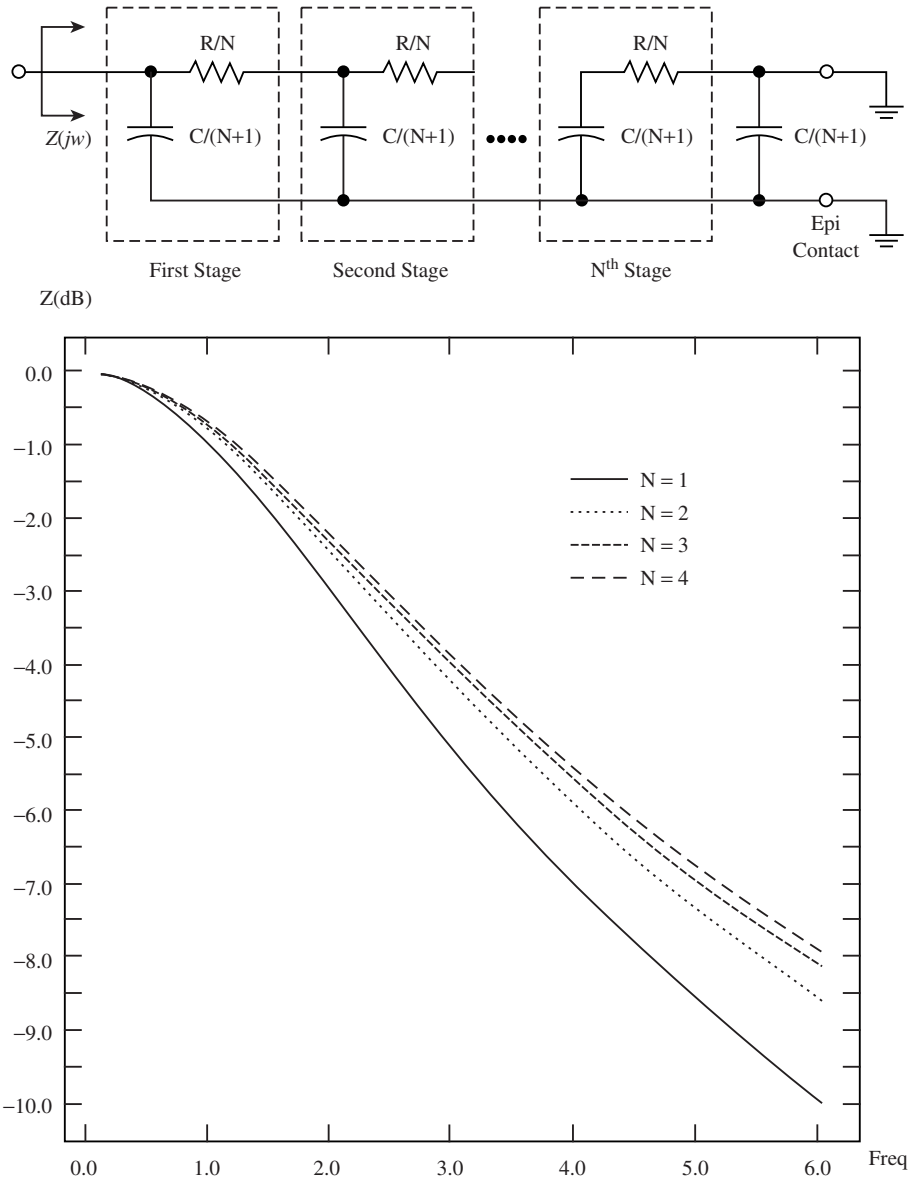

FIGURE 55.63 Normalized frequency response of a diffused resistor for $N = 1, 2, 3, 4$. The epi contact and one end of the resistor are grounded.

parallel but the epi layer is of much higher resistivity due to its lower concentration doping, and thus the effective sheet resistance of the resistor structure is determined solely by the n^+ diffusion layer. The pn junction formed between the p-type substrate and the n-type epi region must always be reverse biased, which is accomplished by connecting the substrate to a most negative potential. Because of the common n-type epi layer, each resistor structure of Fig. 55.64 requires a separate isolation region.

Figure 55.65 shows another emitter diffused resistor structure where the n^+ diffusion layer is situated within a p-type diffused well. Several such resistors can be fabricated in the same p-type well or in the same isolation region because the resistors are all electrically isolated. The p-type well and the n^+ diffusion region form a pn junction that must always be reverse biased for electrical isolation. In order to eliminate the conductive action due to the parasitic npn transistor formed by the n-type resistor body, the p-type

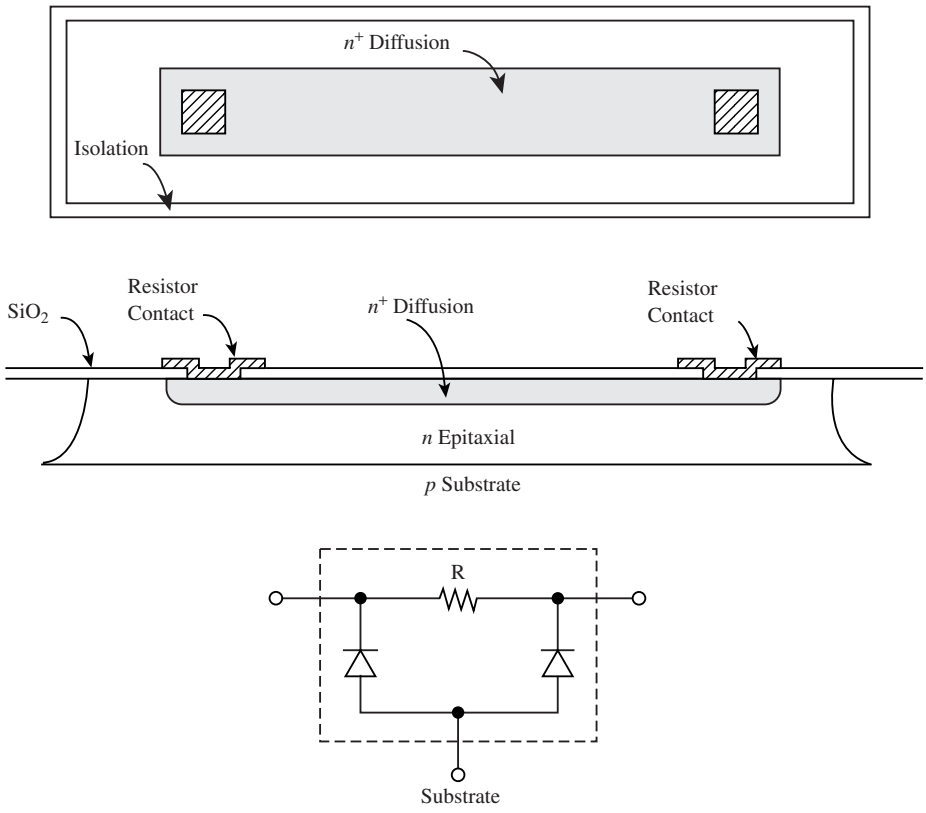

FIGURE 55.64 n-type emitter-diffused resistor I.

well, and the n-type epi, the junction potential across the well contact and the epi contact must be either short-circuited or reverse biased. The maximum voltage that can be applied across the emitter-diffused resistor of Fig. 55.65 is limited by the breakdown voltage between the n^+ diffusion and the p-type well. This voltage equals the breakdown voltage BV_{EBO} of the emitter–base junction of the npn transistor, with typical values between 6 and 8 V.

Pinched Resistors

The active base region for the npn transistor can be used to construct pinched resistors with typical sheet resistance range from 2 to 10 $K\Omega/\square$. These high values can be achieved due to a thin cross-sectional area through which the resistor current traverses. The structure of a p-type base-pinched resistor is shown in Fig. 55.66, where the p-type resistor body is "pinched" between the n^+ diffusion layer and the n-type epitaxial layer. The n^+ diffusion layer overlaps the p-type diffusion layer and is therefore electrically connected to the n-type epi. In many aspects the base-pinched resistor behaves like a p-channel JFET, in which the active base region functions as the p channel, the two resistor contacts assume the drain and source, and the n^+ diffusion and the epi constitute the n-type gate. When the pn junction formed between the active base and the surrounding n^+ diffusion and n epi is subject to a reverse bias potential, the carrier-free depletion region increases and extends into the active base region, effectively reducing the resistor cross section and consequently increasing the sheet resistance. Since the carrier-free depletion region varies with reverse bias potential, the pinched resistance is voltage controlled and is nonlinear.

Absolute values for the base-pinched resistors can vary as much as ±50 percent due to large process variation in the fabrication of the active base region. The maximum voltage that can be applied across the base-pinched resistor of Fig. 55.66 is restricted by the breakdown voltage between the n^+ diffusion layer and the p-type base diffusion. The breakdown voltage has a typical value around 6 V.

© 2003 by CRC Press LLC

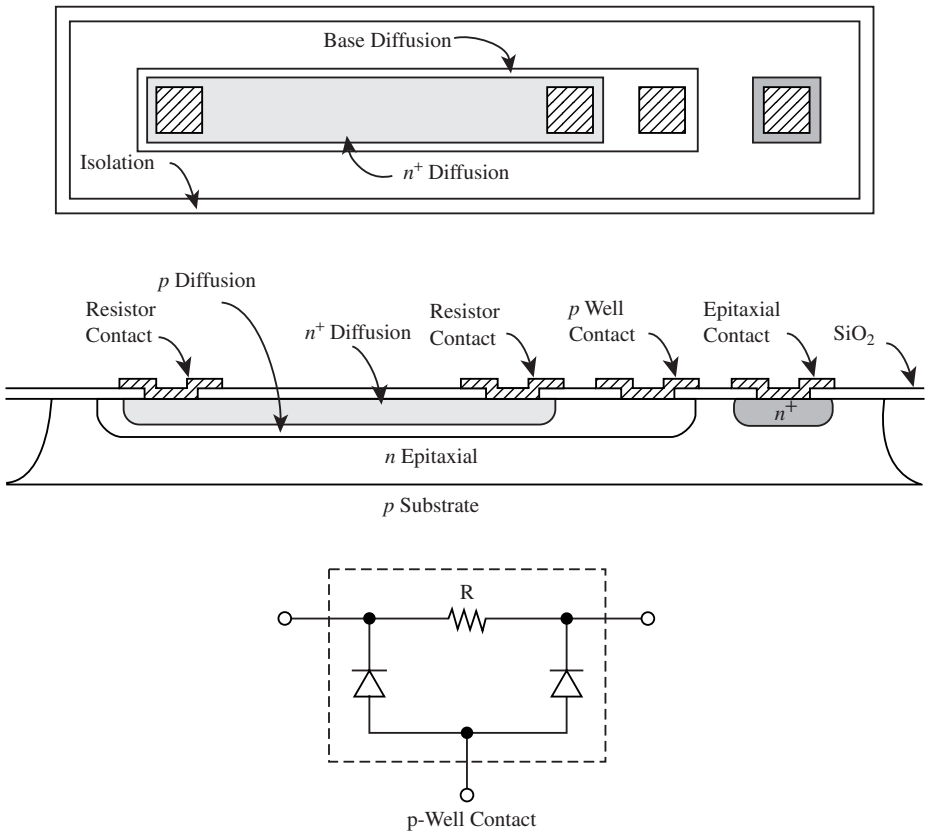

FIGURE 55.65 n-type emitter-diffused resistor II.

Epitaxial Resistors

Large values of sheet resistance can be obtained either by reducing the effective cross-sectional area of the resistor structure or by using a low doping concentration that forms the resistor body. The first technique is used to realize the pinched resistor while the second is used to realize the epitaxial resistor. Figure 55.67 shows an epitaxial resistor structure where the resistor is formed with a lightly doped epitaxial layer. For an epi thickness of 10 μm and a doping concentration of 10^{15} donor atoms/cm^3, this structure achieves a resistivity of 5 Ω-cm and an effective sheet resistance of 5 KΩ/□. The temperature coefficient of the epitaxial resistor is relatively high with typical values around +3000 ppm/°C. This large temperature variation is a direct consequence of the hole and electron mobilities undergoing more drastic variations against temperature at particularly low doping concentrations [13]. The maximum voltage that can be applied across the epitaxial resistor is significantly higher than that for the pinched resistor. This voltage is set by the breakdown voltage between the n-type epi and the p-type substrate which varies inversely with the doping concentration of this pn junction.

Epitaxial Pinched Resistors. By putting a p-type diffusion plate on top of the epitaxial resistor of Fig. 55.67, even larger sheet resistance value can be obtained. The p-type diffusion plate overlaps the epi region and is electrically connected to the substrate through the p-type isolation. The epi layer is thus pinched between the p-type diffusion plate and the p-type substrate. When the n-type epi and the surrounding p-type regions is subject to a reverse bias potential, the junction depletion width extends into the epi region and effectively reduces the cross-sectional area. Typical sheet resistance values are between 4 and 5 KΩ/□. The epitaxial-pinched resistor behaves like an n-channel JFET, in which the effective channel width is controlled by the substrate voltage.

© 2003 by CRC Press LLC

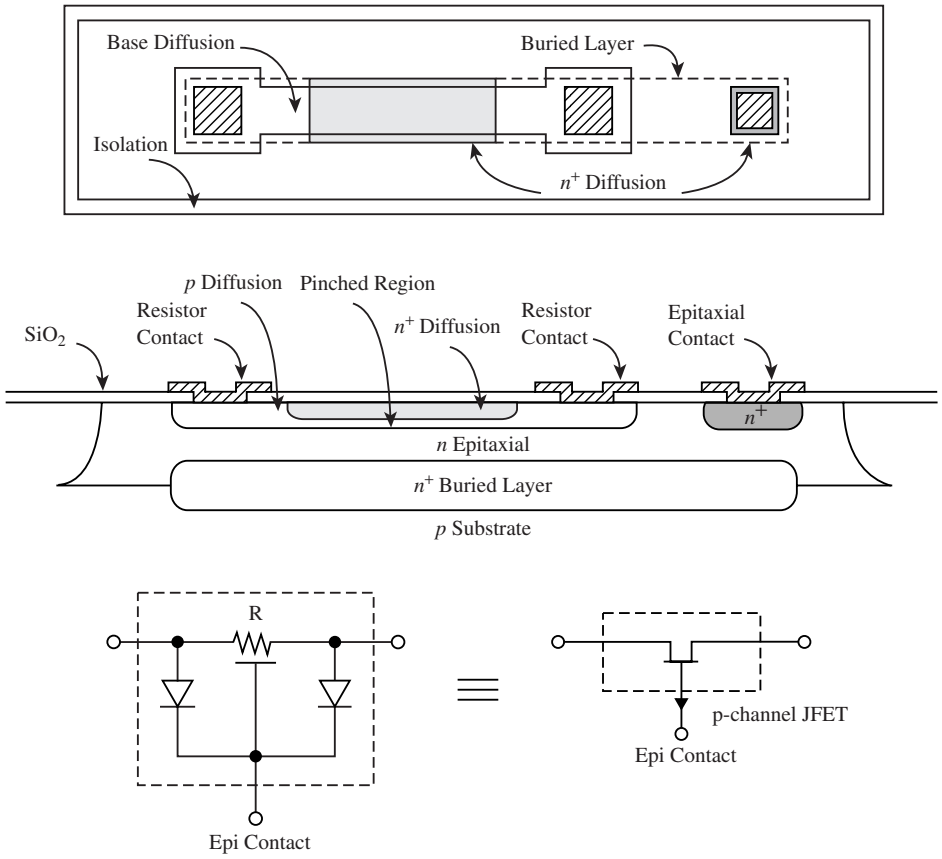

FIGURE 55.66 p-type base-pinched resistor.

Ion-Implanted Resistors

Ion implantation is an alternative technique beside diffusion for inserting impurity atoms into a silicon wafer [17]. Commonly used impurities for implantation are the p-type boron atoms. The desired impurity atoms are first ionized and then accelerated to a high energy by an electric field. When a beam of these high-energy ions is directed at the wafer, the ions penetrate into exposed regions of the wafer surface. The penetration depth depends on the velocity at contact and is typically between 0.1 and 0.8 μm. The exposed regions of the wafer surface are defined by selectively etching a thick thermally grown SiO_2 layer that covers the wafer and functions as a barrier against the implanted ions. Unique characteristics of the ion-implantation technique include a precise control of the impurity concentration, uniformly implanted layers of impurity atoms, and no lateral diffusion. The structure of a p-type ion-implanted resistor is shown in Fig. 55.68, where the p-type diffused regions at the contacts are used to achieve good ohmic contacts to the implanted resistor. The pn junction formed between the p-type implanted region and the n-type epitaxial layer must be reverse biased for electrical isolation. By connecting the epi region to a potential relatively more positive than the substrate potential, the conductive action due to the parasitic pnp transistor formed by the p-type implanted, the n-type epi, and the p-type substrate is also eliminated. Ion-implanted resistors exhibit relatively tight absolute value tolerance and excellent matching. Absolute value tolerance down to ±3 percent and matching tolerance of ±2 percent are typical performance.

Table 55.6 provides a summary of the typical characteristics for the diffused, pinched, epitaxial, and ion-implanted resistors.

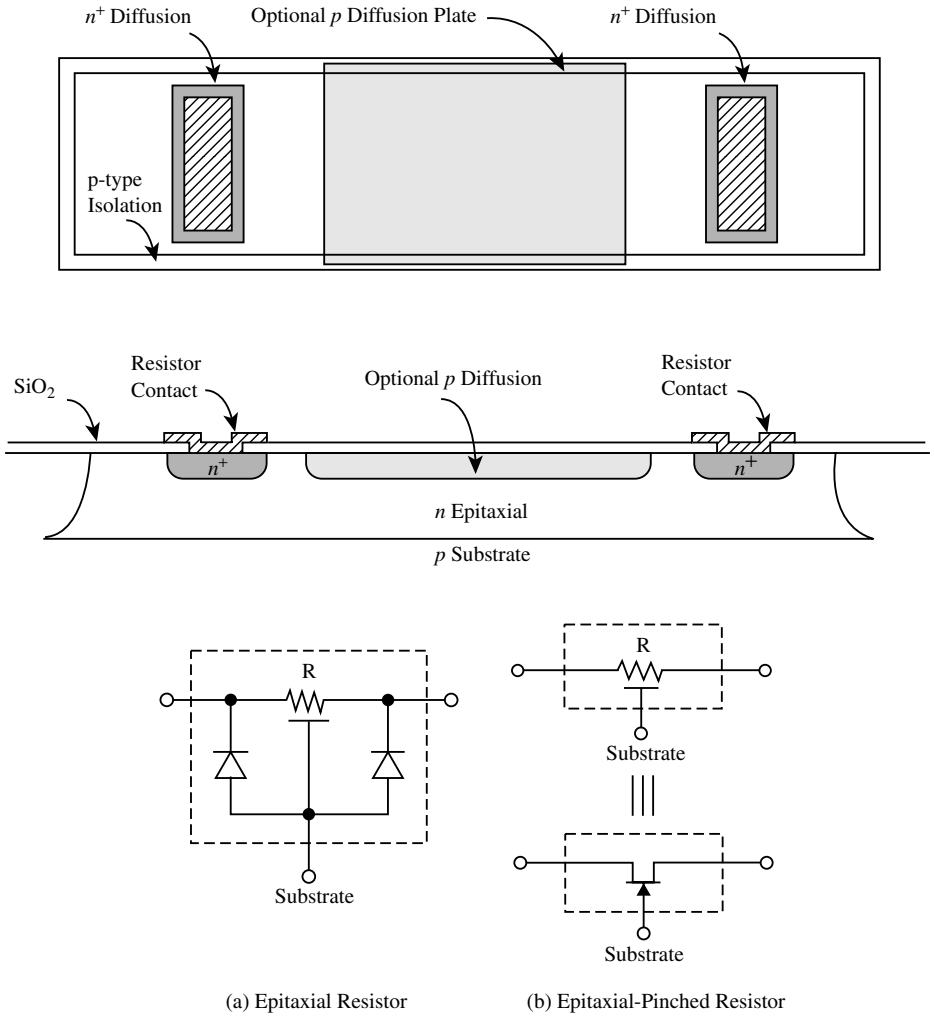

FIGURE 55.67 n-type epitaxial and epitaxial-pinched resistors.

Thin-Film Resistors

Compared with diffused resistors, thin-film resistors offer advantages of a lower temperature coefficient, a smaller absolute value variation, and an excellent high-frequency characteristic. Commonly used resistive thin films are tantalum, nickel–chromium (Ni–Cr), cermet (Cr–SiO), and tin oxide (SnO_2). A typical thin-film resistor structure is shown in Fig. 55.69, where a thin-film resistive layer is deposited on top of a thermally grown SiO_2 layer and a thin-film conductive metal layer is used to form the resistor contacts. The oxide layer functions as an insulating layer for the reistor. Various CVD (chemical vapor deposition) techniques can be used to form the thin films [8]. The oxide passivation layer deposited on top of the resistive film and the conductive film protects the device surface from contamination. The electrical lumped model as shown in Fig. 55.69 is adequate to characterize the high-frequency performance of the resistor. The parallel-plate capacitance formed between the thin-film resistive and the substrate is divided equally between the two capacitors. Table 55.7 provides a summary of the characteristics for some commonly used thin-film resistors.

Capacitors

Monolithic capacitors are widely used in analog and digital integrated circuits for functions such as circuit stability, bandwidth enhancement, ac signal coupling, impedance matching, and charge storage cells. Capacitor structures available in monolithic form include pn junction, MOS, and polysilicon capacitors. pn junctions under reverse-biased conditions exhibit a nonlinear voltage-dependent capacitance. MOS and polysilicon capacitors, on the other hand, closely resemble the linear parallel-plate capacitor structure as shown in Fig. 55.70. If the insulator thickness T of the parallel-plate structure is small compared with the plate width W and length L, the electric field between the plates is uniform (fringing field neglected). Under this condition the capacitance can be calculated by

$$C = \frac{\kappa\varepsilon_0}{T} WL \tag{55.155}$$

where κ is the relative dielectric constant of the insulating material and ε_0 is the permittivity constant in vacuum (8.854×10^{-14} F/cm).

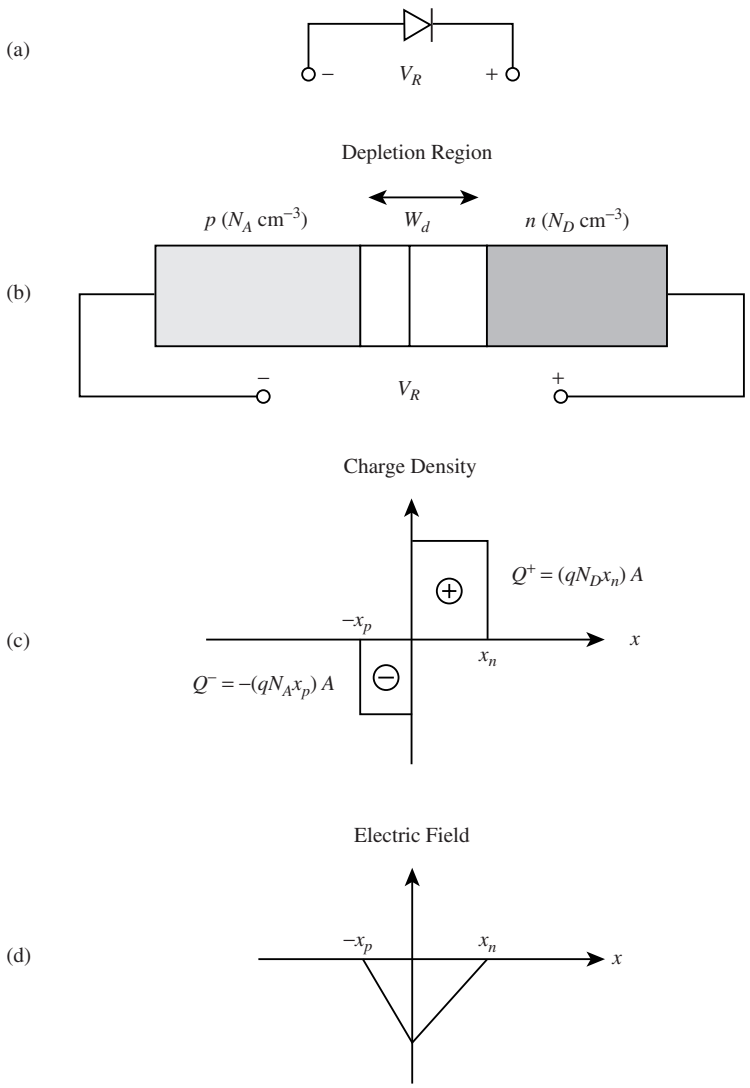

FIGURE 55.71 Abrupt p–n junction: (a) p–n junction symbol; (b) depletion region; (c) charge density within the depletion region; (d) electric field.

Junction Capacitors

The structure of an *abrupt* pn junction is shown in Fig. 55.71, where the doping is assumed uniform throughout the region on both sides. The acceptor impurity concentration of the p region is N_A atoms/cm^3 and the donor impurity concentration of the n region is N_D atoms/cm^3. When the two regions are brought in contact, mobile holes from the p region diffuse across the junction to the n region and mobile electrons diffuse from the n to the p region. This diffusion process creates a *depletion* region that is essentially free of mobile carriers (*depletion approximation*) and contains only fixed acceptor and donor ions. Ionized acceptor atoms are negatively charged and ionized donor atoms are positively charged. In equilibrium the diffusion process is balanced out by a drift process that arises from a *built-in* voltage ψ_o across the junction. This voltage is positive from the n region relative to the p region and is given by [17]

$$\psi_o = \frac{kT}{q} \ln \frac{N_A N_D}{n_i^2} \tag{55.156}$$

© 2003 by CRC Press LLC

where k is the Boltzmann constant (1.38×10^{-23} V · Coulomb/K), T is the temperature in Kelvin (K), q is the electron charge (1.60×10^{-19} C), and n_i (cm^{-3}) is the *intrinsic* carrier concentration in a pure semiconductor sample. For silicon at 300 K, $n_i \approx 1.5 \times 10^{10}$ cm^{-3}.

When the pn junction is subject to an applied reverse bias voltage V_R, the drift process is augmented by the external electric field and more mobile electrons and holes are pulled away from the junction. Because of this effect, the depletion width W_d and consequently the charge Q on each side of the junction vary with the applied voltage. A junction capacitor can thus be defined to correlate this charge–voltage relationship. The Poisson's equation relating the junction voltage $\phi(x)$ to the electric field $\xi(x)$ and the total charge Q is

$$\frac{d^2\phi(x)}{dx^2} = -\frac{d\xi(x)}{dx} = -\frac{q}{\varepsilon_S}\left(p - n + N_D - N_A\right) \tag{55.157}$$

$$\approx \begin{cases} \dfrac{qN_A}{\varepsilon_S} & -x_p < x < 0 \\ -\dfrac{qN_D}{\varepsilon_S} & 0 < x < x_n \end{cases}$$

where ε_S ($11.8\varepsilon_0 = 1.04 \times 10^{-12}$ F/cm) is the permittivity of the silicon material. The first intergral of (55.157) yields the electric field as

$$\xi(x) = \begin{cases} -\dfrac{qN_A}{\varepsilon_S}\left(x + x_p\right) & -x_p < x < 0 \\ -\dfrac{qN_D}{\varepsilon_S}\left(x_n + x\right) & 0 < x < x_n \end{cases} \tag{55.158}$$

The electric field is shown in Fig. 55.71, where the maximum field strength occurs at the junction edge. This value is given by

$$\left|\xi_{\max}\right| = \frac{qN_A}{\varepsilon_S}x_p = \frac{qN_D}{\varepsilon_S}x_n$$

The partial depletion width x_p on the p region and the partial depletion width x_n on the n region can then be related to the depletion width W_d as

$$x_p + x_n = W_d$$

$$x_p = \frac{N_D}{N_A + N_D}W_d$$

$$x_n = \frac{N_A}{N_A + N_D}W_d$$

Taking the second integral of (55.157) yields the junction voltage

$$\phi(x) = \begin{cases} \dfrac{qN_A}{\varepsilon_S}\left(\dfrac{x_p^2}{2} + x_p x + \dfrac{x^2}{2}\right) & -x_p < x < 0 \\ \dfrac{qN_D}{\varepsilon_S}\left(\dfrac{x_n x_p}{2} + x_n x - \dfrac{x^2}{2}\right) & 0 < x < x_n \end{cases} \tag{55.159}$$

where the voltage at x_p is arbitrarily assigned to be zero. The total voltage $\psi_0 + V_R$ can be expressed as

© 2003 by CRC Press LLC

$$\psi_o + V_R = \phi(x_n) = \frac{qN_D}{2\varepsilon_S}\left(1 + \frac{N_D}{N_A}\right)x_n^2$$

Finally, the depletion width W_d and the total charge Q in terms of the total voltage across the junction can be derived to be

$$W_d = \left[\frac{2\varepsilon_S}{q}(\psi_o + V_R)\left(\frac{1}{N_A} + \frac{1}{N_D}\right)\right]^{1/2} \tag{55.160}$$

$$|Q| = A(qN_A x_p) = A(qN_D x_n) = A\left[2q\varepsilon_S(\psi_o + V_R)\left(\frac{1}{N_A} + \frac{1}{N_D}\right)^{-1}\right]^{1/2}$$

The junction capacitance is thus

$$\begin{aligned} C_j &= \left|\frac{dQ}{dV_R}\right| = A\left[\frac{q\varepsilon_S}{2}\left(\frac{1}{\psi_o + V_R}\right)\left(\frac{1}{N_A} + \frac{1}{N_D}\right)^{-1}\right]^{1/2} \\ &= \frac{C_{jo}}{\left(1 + \dfrac{V_R}{\psi_o}\right)^{1/2}} \end{aligned} \tag{55.161}$$

where A is the effective cross-sectional junction area and C_{jo} is the value of C_j for $V_R = 0$. If the doping concentration in one side of the pn junction is much higher than that in the other, the depletion width and the junction capacitance can be simplified to

$$W_d = \left[\frac{2\varepsilon_S}{qN_L}(\psi_o + V_R)\right]^{1/2} \tag{55.162}$$

$$C_j = A\left[\frac{\varepsilon_S qN_L}{2}\left(\frac{1}{\psi_o + V_R}\right)\right]^{1/2} \tag{55.163}$$

where N_L is the concentration of the lightly doped side. Figure 55.72 displays the junction capacitance per unit area as a function of the total voltage $\psi_o + V_R$ and the concentration on the lightly doped side of the junction [3].

In silicon bipolar technology the base–emitter, the base–collector, and the collector–substrate junctions under reverse bias are often utilized for realizing a junction capacitance. The collector–substrate junction has only a limited use since it can only function as a shunt capacitor due to the substrate being connected to an ac ground.

Base–Collector Junction Capacitor. A typical base–collector capacitor structure is shown in Fig. 55.73 together with an equivalent lumped circuit model. A heavily doped n^+ buried layer is used to minimize the series resistance R_C. For the base–collector junction to operate in reverse bias, the n-type collector must be connected to a voltage relatively higher than the voltage at the p-type base. The junction breakdown voltage is determined by BV_{CBO} of the npn transistor, which has a typical value between 25 and 50 V.

© 2003 by CRC Press LLC

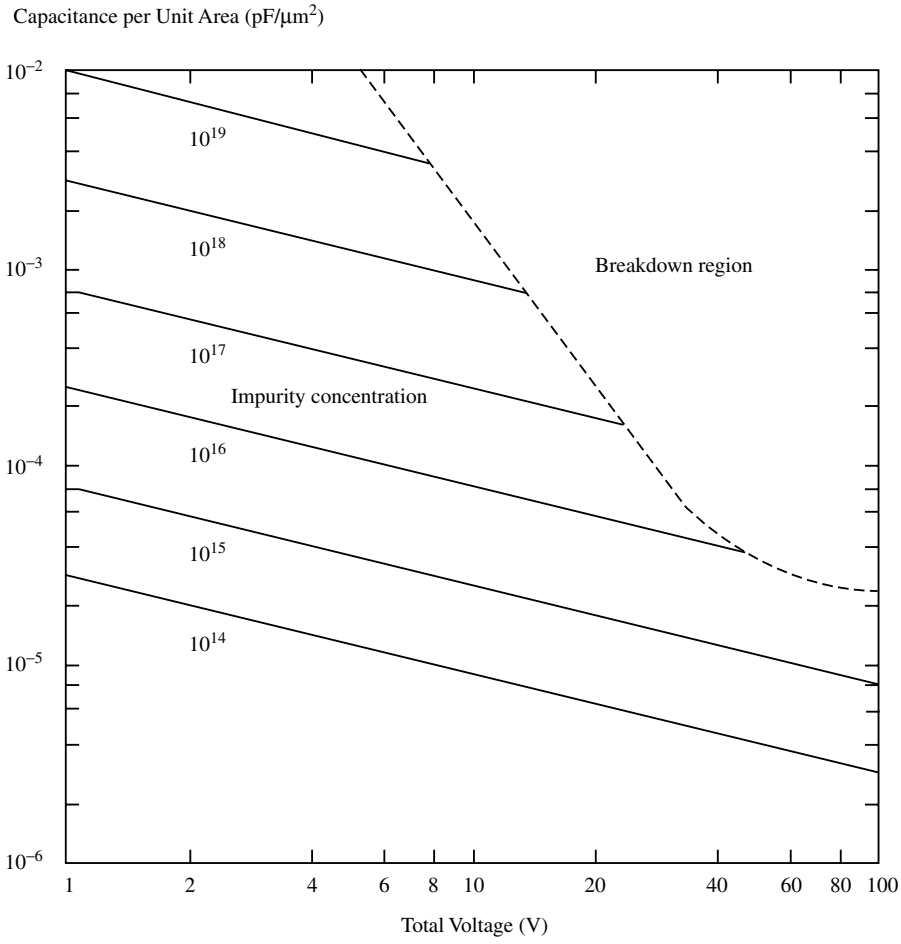

FIGURE 55.72 Junction capacitance as a function of the total voltage and the concentration on the lightly doped side.

Base–Emitter Junction Capacitor. Figure 55.74 shows a typical base–emitter capacitor structure where the parasitic junctions D_{BC} and D_{SC} must always be in reverse bias. The base–emitter junction achieves the highest capacitance per unit area among the base–collector, base–emitter, and collector–substrate junctions due to the relatively higher doping concentrations in the base and emitter regions. For the base–emitter junction to operate in reverse bias, the n-type emitter must be connected to a voltage relatively higher than the voltage at the p-type base. The breakdown voltage of the base–emitter junction is relatively low, determined by the BV_{EBO} of the npn transistor, which has a typical value of about 6 V.

MOS Capacitors

MOS (metal-oxide-semiconductor) capacitors are preferable and commonly used in integrated circuits since they are linear and not confined to a reverse-biased operating condition as in the junction capacitors. The structure of a MOS capacitor is shown in Fig. 55.75, where by means of a local oxidation process a thin oxide layer is thermally grown on top of a heavily doped n^+ diffusion layer. The oxide layer has a typical thickness between 500 and 1500 Å (Å = 10^{-10} m = 10^{-4} μm) and functions as the insulating layer of the parallel-plate capacitor. The top plate is formed by overlapping the thin oxide area with a deposited layer of conductive metal. The bottom-plate diffusion layer is heavily doped for two reasons: to minimize the bottom-plate resistance and to minimize the depletion width at the oxide-semiconductor interface when the capacitor operates in the *depletion* and *inversion* modes [17]. By keeping the depletion width

© 2003 by CRC Press LLC

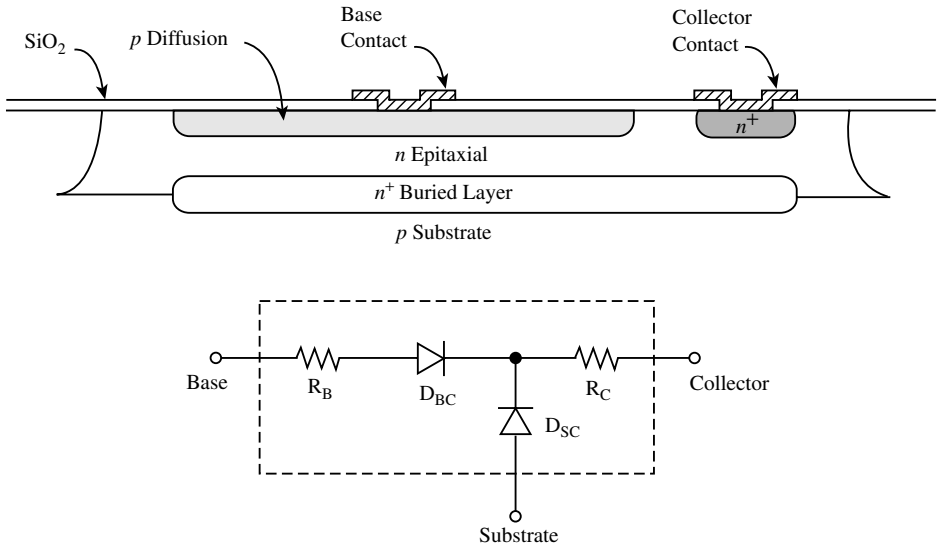

FIGURE 55.73 Base–collector junction capacitor.

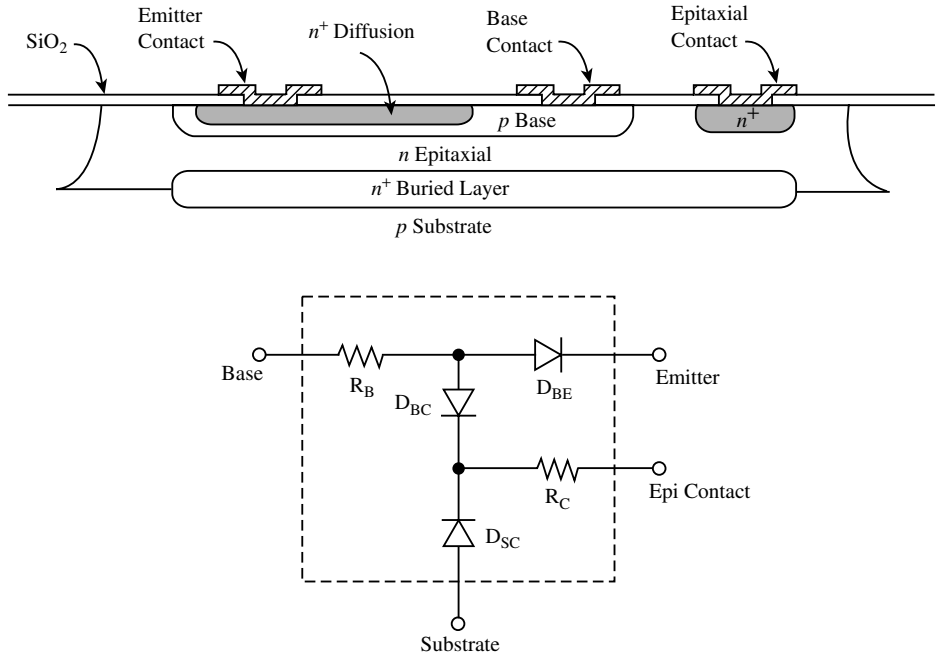

FIGURE 55.74 Base–emitter junction capacitor.

small, the effective capacitance is dominated by the parallel-plate oxide capacitance. The MOS capacitance is thus given by

$$C = \frac{\kappa_{ox}\varepsilon_0}{T} A \tag{55.164}$$

where κ_{ox} is the relative dielectric constant of SiO_2 (2.7 to 4.2), ε_0 is the permittivity constant, T is the oxide thickness, and A is the area defined by the thin oxide layer.

© 2003 by CRC Press LLC

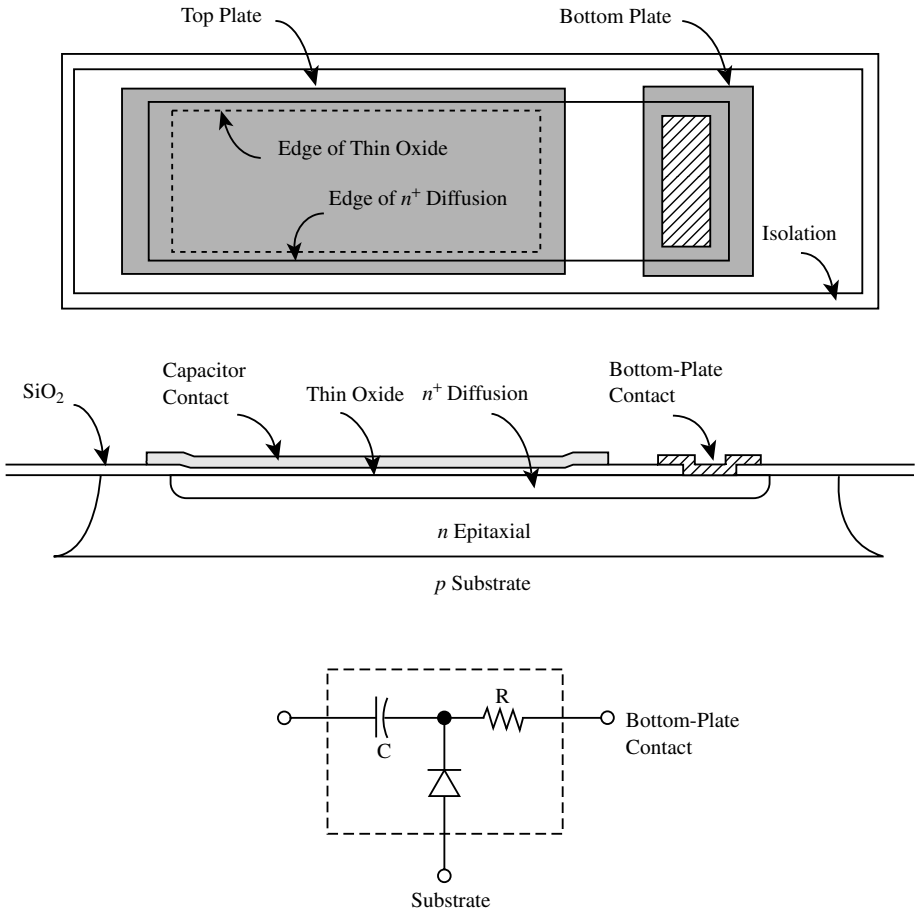

FIGURE 55.75 MOS capacitor.

In practice, a thin layer of silicon nitride ($Si_3 N_4$) is often deposited on the thin oxide layer and is used to minimize the charges inadvertently introduced in the oxide layer during oxidation and subsequent processing steps. These *oxide charges* are trapped within the oxide and can cause detrimental effect to the capacitor characteristic [17]. The silicon nitride assimilates an additional insulating layer and effectively creates an additional capacitor in series with the oxide capacitor. The capacitance for such a structure can be determined by an application of *Gauss's law*. It is given by

$$C = \frac{\varepsilon_o}{\left(\frac{T_{ni}}{\kappa_{ni}}\right) + \left(\frac{T_{ox}}{\kappa_{ox}}\right)} A \tag{55.165}$$

where T_{ni} and T_{ox} are the thickness of the silicon nitride and oxide layers, respectively, and κ_{ni} (2.7 to 4.2) and κ_{ni} (3.5 to 9) are the relative dielectric constant of oxide and silicon nitride, respectively. In the equivalent circuit model of Fig. 55.75, the parasitic junction between the p-type substrate and the n-type bottom plate must always be reverse biased. The bottom-plate contact must be connected to a voltage relatively higher than the substrate voltage.

Polysilicon Capacitors

Polysilicon capacitors are conveniently available in MOSFET technology, where the gate of the MOSFET transistor is made of polysilicon material. Polysilicon capacitors also assimilate the parallel-plate capacitor.

© 2003 by CRC Press LLC

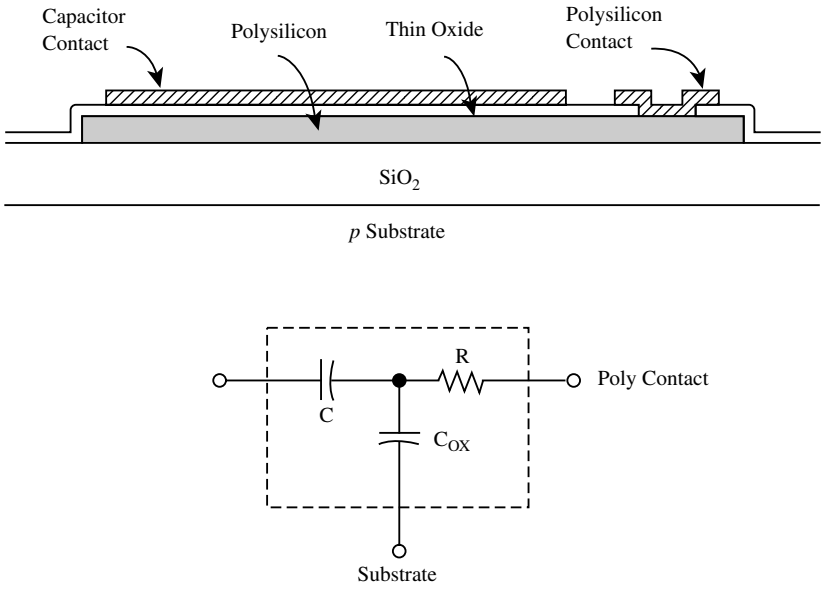

FIGURE 55.76 Polysilicon capacitor.

Figure 55.76 shows a typical structure of a polysilicon capacitor, where a thin oxide is deposited on top of a polysilicon layer and serves as an insulating layer between the top-plate metal layer and the bottom-plate polysilicon layer. The polysilicon region is isolated from the substrate by a thick oxide layer that forms a parasitic parallel-plate capacitance between the polysilicon layer and the substrate. This parasitic capacitance must be accounted for in the equivalent circuit model. The capacitance of the polysilicon capacitor is determined by either (55.164) or (55.165) depending on whether a thin silicon nitride is used in conjunction with the thin oxide.

Inductors

Planar inductors have been implemented using a variety of substrates such as standard PC boards, ceramic and sapphire hybrids, monolithic GaAs [24], and more recently monolithic silicon [18]. In the early development of silicon technology, planar inductors were investigated [26], but the prevailing lithographic limitations and relatively large inductance requirements (for low-frequency applications) resulted in excessive silicon area and poor performance. Reflected losses from the conductive silicon substrate were a major contribution to low inductor *Q*. Recent advances in silicon IC processing technology have achieved fabrication of metal width and metal spacing in the low micrometer range and thus allow many more inductor turns per unit area. Also, modern oxide-isolated processes with multilayer metal options allow thick oxides to help isolate the inductor from the silicon substrate. Practical applications of monolithic inductors in low-noise amplifiers, impedance matching amplifiers, filters and microwave oscillators in silicon technologies have been successfully demonstrated [19], [20].

Monolithic inductors are especially useful in high-frequency applications where inductors of a few nano-Henrys of inductance are sufficient. Inductor structures in monolithic form include strip, loop, and spiral inductors. Rectangular and circular spiral inductors are by far the most commonly used structures.

Rectangular Spiral Inductors

The structure of a rectangular spiral inductor is shown in Fig. 55.77, where the spiral loops are formed with the top metal layer M_2 and the connector bridge is formed with the bottom metal layer M_1. Using the top metal layer to form the spiral loops has the advantage of minimizing the parasitic metal-to-substrate capacitance. The metal width is denoted by W and the metal spacing is denoted by S. The total inductance is given by

© 2003 by CRC Press LLC

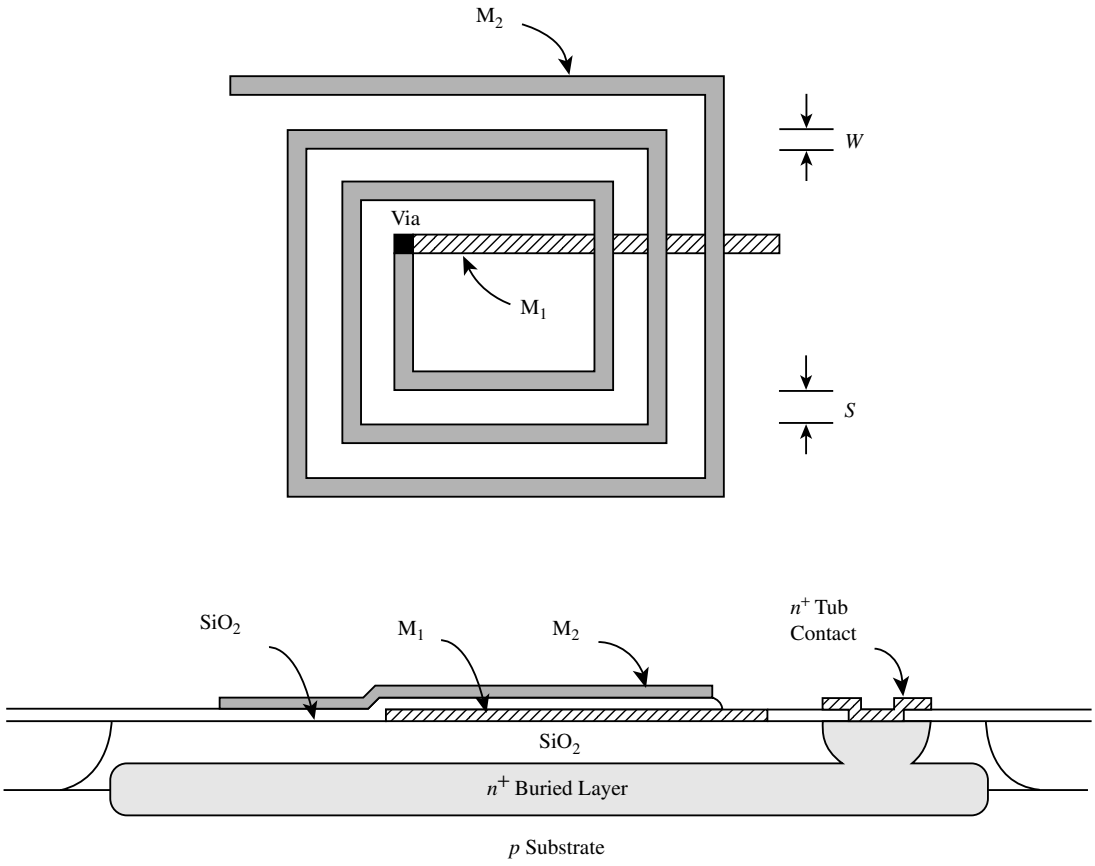

FIGURE 55.77 Rectangular spiral inductor.

$$L_T = \sum_{i=1}^{4N} L_S(i) + 2 \cdot \sum_{i=1}^{4N-1} \sum_{j=i+1}^{4N} L_M(ij) \tag{55.166}$$

where N is the number of turns, $L_s(i)$ is the *self inductance* of the rectangular metal segment i and $L_M(ij)$ is the *mutual inductance* between metal segments i and j. The self-inductance is due to the magnetic flux surrounding each metal segment. The mutual inductance is due to the magnetic flux coupling around every two parallel metal segments and has a positive value if the currents applied to the metal conductors flow in the same direction and a negative value otherwise. Perpendicular metal segments have negligible mutual inductance.

The self-inductance and mutual inductance for straight rectangular conductors can be determined by the *geometric mean distance* method [10], in which the conductors are replaced by equivalent straight filaments whose basic inductive characteristics are well known.

Self-Inductance. The self-inductance for the rectangular conductor of Fig. 55.78 depends on the conductor length L, the conductor width W, and the conductor thickness T. The static self-inductance is given by [9], [10].

$$L_S = 2L\left[\ln\left(\frac{2L}{GMD}\right) - 1.25 + \left(\frac{AMD}{L}\right) + \left(\frac{\mu_r}{4}\right)\zeta\right](\text{nH}) \tag{55.167}$$

© 2003 by CRC Press LLC

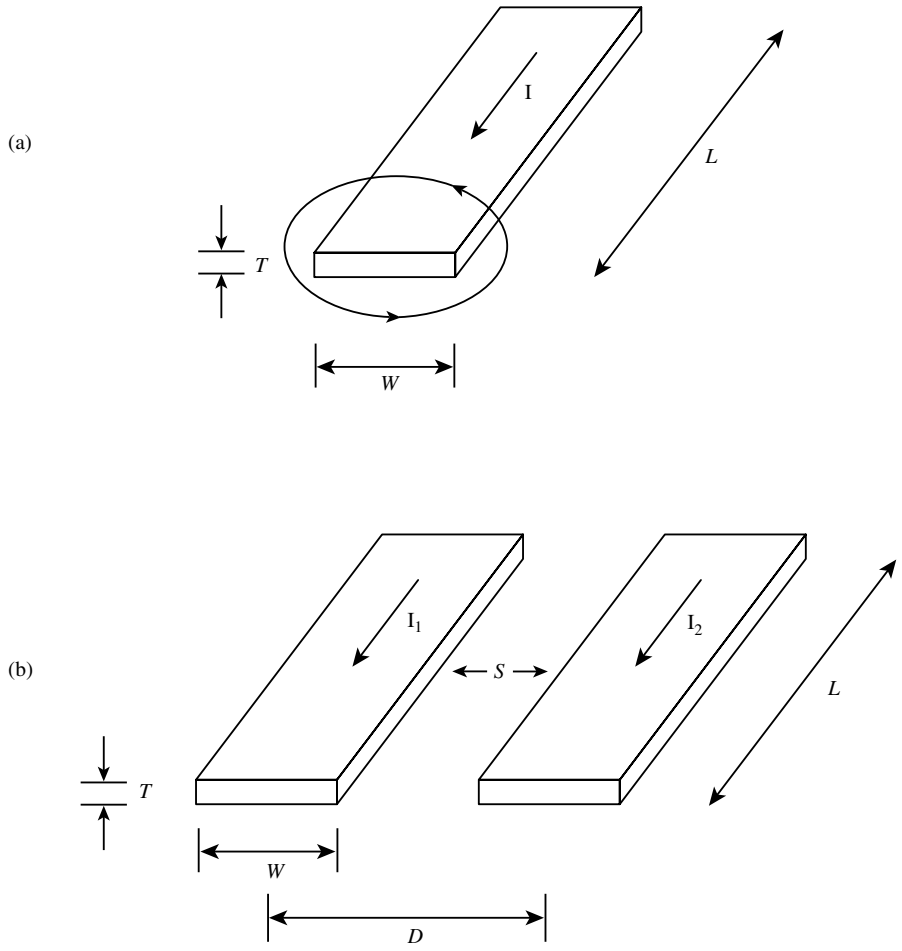

FIGURE 55.78 Calculation of (a) self-inductance and (b) mutual inductance for parallel rectangular conductors.

where μ_r is the relative permeability constant of the conductor, *GMD* is the geometric mean distance, *AMD* is the arithmetic mean distance, and ζ is a frequency-dependent parameter that equals 1 for direct and low-frequency alternating currents and approaches 0 for very high-frequency alternating currents. The *AMD* and *GMD* for the rectangular conductor of Fig. 55.78 are

$$AMD = \left(\frac{W+T}{3}\right)$$

$$GMD = \begin{cases} 0.22313 \cdot (W+T) & T \to 0 \\ 0.22360 \cdot (W+T) & T = W/2 \\ 0.223525 \cdot (W+T) & T \to W \end{cases} \tag{55.168}$$

The rectangular dimensions *L*, *W*, and *T* are normalized to the centimeter in the preceding expressions.

Mutual Inductance. The mutual inductance for the two parallel rectangular conductors of Fig. 55.78 depends on the conductor length *L*, the conductor width *W*, and the conductor thickness *T*, and the distance *D* separating the conductor centers. The static mutual inductance is [10]

© 2003 by CRC Press LLC

$$L_M = 2L\alpha(\text{nH}) \tag{55.169}$$

where

$$\alpha = \ln\left[\left(\frac{L}{GMD}\right)+\left[1+\left(\frac{L}{GMD}\right)^2\right]^{1/2}\right]-\left[1+\left(\frac{GMD}{L}\right)^2\right]^{1/2}+\left(\frac{GMD}{L}\right)$$

and

$$GMD = \exp(\ln D - \beta) \tag{55.170}$$

$$\beta = \begin{cases} \dfrac{1}{12}\left(\dfrac{D}{W}\right)^{-2}+\dfrac{1}{60}\left(\dfrac{D}{W}\right)^{-4}+\dfrac{1}{168}\left(\dfrac{D}{W}\right)^{-6}+\dfrac{1}{360}\left(\dfrac{D}{W}\right)^{-8} \\ \quad +\dfrac{1}{660}\left(\dfrac{D}{W}\right)^{-10}+\cdots \\ 0.1137 \quad \text{for} \quad D = W \end{cases}$$

The GMD closed-form expression (55.170) is valid for rectangular conductors with small thickness-to-width ratios T/W. As the thickness T approaches the width W, the GMD approaches the distance D and the GMD is no longer represented by the above closed-form expression. Figure 55.79 shows plots of the self inductance and the mutual inductance as expressed in (55.167) and (55.169), respectively. The conductor dimensions are given in μm (μm = 10^{-4} cm).

For the inductor structure of Fig. 55.77 it is important to emphasize that since the spiral loops are of nonmagnetic metal material, the total inductance depends only on the geometry of the conductors and not on the current strength. At high-frequencies, especially those above the *self-resonant* frequency of the inductor, the *skin effect* due to current crowding toward the surface and the propagation delay as the current traverses the spiral must be fully accounted for [16], [22]. The ground-plane effect due to the inductor image must also be considered regardless of the operation frequency.

An equivalent lumped model for the rectangular spiral inductor of Fig. 55.77 is shown in Fig. 55.80. This model consists of the total inductance L_T, the accumulated metal resistance R_S, the coupling capacitance C_{CP} between metal segments due to the electric fields in both the oxide region and the air region, the parasitic capacitances C_{IN} and C_{OUT} from the metal layers to the buried layer [2], [11], [15], and the buried-layer resistance R_p. Since the spiral structure of Fig. 55.77 is not symmetrical, the parasitic capacitors C_{IN} and C_{OUT} are not the same, though the difference is relatively small. The self-resonant frequency can be approximated using the circuit model of Fig. 55.80 with one side of the inductor being grounded. For simplicity, let $C_{\text{IN}} = C_{\text{OUT}} \equiv C_P$ and neglect the relatively small coupling capacitor C_{CP}, the self-resonant frequency is given by

$$f_R = \frac{1}{2\pi}\frac{1}{\sqrt{L_T C_P}}\left[\frac{1-R_S^2\left(\dfrac{C_P}{L_T}\right)}{1-R_P^2\left(\dfrac{C_P}{L_T}\right)}\right]^{1/2} \tag{55.171}$$

Transformer Structures. Transformers are often used in high-performance analog integrated circuits that require conversions between single-ended signals and differential signals. In monolithic technology, transformers can be fabricated using the basic structure of the rectangular spiral inductor. Figure 55.81 shows a planar interdigitated spiral transformer that requires only two metal layers M_1 and M_2. The

structure of Fig. 55.82, on the other hand, requires three layers of metal for which the top metal layer M_3 is used for the upper spiral, the middle metal layer M_2 is used for the lower spiral, and the bottom metal layer M_1 is used for the two connector bridges. This structure can achieve a higher inductance per unit than that of Fig. 55.81 due to a stronger magnetic coupling between the upper spiral and the lower spiral through a relatively thin oxide layer separating metal layers M_2 and M_3. An equivalent lumped

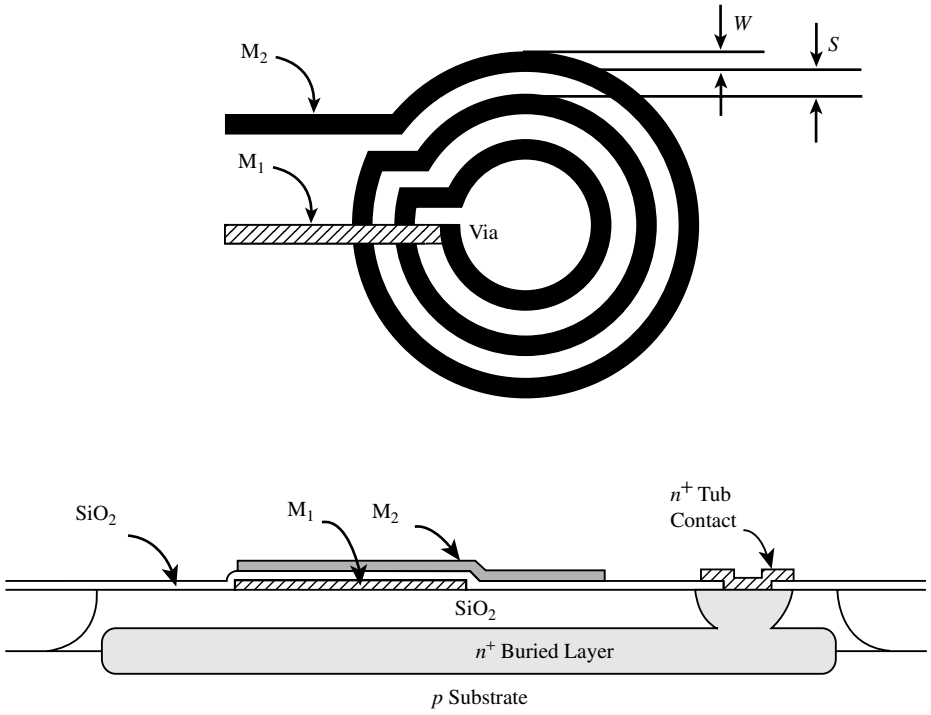

FIGURE 55.84 Concentric circular spiral inductor.

model is shown in Fig. 55.83. In addition to all the circuit elements of the two individual spiral inductors, there are also a magnetic coupling factor k and a coupling capacitance C_C between the primary and secondary coils.

Circular Spiral Inductors

The structure of a concentric circular spiral inductor is shown in Fig. 55.84 where the circular loops share the same center point. The top metal layer M_2 is used for the circular conductors and the bottom metal layer M_1 is used for the connector bridge. The metal width is denoted by W and the spacing between two adjacent loops is denoted by S. The total inductance is given by

$$L_T = \sum_{i=1}^{N} L_S(i) + 2 \cdot \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} L_M(ij) \tag{55.172}$$

where N is the number of circular turns, L_S(i) is the *self-inductance* of the circular conductor i and $L_M(ij)$ is the *mutual inductance* between conductors i and j.

Self-Inductance. Consider the single circular conductor of Fig. 55.85(a) that has a radius R and a width W. A current I applied to this conductor produces a magnetic flux encircled by the loop and another magnetic flux inside the conductor itself. The inductance associated with the former and the latter magnetic flux component is referred to as the *external* self-inductance and the *internal* self-inductance, respectively. The external self-inductance characterizing the change in the encircled magnetic flux to the change in current is [25].

$$L_S = \mu(2R - \delta)\left[\left(1 - \frac{k^2}{2}\right)K(k) - E(k)\right] \text{(nH)} \tag{55.173}$$

© 2003 by CRC Press LLC

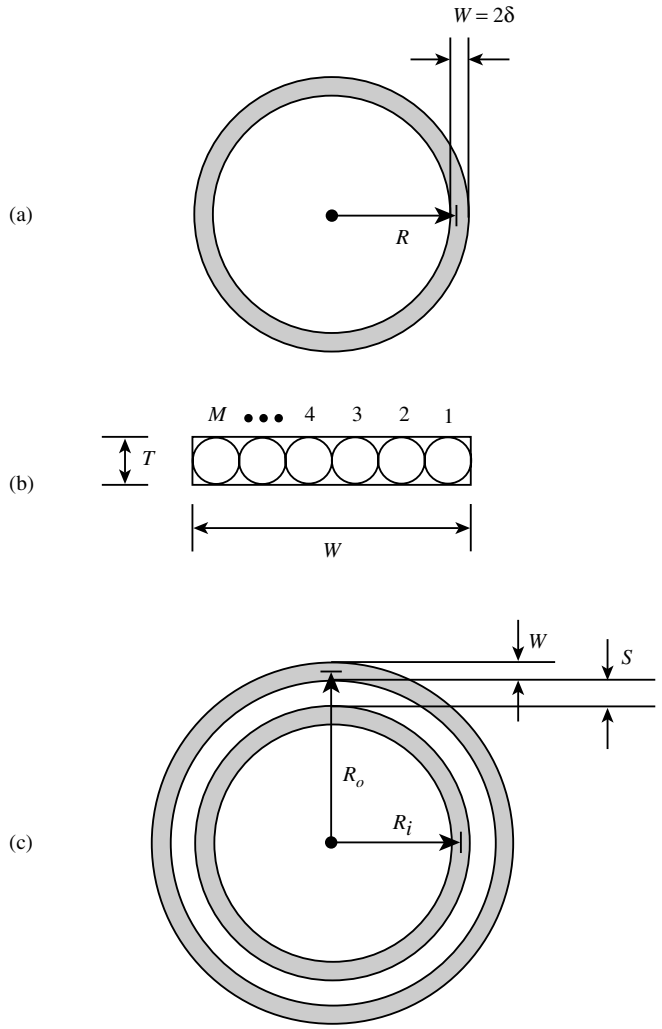

FIGURE 55.85 Calculation of self-inductance and mutual inductance for circular conductors. (a) External self-inductance; (b) internal self-inductance; (c) mutual inductance.

where

$$k^2 = \frac{4R(R-\delta)}{(2R-\delta)^2} \tag{55.174}$$

and μ is the permeability of the conductor (equals 4π nH/cm for nonmagnetic conductors), and δ is one-half the conductor width *W*. $K(k)$ and $E(k)$ are the *complete elliptic integrals* of the first and second kind, respectively, and are given by

$$K(k) = \int_0^{\pi/2} \frac{d\phi}{\sqrt{1-k^2\sin^2\phi}}$$

$$E(k) = \int_0^{\pi/2} \sqrt{1-k^2\sin^2\phi}\, d\phi$$

© 2003 by CRC Press LLC

The internal self-inductance is determined based on the concept of magnetic field energy. As shown in Fig. 55.85(b), the flat circular conductor is first approximated by an M number of round circular conductors [14] that are electrically in parallel and each conductor has a diameter equal to the thickness T of the flat conductor. The internal self-inductance of each round conductor is then determined as [25].

$$L = \frac{\mu}{8\pi}(\text{nH/cm})$$

The internal self-inductance of the flat conductor thus equals the parallel combination of these M components

$$L_S \approx \frac{\mu}{4}\left\{\sum_{i=1}^{M}\left[R - \delta + T(i-0.5)\right]^{-1}\right\}^{-1} \quad (\text{nH}) \tag{55.175}$$

where $R - \delta + T(i - 0.5)$ is the effective radius from the center of the loop to the center of the round conductor i. The typical contribution from the internal self-inductance of (55.175) is less than 5% the contribution from the external self-inductance of (55.173).

Mutual Inductance. The mutual inductance of the two circular loops of Fig. 55.85(c) depends on the inner radius R_i and the outer radius R_o. For any two adjacent loops of the circular spiral inductor, the outer radius is related to the inner radius by the simple relation $R_o = R_i + (W + S)$. The mutual inductance is determined based on the *Neumann's* line integral given as follows:

$$L_M = \frac{\mu}{4\pi}\int_C\int_C \frac{d\mathbf{l}_1 \cdot d\mathbf{l}_2}{D}$$

where $d\mathbf{l}_1 \cdot d\mathbf{l}_2$ represents the dot product of the differential lengths and D is the distance separating the differential l_1 vector and l_2 vector. The static mutual inductance [25] is

$$L_M = \mu\sqrt{R_i R_o}\left[\left(\frac{2}{k} - k\right)K(k) - \frac{2}{k}E(k)\right] \quad (\text{nH}) \tag{55.176}$$

where

$$k^2 = \frac{4R_iR_o}{(R_i + R_o)^2} \tag{55.177}$$

Fig. 55.86 shows plots of the external self-inductance and the mutual inductance as expressed in (55.173) and (55.176), respectively. The conductor dimensions are given in μm.

As in the rectangular spiral inductor, the ground-plane effect and the retardation effect of the circular spiral inductor must be fully accounted for. The circuit model of Fig. 55.80 can be used to characterize the electrical behavior of the circular inductor.

A comparison between the rectangular spiral of Fig. 55.77 and the circular spiral of Fig. 55.84 is shown in Fig. 55.87, where the total inductance L_T is plotted against the turn number N. Both inductors have the same innermost dimension, the same conductor width, space, and thickness. The dimensions are given in μm, and the ground-plane effect and the retardation effect are not considered. For a given turn number, the rectangular spiral yields a higher inductance per semiconductor area than the circular spiral. Figure 55.88 shows a plot of the inductor Q vs. the total inductance of the same spiral inductors under consideration. Due to a higher inductance per length ratio, the Q of the circular inductor is higher than that of the rectangular inductor, about 10 percent for high inductance values.

55.5 Chip Parasitics in Analog Integrated Circuits

Martin A. Brooke

The parasitic elements in electronic devices and interconnect limit the performance of all integrated circuits. No amount of improvement in device performance or circuit design can completely eliminate these effects. Thus, as circuit speeds increase, unaccounted for interconnect parasitics become a more and more common cause of analog integrated circuit design failure. Hence, the causes, characterization, and modeling of significant interconnect parasitics are essential knowledge for good analog integrated circuit design [1]–[4].

Interconnect Parasitics

The parasitics due to the wiring used to connect devices together on chip produce a host of problems. Unanticipated feedback through parasitic capacitances can cause unwanted oscillation. Mismatch due to differences in interconnect resistance contribute to unwanted offset voltages. For very-high-speed integrated circuits, the inductance of interconnects is both a useful tool and a potential cause of yield problems.

Even the interactions between interconnect lines are both important and very difficult to model. So too are the distributed interactions of resistance, capacitance, and (in high-speed circuits) inductance that produce transmission line effects.

Parasitic Capacitance

Distributed capacitance of integrated circuit lines is perhaps the most important of all integrated circuit parasitics. It can lower the bandwidth of amplifiers, alter the frequency response of filters, and cause oscillations.

Physics. Every piece of integrated circuit interconnect has capacitance to the substrate. In the case of silicon circuitry, the substrate is conductive and connected to an ac ground, thus there is a capacitance to ground from every circuit node due to the interconnect. Figure 55.89 illustrates this substrate capacitance interconnect parasitic. The capacitance value will depend on the total area of the interconnect, and on the length of edge associated with the interconnect. This edge effect is due to the nonuniformity

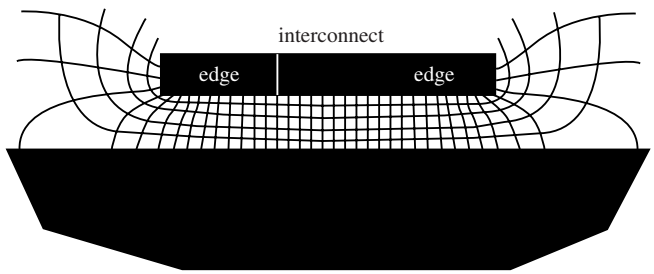

FIGURE 55.89 Substrate capacitance. The electric field distorts at the edges, making the capacitance larger there than elsewhere.

© 2003 by CRC Press LLC

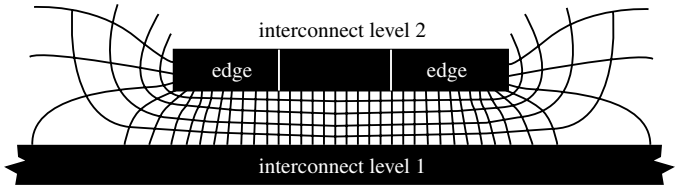

FIGURE 55.90 Overlap capacitance. The bottom interconnect level will have edges into and out of the page with distorted electric field similar to that shown for the top level of interconnect.

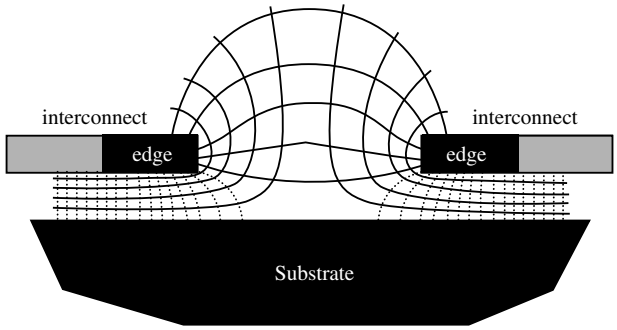

FIGURE 55.91 Parallel line capacitance. Only the solid field lines actually produce line-to-line capacitance, the dashed lines form substrate capacitance.

of the electric field at the interconnect edges. The nonuniformity of the electric field at edges is such that the capacitance value is larger for a given area of interconnect near the edge than elsewhere.

In addition to the substrate capacitance, all adjacent pieces of an interconnect will have capacitance between them. This capacitance is classified into two forms, overlap capacitance, and parallel line capacitance (also known as proximity capacitance). Overlap capacitance occurs when two pieces of interconnect cross each other, while parallel line capacitance occurs when two interconnect traces run close to each other for some distance.

When two lines cross each other, the properties of the overlapping region will determine that size of the overlap capacitance. The electric field through a cross section of two overlapping lines is illustrated in Fig. 55.90. The electric field becomes nonuniform near the edges of the overlapping region, producing an edge-dependent capacitance term. The capacitance per unit area at the edge is always greater than elsewhere and, if the overlapping regions are small, the edge capacitance effect can be significant.

The size of parallel line capacitance depends on the distance for which the two lines run side by side and on the separation of the lines. Since parallel line capacitance occurs only at the edges of an interconnect, the electric field that produces it is very nonuniform. This particular nonuniformity, as illustrated in Fig. 55.91, makes the capacitance much smaller for a given area of interconnect than either overlap or substrate capacitance. Thus, two lines must run parallel for some distance for this capacitance to be important. The nonuniformity of the electric field makes the dependence of the capacitance on line separation highly nonlinear, as a result the capacitance value decreases much more rapidly with separation than it would if it depended linearly on the line separation.

Modeling. In the absence of significant interconnect resistance effects, all of the parasitic capacitances can be modeled with enough accuracy for most analog circuit design applications by dissecting the interconnect into pieces with similar capacitance characteristics and adding up the capacitance of each piece to obtain a single capacitance term. For example, the dissected view of a piece of interconnect with substrate capacitance is shown in Fig. 55.92. The interconnect has been dissected into squares that fall into three classes: two types of edges, and one center type. The capacitance to the substrate for each of

© 2003 by CRC Press LLC

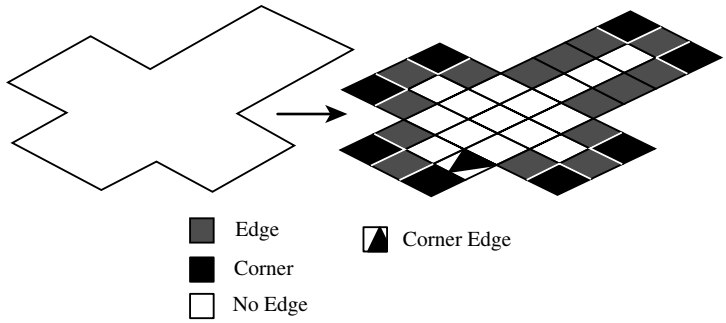

FIGURE 55.92 Determining substrate capacitance. The capacitance of each square in the dissected interconnect segment is summed.

these squares in parallel and thus the total capacitance of the interconnect segment is simply the sum of the capacitance of each square. If the substrate capacitance contribution of each square has been previously measured or calculated, the calculation of the total interconnect segment substrate capacitance involves summing each type of squares capacitance multiplied by the number of squares of that type in the segment.

The accuracy of this modeling technique depends solely on the accuracy of the models used for each type of square. For example, in Fig. 55.92, the accuracy could be improved by adding one more type of edge square to those that are modeled. One of these squares has been shaded differently in the figure and is called the corner edge square.

For the nonedge pieces of the interconnect the capacitance is approximately a parallel-plate capacitance and can be computed from (55.178).

$$C = \frac{A \cdot \varepsilon_r \cdot \varepsilon_0}{t} \tag{55.178}$$

In (55.178), A is the area of the square or piece of interconnect, t is the thickness of the insulation layer beneath the interconnect, ε_r is the relative dielectric constant of the insulation material, and ε_0 is the dielectric constant of free space. For silicon integrated circuits insulated with silicon dioxide the parameters are given in Table 55.8.

The capacitance of edge interconnect pieces will always be larger than nonedge pieces. The amount by which the edge capacitance increases will depend on the ratio of the size of the piece of interconnect and the thickness of the insulation layer beneath the interconnect. If the interconnect width is significantly larger than the thickness of the insulation then edge effects are probably small and can be ignored. However, when thin lines are used in integrated circuits the edge effects are usually significant. The factor by which the edge capacitance can increase over the parallel-plate approximation can easily be as high as 1.5 for thin lines.

TABLE 55.8 Parameters for Calculation of Substrate Capacitance in Silicon Integrated Circuits Insulated with Silicon Dioxide

Parameter	Value
ε_r	3.9
ε_0	$8.854 \cdot 10^{-12}$ F/m
t	$1–5 \cdot 10^{-6}$ m

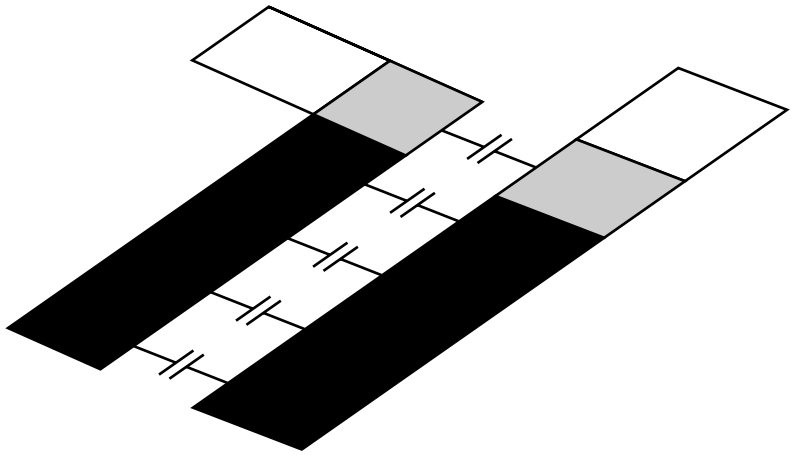

FIGURE 55.93 Determining parallel line capacitance. The differently shaded pairs of squares are different types and will each have a different capacitance between them.

The modeling of overlap capacitance is handled in the same fashion as substrate capacitance. The region where interconnect lines overlap is dissected into edges and nonedges and the value of capacitance for each type of square summed up to give a total capacitance between the two circuit nodes associated with each piece of interconnect that overlaps. The area of overlap between the two layers of interconnect can be used as A in (55.178), while that separation between the layers can be used as t. The strong distortion of the electric fields will increase the actual value above this idealized computed value by a factor that depends on the thickness of the lines. This factor can be as high as 2 for thin lines.

Parallel line capacitance can also be handled in a manner similar to that used for substrate and overlap capacitance. However, we must now locate *pairs* of edge squares, one from each of the adjacent interconnect lines. In Fig. 55.93, one possible pairing of the squares from adjacent pieces of interconnect is shown. The capacitance for each type of pair of squares is added together, weighted by the number of pairs of each type to get a single capacitance that connects the circuit nodes associated with each interconnect line.

The effect on the capacitance of the spacing between pairs must be either measured or computed for each possible spacing, and type of pair of squares. One approach to this is to use a table of measured or computed capacitances and separation distances. The measured parallel line capacitance between silicon integrated circuit lines for a variety of separations is presented in Fig. 55.94. From the figure, we see that the capacitance value decreases exponentially with line separation. Thus an exponential fit to measured or simulated data is good choice for computing the capacitance [7], [8].

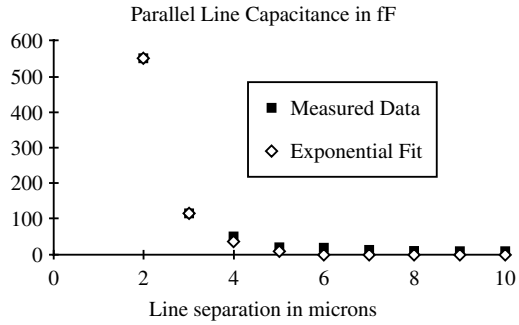

FIGURE 55.94 Parallel line capacitance measured from a silicon integrated circuit. The diamonds are an exponental fit to the data [using (55.179)]. The fit is excellent at short separations when the capacitance is largest.

© 2003 by CRC Press LLC

Equation (55.179) can be used to predict the parallel line capacitance C for each type of pair of edge squares. L is the length of the edge of the squares, and the parameters C_c and S_d are computed or fit to measured coupling capacitance data like that in Fig. 55.94.

$$C = C_c \cdot L \cdot e^{-(s/S_d)} \tag{55.179}$$

Effects on Circuits. The effects that parasitic capacitances are likely to produce in circuits range from parametric variations, such as reduced bandwidth, to catastrophic failures, such as amplifier oscillation. Each type of parasitic capacitance produces a characteristic set of problems. Being aware of these typical problems will ease diagnosis of actual, or potential, parasitic capacitance problems.

Substrate capacitance usually causes lower than expected bandwidth in amplifiers and lowering of the poles in filters. The capacitance is always to ac ground and thus increases device and circuit capacitances to ground. Thus, circuit nodes that have a dominant effect on amplifier bandwidth, or filter poles, should be designed to have as little substrate capacitance as possible. Another, more subtle, parametric variation that can be caused by substrate capacitance is frequency-dependent mismatch. For example, if the parasitic capacitance to ground is different between the two inputs of a differential amplifier, then, for fast transient signals, the amplifier will appear unbalanced. This could limit the accuracy high-speed comparators, and is sometimes difficult to diagnose since the error only occurs at high speeds.

Overlap and parallel line capacitance can cause unwanted ac connections to be added to a circuit. These connections will produce crosstalk effects and can result in unstable amplifiers. The output interconnect and input interconnect of high-gain or high-frequency amplifiers must thus be kept far apart at all times. Care must be taken to watch for series capacitances of this type. For example, if the output and input interconnect of an amplifier both cross the power supply interconnect, unwanted feedback can result if the power supply line is not well ac grounded. This is a very common cause of integrated circuit amplifier oscillation. Because of the potential for crosstalk between parallel or crossing lines, great care should also be taken to keep weak (high-impedance) signal lines away from strong (low-impedance) signal lines.

Parasitic Resistance

For analog integrated circuit designers, the second most important interconnect parasitic is resistance. This unexpected resistance can cause both parametric problems, such as increased offset voltages, and catastrophic problems such as amplifier oscillation (for example, poorly sized power supply lines can cause resistive positive feedback paths in high gain amplifiers called “ground loops”). To make matters worse, the resistivity of integrated circuit interconnect has been steadily increasing as the line widths of circuits have decreased.

Physics. Except for superconductors, all conductors have resistance. A length of interconnect used in an integrated circuit is no exception. The resistance of a straight section of interconnect is easily found by obtaining the resistance per square for the particular interconnect layer concerned, and then adding up the resistance of each of the series of squares that makes up the section. This procedure is illustrated in Fig. 55.95.

For more complicated interconnect shapes the problem of determining the resistance between two points in the interconnect is also more complex. The simplest approach is to cut the interconnect up into rectangles and assume each rectangle has a resistance equal to the resistance per square of the interconnect material times the number of full and partial squares that will fit along the direction of current flow in the rectangle [5]. This scheme works whenever the direction of current flow is clear; however, for corners and intersections of interconnect the current flow is in fact quite complex. Figure 55.96 shows the kind of current flow that can occur in an interconnect section with complex geometry.

Modeling. To account for the effects of complex current flows the resistance of complex interconnect geometries must be determined by measurement or simulation. One simple empirical approach is to cut

© 2003 by CRC Press LLC

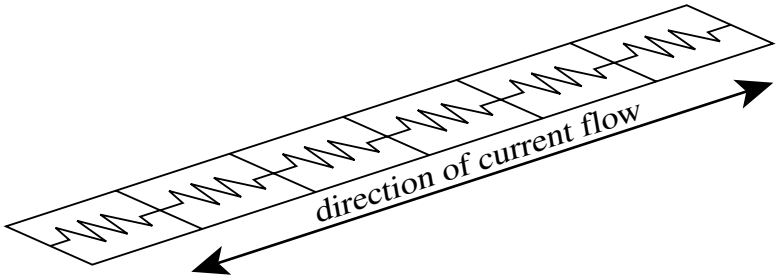

FIGURE 55.95 Determining the resistance of a length of interconnect. Each square has the same resistance regardless of size.

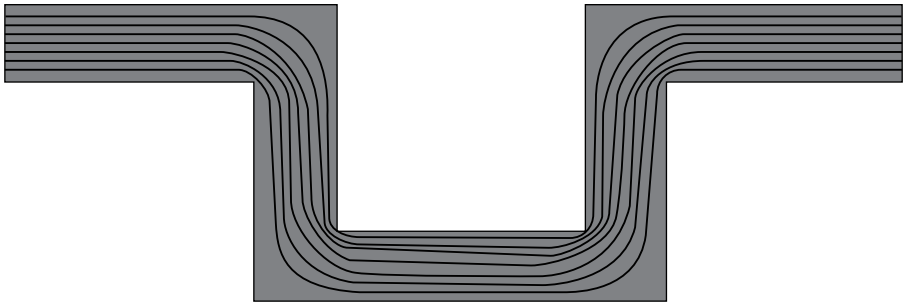

FIGURE 55.96 Current flow in a complex interconnect geometry.

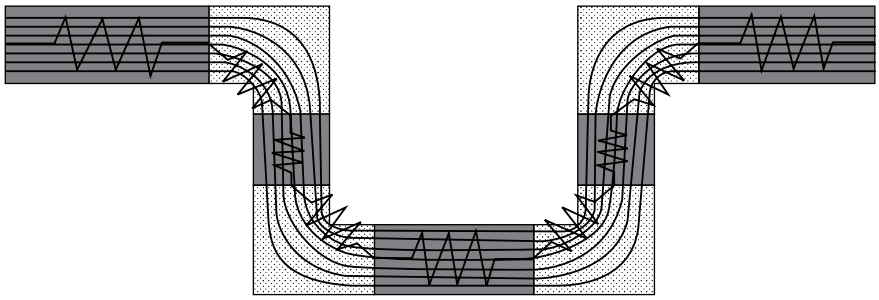

FIGURE 55.97 The process of breaking a complex geometry into subgeometries, constructing the equivalent connected resistance, and forming a single resistance for an interconnect section. In this example, only two subgeometries are used: a corner subgeometry and a basic rectangular subgeometry.

out sections of resistive material in the same shape as the interconnect shape to be modeled, and then measure the resistance. The resistance for other materials can be found by multiplying by the ratio of the respective resistances per square of the two materials.

Once the resistance has been found for a particular geometry it can be used for any linear scaling of that geometry. For most types of integrated circuit interconnect all complex geometries can be broken up into relatively few important subgeometries. If tables of the resistance of these subgeometries for various dimensions and connection patterns are obtained, the resistance of quite complex shapes can be accurately calculated by connecting the resistance of each subgeometry together and calculating the resistance of the connected resistances. This calculation can usually be performed quickly by replacing series and parallel connected resistor pairs with their equivalents. The process of breaking a complex geometry into subgeometries, constructing the equivalent connected resistance, and forming a single resistance for an interconnect section is illustrated in Fig. 55.97.

© 2003 by CRC Press LLC

Effects on Circuits. The resistance of interconnect can have both parametric and catastrophic effects on circuit performance. Even small differences in the resistance on either input side of a differential amplifier can lead to increased offset voltage. Thus, when designing differential circuits care must be taken to make the interconnect identical on both input sides, as this ensures that the same resistance is present in both circuits.

The resistance of power supply interconnect can lead to both parametric errors in the voltages supplied and catastrophic failure due to oscillation. If power supply voltages are assumed to be identical in two parts of a circuit and, due to interconnect resistance, there is a voltage drop from one point to the next, designs that rely on the voltages being the same may fail. In high-gain and feedback circuits the resistance of the ground and power supply lines may become an unintentional positive feedback resistance which could lead to oscillation. Thus output and input stages for high-gain amplifiers will usually require separate ground and power supply interconnects. This ensures that no parasitic resistance is in a feedback path.

When using resistors provided in an integrated circuit process, the extra resistance provided by the interconnect may cause inaccuracies in resistor values. This would be most critical for small resistance values. The only solution in this case is to accurately compute the interconnect resistance. Since most resistance layers provided in analog integrated circuit processes are just a form of high resistivity interconnect, the methods described here for accurately computing the resistance of interconnect are also useful for predicting the resistance of resistors to be fabricated.

Parasitic Inductance

In high-speed integrated circuits the inductance of long lines of interconnect becomes significant. In integrated circuit technologies that have an insulating substrate, such as gallium arsenide (GaAs) and silicon on insulator (SOI), reasonably high-performance inductive devices can be made from interconnect. In technologies with conductive substrates, resistive losses in the substrate restrict the application of interconnect inductance. High-frequency circuits are often tuned using interconnect inductance and capacitance (*LC*) to form a narrow bandpass filter or tank circuit, and *LC* transmission lines, or stubs, made from interconnect are useful for impedance matching. There is much similarity between this use of parasitic inductance and the design of microstripline-printed circuit boards. The major difference being that inductance does not become significant in integrated circuit interconnect until frequencies in the gigahertz are reached.

In order to make a good interconnect inductance, there are two requirements. First, there must not be any resistive material within range of the magnetic field of the inductance. If this occurs then induced currents flowing in the resistive material will make the inductor have high series resistance (low *Q* factor). This would make narrow bandwidth bandpass filters difficult to make using the inductance, and make transmission lines made from the interconnect lossy. The solution is to have an insulating substrate, or to remove the substrate from beneath the inductor.

The second requirement for large inductance is to form a coil or other device to concentrate the magnetic field lines. Within the confines of current integrated circuit manufacturing, spiral inductors, like that illustrated in Fig. 55.98 are the most common method used to obtain useful inductances.

Transmission Line Behavior

Two types of transmission line behavior are important in integrated circuits, *RC* transmission lines and *LC*/*RLC* transmission lines. For gigahertz operation inductive transmission lines are important. These can be lossy *RLC* transmission lines if a conductive substrate such as silicon is used, or nearly lossless *LC* transmission lines if an insulating substrate such as gallium arsenide is used. The design of inductive transmission lines is very similar to designing microstripline-printed circuit boards. At lower frequencies of 10 to 1000 MHz resistive capacitive (*RC*) transmission lines are important for long low resistivity interconnect lines or short high resistivity lines.

RC transmission lines are of concern to analog circuit designers working in silicon integrated circuits. When used correctly, an interconnect can behave as though it were purely capacitive in nature. However,

© 2003 by CRC Press LLC

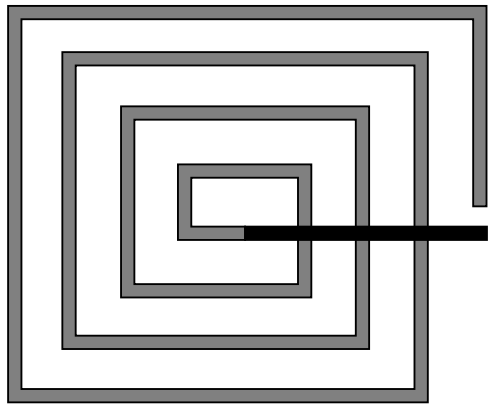

FIGURE 55.98 Spiral inductance used in insulated substrate integrated circuits for gigahertz frequency operation.

when a higher resistivity interconnect layer, such as polysilicon or diffusion is used, the distributed resistance and capacitance can start to produce transmission line effects at relatively short distances. Similarly, for very long signal distribution lines or power supply lines, if they are not correctly sized, transmission line behavior ensues.

Physics. One method for modeling distributed transmission line interconnect effects is lumped equivalent modeling [6]. This method is useful for obtaining approximate models of complex geometries quickly, and is the basis of accurate numerical finite element simulation techniques. For analog circuit designers the conversion of interconnect layout sections into lumped equivalent models also provides an intuitive tool to understanding distributed transmission line interconnect behavior.

To be able to model a length of interconnect as a lumped *RC* equivalent, the error between the impedance of the interconnect when correctly treated as a transmission line, and when replaced with the lumped equivalent, must be kept low. If this error is *e*, then it can be shown that the maximum length of interconnect that can be modeled as a simple *RC T* or Π network is given in (55.180). In the equation, *R* is the resistance per square of the particular type of interconnect used, *C* is the capacitance per unit area, and ω is the frequency of operation in radians per second.

$$D \le \sqrt{\frac{3 \cdot e}{\omega \cdot R \cdot C}} \tag{55.180}$$

This length can be quite short. Consider the case of a polysilicon interconnect line in a 1.2 μm CMOS process that has a resistance per square of 40 Ω a capacitance per unit are of 0.1 fF/μm^2. For an error *e* of 10 percent the maximum line length of minimum width line that can be treated as a lumped *T* or Π network for various frequencies is given in Table 55.9. Longer interconnect lines than this must be cut up into lengths less than or equal to the length given by (55.180).

TABLE 55.9 The Maximum Length of Minimum Width Polysilicon Line That Can Be Modeled with a Single Lumped *RC T* or Π Network and Remain 10 percent Accurate

Frequency (MHz)	Length (micrometers)
10	1262
100	399
1000	126

Modeling. The accurate modeling of distributed transmission line effects in integrated circuits is best performed with lumped equivalent circuits. These circuits can be accurately extracted by dissecting the interconnect geometry into lengths that are, at most, as long as the length given by (55.180). These lengths are then modeled by either a *T* or Π lumped equivalent *RC* network. The extraction of the resistance and capacitance for these short interconnect sections can now follow the same procedures as were

© 2003 by CRC Press LLC

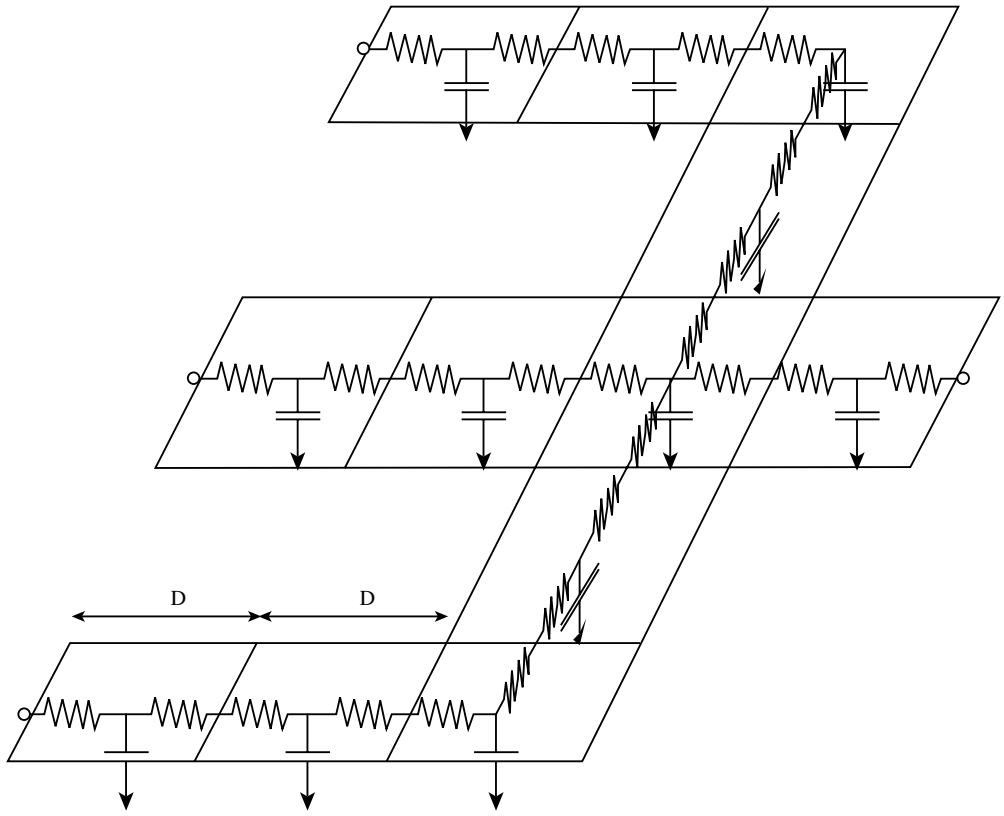

FIGURE 55.99 The extraction of an accurate *RC* transmission line model for resistive interconnect. The maximum allowable length *D* is computed from (55.180).

described in the previous sections on parasitic interconnect resistance and capacitance. The resulting *RC* network is then an accurate transmission line model of the interconnect. Fig. 55.99 shows an example of this process.

Effects on Circuits. Several parametric and catastrophic problems can arise due to unmodeled transmission line behavior. Signal propagation delays in transmission lines are longer than predicted by a single lumped capacitance and resistance model of interconnect. Thus, ignoring the effects of transmission lines can result in slower circuits than expected. If the design of resistors for feedback networks results in long lengths of the resistive interconnect used to make the resistors, these resistors may in fact be *RC* transmission lines. The extra delay produced by the transmission line may well cause oscillation of the feedback loops using these resistors. The need for decoupling capacitors in digital and analog circuit power supplies is due to the *RC* transmission line behavior of the power supply interconnect. Correct modeling of the *RC* properties of the power distribution interconnect is needed to see whether fast power supply current surges will cause serious changes in the supply voltage or not.

Nonlinear Interconnect Parasitics

A number of types of interconnect can have nonlinear parasitics. These nonlinear effects are a challenge to model accurately because the effect can change with the operating conditions of the circuit. A conservative approach is to model the effects as constant at the worst likely value they can attain. This is adequate for predicting parameters, like circuit bandwidth, that need only exceed a specification value. If the specifications call for accurate prediction of parasitics then large nonlinear parasitics are generally undesirable and should be avoided.

© 2003 by CRC Press LLC

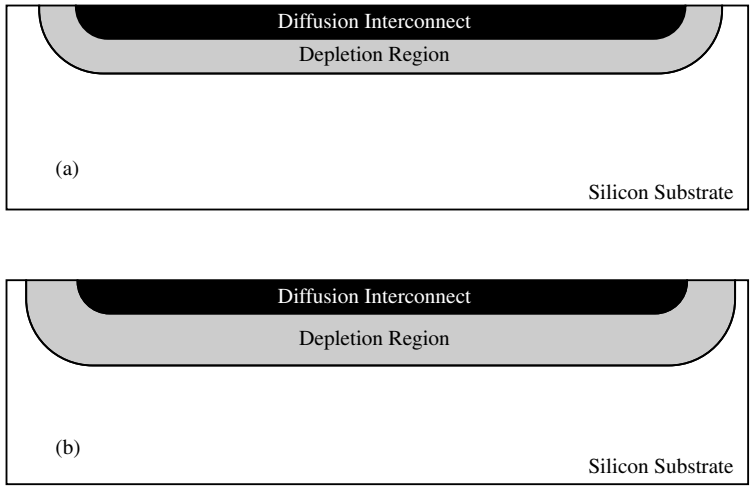

FIGURE 55.100 Diffusion interconnect has a voltage-dependent capacitance produced by the depletion region between the interconnect and the substrate. At low voltage difference between the interconnect and substrate (a), the capacitance is large. However, the capacitance decreases for larger voltage differences (b).

Most nonlinear interconnect parasitics are associated with depletion or inversion of the semiconductor substrate. A diffusion interconnect is insulated from conducting substrates such as silicon by a reversed biased diode. This diode's depletion region width varies with the interconnect voltage and results in a voltage-dependent capacitance to the substrate. For example, the diffusion interconnect in Fig. 55.100 has voltage dependent capacitance to the substrate due to a depletion region. The capacitance value depends on the depletion region thickness, which depends on the voltage difference between the interconnect and the substrate.

$$C = C_0 \cdot \left(1 - \left(\frac{V_s}{\phi_B}\right)\right)^M \tag{55.181}$$

The typical equation for depletion capacitance is given in (55.181). In this equation V_S is the voltage from the interconnect to the substrate, ϕ_B is the built-in potential of the semiconductor junction, M is the grading coefficient of the junction, while C_0 is the zero-bias capacitance of the junction. Since the capacitance is less than C_0 for reverse bias and the junction would not insulate for forward bias, we can assume that the capacitance is always less than C_0 and use C_0 as a conservative estimate of C. Because of the uncertainty in the exact structure of most semiconductor junctions ϕ_B and M are usually fit to measured capacitance versus voltage (CV) data.

Another common nonlinear parasitic occurs when metal interconnect placed over a conducting semiconductor substrate creates inversions at the semiconductor surface. This inversion layer increases the substrate capacitance of the interconnect and is voltage dependent. To prevent this most silicon-integrated circuit manufacturers place an inversion-preventing implant on the surface of the substrate. The depletion between the substrate and n-type or p-type wells diffused into the substrate also creates a voltage-dependent capacitance. Thus use of the well as a high resistivity interconnect for making high value resistors will require consideration of a nonlinear capacitance to the substrate.

Pad and Packaging Parasitics

All signals and supply voltages that exit an integrated circuit must travel across the packaging interconnections. Just like the on-chip interconnect, the packaging interconnect has parasitic resistance, capacitance, and inductance. However, some of the packaging materials are significantly different in properties

© 2003 by CRC Press LLC

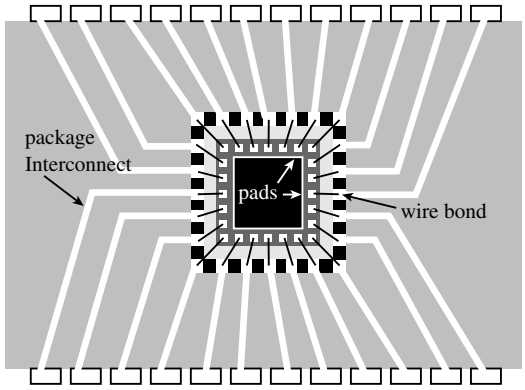

FIGURE 55.101 A packaged integrated circuit. The main sites of parasitics are the pad, bond, and package interconnect.

and dimension to those used in the integrated circuit, thus there are major differences in the importance of the various types of parasitics. Fig. 55.101 is a typical packaged integrated circuit. The chief components of the packaging are the pads on the chip, the wire or bump bond used to connect the pad to the package, and then the package interconnect.

The pads used to attach wire bonds or bump bonds to integrated circuits are often the largest features on an integrated circuit. The typical pad is 100 μm on a side and has a capacitance of 100 fF. In addition, protection diodes are often used on pads that will add a small nonlinear component to the pad capacitance.

The wire bonds that attach the pads to the package are typically very low resistivity and have negligible capacitance. Their major contribution to package parasitics is inductance. Typically, the package interconnect inductance is greater than the wire bond inductance; however, when wire bonds are used to connect two integrated circuits directly together, then the wire bond inductance is significant.

Often, the dominant component of package parasitics comes from the packaging interconnect itself. Depending on the package, there is inductance, capacitance to ground, and parallel line capacitance produced by this interconnect. Carefully made high-frequency packages do not exhibit much parallel line capacitance (at the expense of much capacitance to ground due to shielding), but in low-frequency packages with many connections this can become a problem.

Typical inductance and capacitance values for a high-speed package capable of output bandwidths around 5 GHz are incorporated into a circuit model for the package parasitics in Fig. 55.102. When

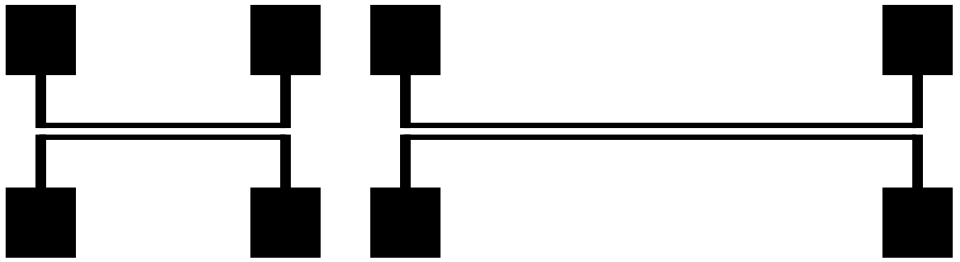

FIGURE 55.105 Test structures for measuring parallel line capacitance.

Parasitic Measurement

The major concern when measuring parasitics is to extract the individual parasitic values independently from measured data. This is normally achieved by exaggerating the effect that causes each individual parasitic in a special test structure, and then reproducing the structure with two or more different dimensions that will affect only the parasitic of interest. In this fashion, the effects of the other parasitics are minimized and can be subtracted from the desired parasitic in each measurement.

$$C_P = \frac{C_1 - C_2}{L_1 - L_2} \tag{55.182}$$

For example, to measure parallel line capacitance, the test structures in Fig. 55.105 would be fabricated. These structures vary only in the length of the parallel lines. This means that if other parasitic capacitance ends up between the two signal lines used to measure the parasitic, then it will be a constant capacitance that can be subtracted from both measurements. The parallel line capacitance will vary in proportion to the variation of length between the two test structures. Thus the parallel line capacitance per unit length can be found from (55.182). In this equation C_P is the parallel line capacitance per unit length, C_1 and C_2 are the capacitances measured from each test structure, and L_1 and L_2 are the length of the two parallel interconnect segments.

56.1 Bipolar Biasing Circuits

K. V. Noren

Fundamental to the design of bipolar circuits is establishing the bias currents and voltages at which the subcircuits of the design are to operate. This of course determines the small-signal parameters of transistors meant to be operated as small-signal linear devices and the dc voltage levels used in direct-coupled circuits, such as op amps. The subcircuits that perform biasing include current sources, voltage references, and level shifters. Typically, it is desired that BJT circuit design be robust and independent of a variety of external conditions that can affect circuit performance. These factors include variations in supply voltages, in temperature, and process parameters. Desires to improve on these issues have led to many refinements and developments based upon simple ideas and basic building blocks. We present in this section some of the fundamental biasing building blocks that are used in bipolar integrated circuit technology and the refinements of them that have evolved over time.

Common BJT Biasing Circuits

Current Mirrors and Sources

The current mirror is a circuit that reproduces a reference current at one or more locations in the circuit. A simple current mirror is depicted in Fig. 56.1. Since $V_{BE1} = V_{BE2}$, $I_{OUT} \approx I_{REF}$, and the reference current is mirrored to another part of the circuit. In order to classify and characterize current mirrors, we must first define an ideal current mirror. An ideal current mirror can be characterized as follows:

© 2003 by CRC Press LLC

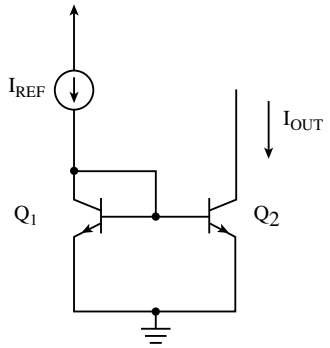

FIGURE 56.1 Simple current mirror.

1. It reproduces the reference current, exactly.
2. It does not vary with loading (infinite output resistance).
3. It is insensitive to power supply variations.
4. It is insensitive to temperature.

Simple Current Mirror. For the simple current mirror, including the effects of finite β (base–current drain) for matched transistors, the transfer function is

$$\frac{I_{OUT}}{I_{REF}} \approx \frac{1}{1+2/\beta} \tag{56.1}$$

The error due to β results from the fact that the I_{REF} must supply current to the bases of both Q_1 and Q_2. From the small-signal equivalent circuit of Fig. 56.1, it is seen that the output resistance of the simple current source is simply r_o of the transistor Q_2.

If the mirror in Fig. 56.1 is configured with N output transistors, the transfer function becomes

$$\frac{I_{OUT}}{I_{REF}} \approx \frac{1}{1+(N+1)/\beta} \tag{56.2}$$

Wilson Current Mirror. A current source that has improved output resistance and β sensitivity to the transistors is the Wilson current mirror shown in Fig. 56.2 [1].

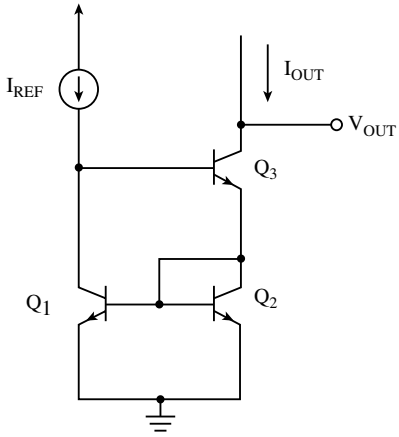

FIGURE 56.2 Wilson current mirror.

© 2003 by CRC Press LLC

An analysis of the circuit shows the need to supply base current to Q_1 and Q_2 still exists. This is supplied by the emitter current of Q_3, which still draws the current from I_{REF}, but is reduced by a factor of β over the drain from I_{REF} from the original current source. A rigorous analysis will show, neglecting the effects of r_o,

$$\frac{I_{OUT}}{I_{REF}} \approx \frac{1}{1+2/(\beta^2+2\beta)} \approx \frac{1}{1+2/\beta^2} \tag{56.3}$$

This supports the intuitive analysis. It should be noted that Eq. (56.3) assumes the β's of the transistors are matched. An improvement in output resistance can be seen by noting the circuit has negative feedback. For example, assuming matched transistors and the effects of output voltage for all of the transistors, an increase in V_{OUT} gives rise to an increase in output current. This, in turn, causes an increase in I_{C2}. Since Q_1 and Q_2 form a simple current mirror, I_{C1} also increases, which forces a decrease in I_{B3}, since I_{REF} is taken to be constant, thus forcing a reduction in I_{OUT}. Changes in I_{OUT} due to changes in V_{OUT} have been reduced due to the feedback. Inserting the small-signal model for the transistors and solving for R_o gives

$$R_o \approx \beta r_o/2 \tag{56.4}$$

The Wilson current mirror can also be extended to N multiple outputs by placing extra transistors across Q_3. It can be shown that for N total transistors

$$\frac{I_{OUT}}{I_{REF}} \approx \frac{1}{N}\frac{1}{1+2/\beta^2} \tag{56.5}$$

dividing the current between the devices with about the same error as the $N = 1$ case.

Widlar Current Mirror. In bipolar integrated circuit design, it is sometimes desirable to create low-level currents, on the order of μA, for example [2]. With the simple current mirror or the Wilson current mirror, this must be done by creating very low reference currents and may require large values of resistors. This is undesirable. The current mirror depicted in Fig. 56.3 is capable of producing a small output current, from a nominal valued reference current.

To analyze the circuit, it is assumed that I_{REF} determines the voltage V_{BE1}. In the simple current mirror, all of V_{BE1} appears across V_{BE2}. In the Widlar current mirror, only a fraction of V_{BE1} is across V_{BE2}, since

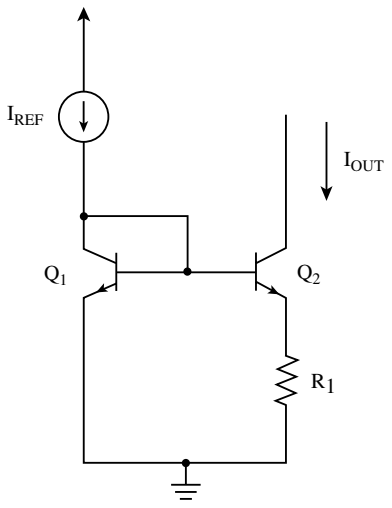

FIGURE 56.3 Widlar current mirror.

© 2003 by CRC Press LLC

a fraction must be placed across R_1. Thus, with proper selection of R_1, it is expected that we are capable of producing lower current levels due to the lower V_{BE2}, achieved by voltage dividing V_{BE1}. It can be shown, neglecting the effects of β, that

$$I_{\text{OUT}}R_1 = V_T \ln\left(\frac{I_{\text{REF}}}{I_{\text{OUT}}}\right) \tag{56.6}$$

For example, to create an I_{OUT} of 5 μA, from a reference of 1 mA, with V_T = 26 mV, we have R_1 = 27 kΩ. If the same 5 μA were desired from the simple current mirror, and we assume that the emitter areas of Q_1 and Q_2 are equal, we would need to generate a reference current of 5 μA. To do this, I_{REF} is replaced by a resistor R_{REF} tied to the positive supply V_{CC}, for example. Suppose that V_{CC} is 5 V. Then, the voltage drop across R_{REF} is $V_{\text{CC}} - V_{BE}$. Taking V_{BE} = 0.7 V, gives a value of R_{REF} = (5 – 0.7)/5 μm = 860 kΩ. This takes up much more chip real estate than for R_1 = 27 kΩ and is undesirable.

If the effects of β are included, as in the simple current mirror, it is necessary to draw the equivalent of 2 base currents, here I_{B2} although being less than I_{B1}. It can be expected that (56.2) gives an upper bound for beta errors for the Widlar current mirror (the upper bound being that of $I_{\text{OUT}} = I_{\text{REF}}$) and errors for the lower bound being 1/(1+1/β), supplying base current to only 1 transistor. Thus, the errors due to base current drain are on the same order as that of the simple current mirror.

R_1 provides negative feedback to help increase the output resistance. This is identical to emitter degeneration in a common-emitter amplifier, and in fact, when using the small-signal equivalent circuit to derive the output resistance, the topology is identical to this amplifier, neglecting a collector resistance. Thus, it is easily verified that

$$R_o \approx r_o\left(1 + g_m R_1 \| r_\pi\right) \tag{56.7}$$

Low-Bias Current Mirror. An alternative to the Widlar current source that also provides a low output current is the current source shown in Fig. 56.4 [3], [4].

Again, V_{BE1} is generated and forced by I_{REF}. Using KVL,

$$V_{BE2} = V_{BE1} - I_{\text{REF}}R_1 \tag{56.8}$$

Thus, the voltage generated at V_{BE2} is smaller than V_{BE1} and only a fraction of I_{REF} is mirrored. A more exact relationship for the output current and reference current can be derived from (56.8), and this is

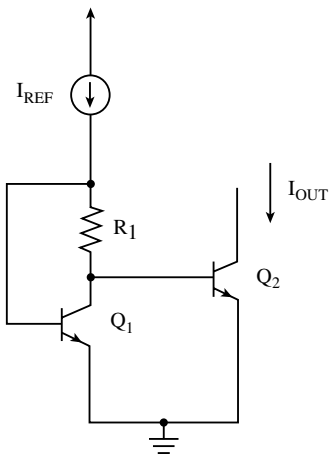

FIGURE 56.4 Low-bias current source.

© 2003 by CRC Press LLC

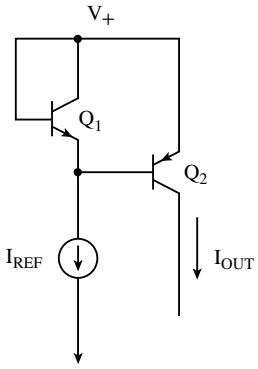

FIGURE 56.5 Current mirror for complementary bipolar design.

$$I_{\text{OUT}} = I_{\text{REF}} \exp\left(\frac{-I_{\text{REF}} R_1}{V_T}\right) \tag{56.9}$$

and

$$R_1 = \frac{-V_T \ln\left(\dfrac{-I_{\text{OUT}}}{I_{\text{REF}}}\right)}{I_{\text{REF}}} \tag{56.10}$$

In fact, this current source is capable of supplying even lower currents than the Widlar current source for a given I_{REF} and an upper bound for R_1. Consider the same example as was given for the Widlar current source. With $I_{\text{REF}} = 1$ mA, $I_{\text{OUT}} = 5$ μA, and $V_T = 26$ mV, we find that $R_1 = 137.75$ Ω. This is a substantial decrease in resistance from the Widlar current mirror.

This current mirror is also called a g_m-compensated mirror, and derives this name from its performance when R_1 is selected to be $1/g_{m1}$ [5]. To understand the operation, consider the effect of a small change in I_{REF}. Neglecting base current, the change in voltage for V_{BE1} is $\Delta I_{\text{REF}} r_{el}$. The change in voltage across R_1 is $\Delta I_{\text{REF}} R_1 = \Delta I_{\text{REF}} / g_{m_1} \approx \Delta I_{\text{REF}} r_{e1}$. This means, as seen by (56.8), the net change in voltage across the base-emitter of Q_2 is about 0 V.

The basic current mirrors can be extended to complementary bipolar technology (CBT) as well. Figure 56.5 gives an example of a current mirror that can be found in CBT. A problem that arises in the current mirrors used in bipolar technology results in the fact that pnp and npn transistors have a different gummel number [5]. This results in different base-emitter voltages (magnitudes) for the same collector currents. The effects of this can be deduced from Fig. 56.5, where now ΔV_{BE} errors must be considered. Thus, care must be taken when biasing complementary bipolar designs. The issue of balancing and matching is a fundamental problem in this technology [5].

Supply-Independent Biasing. For many current mirrors, I_{REF} is determined by a resistor tied to the positive power supply. In the Widlar current mirror example, $I_{\text{REF}} = (V_{CC} - V_{BE})/\text{R}_{\text{REF}}$. The reference current is directly proportional to the supply voltage. In many situations, this is undesirable. One solution is to replace V_{CC} by one of the many available circuits that provide a voltage reference that is independent of supply voltage. Another solution is shown in Figure 56.6.

A current is generated through R_2 via the V_{BE1} that is forced across it. Neglecting finite betas for the transistors, this current is approximately I_{OUT}. A complete derivation yields

$$I_{\text{OUT}} = \frac{V_T}{R_2} \ln\left(\frac{V_{CC}}{R_1 I_S}\right) \tag{56.11}$$

© 2003 by CRC Press LLC

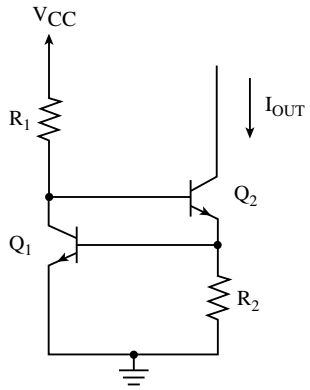

FIGURE 56.6 Current source that has reduced supply voltage dependency.

This shows the output current has a logarithmic variation with V_{CC}, an improvement over the linear relationship found in other current mirrors.

Voltage References

Also fundamental to biasing in BJT circuits are voltage references. As with the current sources, we may define an ideal voltage source in order to characterize and evaluate references. An ideal voltage reference can be defined as follows.

1. It does not vary with loading (zero output resistance).
2. It is insensitive to power supply variations.
3. It is insensitive to temperature.

The simplest voltage reference is the zener diode reference, but is it well known that a zener diode exhibits temperature dependence and has a fairly high equivalent output resistance. Some of the modifications include placing a diode series with a zener, strings of diodes, and a common-collector stage. Figure 56.7 gives an example. Here it is assumed that V_{DZ} has a positive coefficient and V_{D1} has a negative temperature coefficient. The two coefficients cancel to provide an ideal O net coefficient. Literally hundreds of deviations are based on this fundamental principle.

A circuit that produces a voltage that is an arbitrary multiple of V_{BE} is the V_{BE} multiplier circuit shown in Fig. 56.8.

The circuit works on the principle that a current equal to V_{BE}/R_2 is generated and, neglecting base current, flows through R_1. Thus, the voltage across R_1 is $(V_{BE}/R_2)R_1$ and the total voltage can be written as

$$V_{\text{REF}} = V_{BE}\left(1 + R_2/R_1\right) \tag{56.12}$$

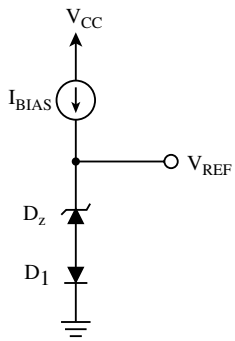

FIGURE 56.7 Zener-based voltage references.

© 2003 by CRC Press LLC

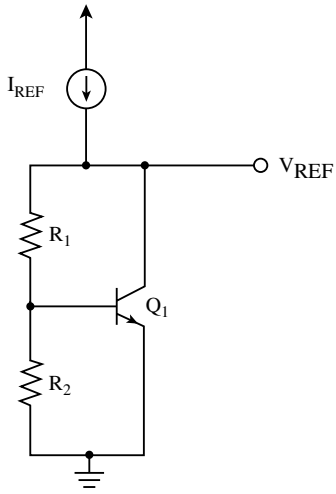

FIGURE 56.8 V_{BE} multiplier circuit.

Thermal Desensitization

Many applications for biasing circuits demand that their performance remain constant through a wide range of temperatures. Thus, many schemes for temperature insensitive biasing have emerged. Ideally, a temperature insensitive output, voltage or current, would depend on a temperature insensitive element. Since all semiconductor components exhibit variation with temperature, most of the schemes for temperature independence involve some form of cancellation technique or compensation [6]. Instead of eliminating all sensitivity, the design techniques strive to minimize the errors. For example, a common solution is to place devices with positive temperature coefficients in series with devices with negative temperature coefficients, scaling some of these coefficients if necessary, to provide nearly zero sensitivity to temperature for an output is taken across the devices. Figs. 56.7 and 56.9 are examples.

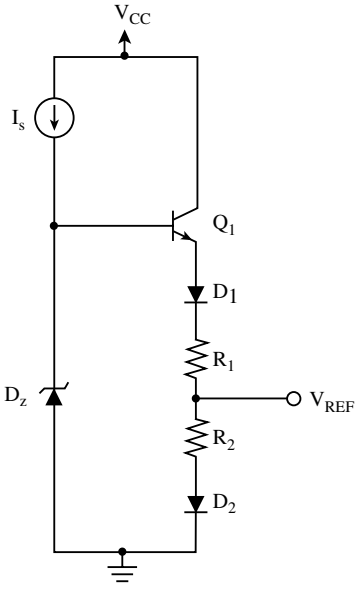

FIGURE 56.9 Simple zener-biased circuit with temperature coefficient cancellation scheme.

© 2003 by CRC Press LLC

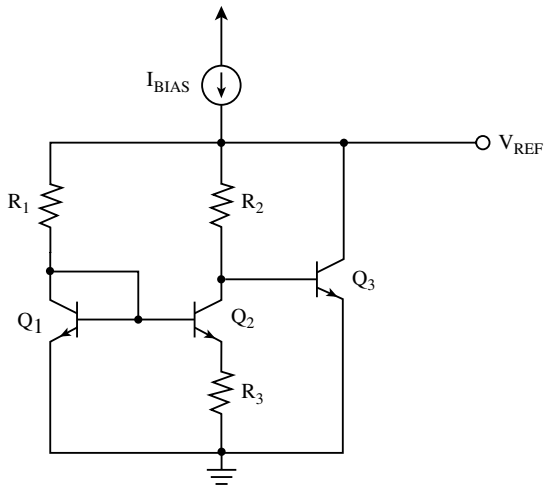

FIGURE 56.10 Simple bandgap reference.

Consider the circuit in Fig. 56.9. The expression for the reference voltage is

$$V_{\text{REF}} = \frac{R_2 V_{DZ} + V_{BE}(R_1 - 2R_2)}{R_1 + R_2} \tag{56.13}$$

where $V_{BE1} = V_{D1} = V_{D2} = V_{BE}$. By taking the partial derivative of V_{REF} with respect to temperature and setting it equal to zero, a relationship can be determined from which a zero temperature coefficient for the reference voltage can be attained and this is

$$\frac{R_1 - 2R_2}{R_2} = -\frac{TC_{VDZ}}{TC_{VBE}} \tag{56.14}$$

where TC_{VZ} and TC_{VBE} are the temperature coefficients of the zener diode and base-emitter voltage.

An alternative to this is one of the many variations of bandgap references available. A simple bandgap reference is depicted in Fig. 56.10.

Bandgap circuits also operate on a principle of cancellation of temperature coefficients. Generally, a voltage is developed that is a scaled value of V_T. This scaled value has a well-defined temperature coefficient that is the scaling constant times the temperature coefficient of V_T, which is positive. This voltage is added to base–emitter voltage that has a negative temperature coefficient. The scaling factor is chosen so that the sum of the temperature coefficients is zero. The output is then taken across the two voltages to produce a voltage with a temperature coefficient of approximately zero. Generally, the output voltage has the form

$$V_{\text{REF}} = V_{BE} + KV_T \tag{56.15}$$

If the temperature coefficient of V_{BE} is taken to be –2 mV/°C and the temperature coefficient of V_T is taken to be $k/q \approx +0.085$ mV/°C, this results in a value for K of about 23.52. This gives a value for V_{OUT} of about 0.7 V + 23.52(25.9 mV) = 1.3 V, close to the bandgap voltage of silicon, and gives rise to the nomenclature of bandgap references.

For the circuit in Fig. 56.10, we assume that Q_1 and Q_2 operate at different current densities. This is done either by operating Q_1 and Q_2 at different collector current levels, with matched emitter areas, or by operating them at the same collector currents with emitter areas being mismatched. A voltage ΔV_{BE} is developed across R_3 and then current through R_3 and R_2, neglecting the effects of β, is $\Delta V_{BE}/R_3$. This gives $V_{\text{REF}} = \Delta V_{BE} R_2/R_3 + V_{BE3}$. Since $\Delta V_{BE} = V_T \ln(J_1/J/_2)$, this gives the constant K as being $R_2/R_3 \ln(J_1/J_2)$.

© 2003 by CRC Press LLC

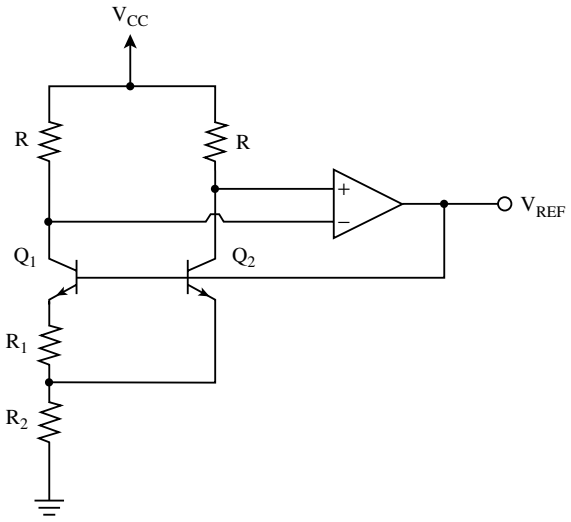

FIGURE 56.11 Improved bandgap reference.

An improved bandgap reference is depicted in Fig. 56.11. This reference forms a basic building block for several commercial voltage references.

In this circuit, I_{C1} and I_{C2} are forced equal by the high-gain amplifier operating with negative feedback. The current densities of Q_1 and Q_2 are made unequal by sizing the emitter areas of Q_1 and Q_2 differently. In this case, $A_1 = nA_2$. This means $\Delta V_{BE} = V_T \ln(J_1/J_2) = V_T \ln(n)$. The voltage drop across R_2 is $\Delta V_{BE} R_2/R_1$. Finally, $V_{REF} = V_{BE} + V_T \ln(n) R_2/R_1$. Thus, in this case, $K = R_2/R_1 \ln(n)$.

Process and Modeling Parameter Desensitization

It is given that fabricated devices exhibit deviation from some "nominal" value assumed in the fabrication process. In designing process-insensitive and model-parameter-insensitive circuits, it is sought to minimize the effects of variation-process- and model-parameters-desensitization techniques. A good example of this is the simple current mirror with emitter degeneration shown in Fig. 56.12.

If I_{REF} and R_1 are such that the voltage drop across V_{BE1} is small in comparison, then the dominant voltage at V_B is $I_{REF} R_1$. Likewise, if R_2 and I_{OUT} are such that the voltage drop across V_{BE2} can be neglected, then we have $I_{REF} R_1 \approx I_{OUT} R_2$ and

$$I_{OUT} \approx \frac{R_2}{R_1} I_{REF} \tag{56.16}$$

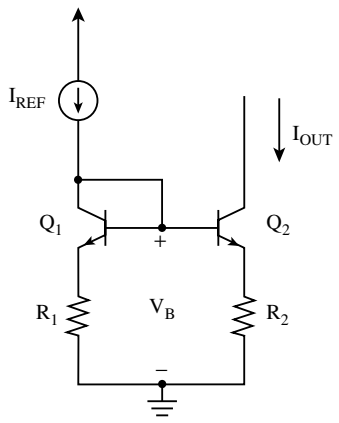

FIGURE 56.12 Simple current mirror with emitter degeneration.

© 2003 by CRC Press LLC

For the simple current mirror, neglecting β and considering the possibility of mismatched emitter areas, we have

$$I_{OUT} \approx \frac{A_2}{A_1} I_{REF} \tag{56.17}$$

Since resistors can be matched to ±.1 percent and NPN matching for transistors can be as poor as ±1 percent, the current mirror with emitter degeneration is less susceptible to processing errors.

A wealth of information is available in the literature. Further depth into bias circuit behavior is provided in the accompanying references for this section.

56.2 Canonic Cells of Linear Bipolar Technology

John Choma, Jr. and J. Trujillo

Introduction

The circuit configurations of linear signal processors realized in bipolar technology are as diverse as are the system operating requirements that these circuits are designed to satisfy. Despite topological diversity, most practical open-loop linear bipolar circuits are derived from interconnections of surprisingly few basic subcircuits. These subcircuits include the diode-connected bipolar junction transistor (BJT), the common-emitter amplifier, the common-base amplifier, the common-emitter-common base cascode, the emitter follower, the Darlington connection, and the balanced differential pair. Because these open-loop subcircuits underpin linear bipolar circuit technology, they are rightfully termed the *canonic cells* of linear bipolar circuit design.

By examining the low-frequency performance characteristics of the canonic cells of linear bipolar technology, this section achieves two objectives. First, the forward gain, the driving point input resistance, and the driving point output resistance are catalogued for each canonic circuit. This information produces Thévenin and Norton I/O port equivalent circuits that expedite the analysis and design of multistage electronics. Second, the forthcoming work establishes a basis for prudent circuit design in that all analytical results are studied by highlighting the attributes and uncovering the limitations of each cell. The understanding that resultantly accrues paves the way toward systematic design procedures that yield optimal circuit architectures capable of circumventing observed subcircuit shortcomings.

Small-Signal Model

The fundamental tool exploited in the analyses that follow is the low-frequency small-signal equivalent circuit of a bipolar junction transistor shown in Fig. 56.13(a). This equivalent circuit, which applies to

© 2003 by CRC Press LLC

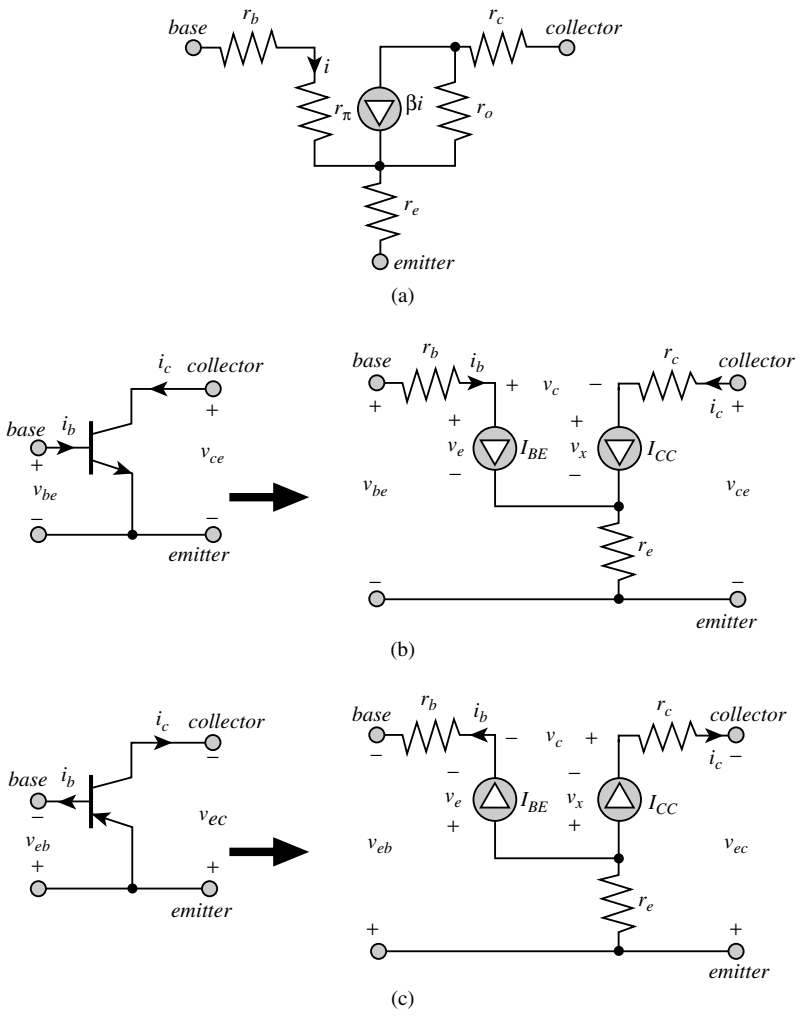

FIGURE 56.13 (a) Low-frequency, small-signal model of a bipolar junction transistor. (b) Low-frequency, large-signal model of an NPN bipolar junction transistor. (c) Low-frequency, large-signal model of a PNP bipolar junction transistor.

NPN and PNP discrete component and monolithic transistors, is derived from the low-frequency, large-signal NPN BJT model offered in Fig. 56.13(b) [1], [2]. As is depicted in Fig. 56.13(c), the PNP large-signal transistor model is topologically identical to its NPN counterpart. The only difference between the two models is a reversal in the direction of all controlled current sources and branch currents and a reversal in polarity of all assigned branch and port voltages.

The large-signal models in Fig. 56.13(b) and (c) are simplified to reflect transistor biasing that assures nominally linear device operation for all values of applied input signal voltages. A necessary condition for linear operation is that the internal emitter–base junction voltage v_e be at least as large as the threshold voltage, say v_γ, of the junction for all time; that is

$$v_e(t) \geq v_\gamma \quad \text{for all time } t \tag{56.18}$$

For silicon transistors, v_γ is typically in the neighborhood of 700 to 750 mV. A second condition underlying transistor operation in its linear regime is that the internal base–collector junction voltage v_c is never positive, that is

© 2003 by CRC Press LLC

$$v_c(t) \le 0 \quad \text{for all time } t \tag{56.19}$$

In the models of Fig. 56.13(b) and (c), r_b represents the **effective base resistance** of a BJT, r_c is its net *internal* **collector resistance**, and r_c is the net *internal* **emitter resistance**. All three resistances, and particularly r_b, decrease monotonically with increasing quiescent base and collector currents, I_{BQ} and I_{CQ}, respectively [3], [4]. The collector resistance also decreases with increases in the intrinsic collector–emitter voltage v_x. Large base, collector, and emitter resistances conduce reduced circuit gain, diminished gain–bandwidth product, and increased electrical noise. In view of these observations and in the interest of formulating a mathematically tractable analysis that produces conservative estimates of bipolar circuit performance, these resistances are usually interpreted as constants equal to their respective low current, low voltage values.

In a monolithic fabrication process, unacceptably large internal device resistances can be reduced by exploiting the fact that r_b, r_c, and r_e are inversely proportional to the emitter–base junction injection area. This area is a designable parameter chosen to ensure that the transistor in question conducts the proper density of collector current. Unfortunately, the engineering price potentially paid for a reduction of device resistances through increases in junction area is circuit response speed, since the capacitances associated with transistor junctions are directly proportional to device injection area.

The current I_{BE} in Fig. 56.13(b) and (c) is given approximately by

$$I_{BE} = \frac{A_E J_S}{\beta_F} e^{v_e/n_f V_T} \tag{56.20}$$

where A_E is the aforementioned *emitter–base junction area*, J_s, is the *density of transistor saturation current*, and β_F is the *forward short-circuit current transfer ratio*. Moreover, n_f is the *injection coefficient of the emitter–base junction*, v_e is the *internal junction voltage* serving to forward bias the emitter–base junction, and

$$V_T = \frac{kT_j}{q} \tag{56.21}$$

is the **Boltzmann voltage**. In the last expression, k is *Boltzmann's constant* [1.38 (10^{-23}) J/K], T_j is the *absolute temperature of the emitter–base junction*, and q is the *magnitude of electron charge* [1.6 (10^{-19}) C].

The current I_{CC} is derived from [5]

$$I_{CC} = A_E J_S e^{v_e/n_f V_T} \left(1 - \frac{I_{CC}}{I_{KF}}\right)\left(1 + \frac{v_x}{V_{AF}}\right) \tag{56.22}$$

where I_{KF}, which is proportional to A_E, is the **forward knee current** of the transistor [6], and V_{AF}, which is independent of A_E, is the *forward Early voltage* [7]. Note that the base current i_b is the current I_{BE}, while the collector current i_c is I_{CC}. Thus, the *static* **common-emitter current** gain (often referred to as the **DC beta**), h_{FE}, of a bipolar junction transistor is

$$h_{FE} = \frac{i_c}{i_b} = \frac{I_{CC}}{I_{BE}} = \beta_F \left(1 - \frac{i_c}{I_{KF}}\right)\left(1 + \frac{v_x}{V_{AF}}\right) \tag{56.23}$$

which is functionally dependent on both the collector current and the intrinsic collector–emitter voltage.

Unlike the base, collector, and emitter resistances, the resistance r_π in the small-signal model of Fig. 56.13(a) is not an ohmic branch element. It is a mathematical resistance that arises from the Taylor series expansion of the current I_{BE} about the **quiescent operating point**, or *Q-point* of the transistor. In particular, r_π, which is known as the **emitter–base junction diffusion resistance**, derives from

© 2003 by CRC Press LLC

$$\frac{1}{r_\pi} = \left.\frac{\partial I_{BE}}{\partial v_e}\right|_Q \tag{56.24}$$

where it is understood that the indicated derivative is evaluated at the *Q*-point of the device. This *Q*-point is unambiguously defined by the *zero signal,* or *static*, values of the base current I_{BQ}, the collector current I_{CQ}, and the internal collector–emitter voltage V_{XQ}. Using (56.20), (56.23), and the fact that $i_b \equiv I_{BE}$,

$$r_\pi = \frac{h_{FE} n_f V_T}{I_{CQ}} \tag{56.25}$$

The inverse dependence of r_π on quiescent collector current renders r_π large at low collector current biases.

Similarly, r_o, the *forward Early resistance,* derives from

$$\frac{1}{r_o} = \left.\frac{\partial I_{CC}}{\partial v_x}\right|_Q \tag{56.26}$$

It can be shown that

$$r_o = \frac{V_{XQ} + V_{AF}}{I_{CQ}\left(1 - \dfrac{I_{CQ}}{I_{KF}}\right)} \tag{56.27}$$

Like r_π, r_o is also large for low-level biasing.

Finally, the parameter β, which is the *low-frequency small-signal common-emitter short current gain* (often more simply referred to as the **AC beta**) of the transistor, is

$$\beta = g_m r_\pi \tag{56.28}$$

where g_m, the *forward transconductance* of a BJT is

$$g_m = \left.\frac{\partial I_{CC}}{\partial v_e}\right|_Q \tag{56.29}$$

From (56.22), (56.23), (56.25), and (56.28),

$$\beta = h_{FE}\left(1 - \frac{I_{CQ}}{I_{KF}}\right) \tag{56.30}$$

To the extent that $I_{CQ} \ll I_{KF}$, β is nominally independent of both *Q*-point collector current and emitter–base junction injection area.

Single-Input-Single-Output Canonic Cells

Diode-Connected Transistor

The simplest of the single-input-single-output, or *single-ended* canonic cells for linear bipolar circuits is the *diode-connected transistor* offered in Fig. 56.14(a). This transistor connection emulates the volt–ampere characteristics of a conventional PN junction diode. It can therefore be used in rectifier, voltage regulator, dc level shifting, and other applications that exploit conventional diodes. But unlike a conventional PN junction diode, the diode-connected transistor proves especially useful in current mirror

(c) Low-frequency, small-signal model of the diode-connected transistor in (a). The ratio V_{test}/I_{test} is the small-signal resistance R_d presented at the terminals of the diode-connected transistor. (d) The model in (c) approximated for the case of very large Early resistance.

biasing schemes. These and other similar circuits require that the base–emitter terminal voltage, v, of the diode track the base–emitter terminal voltage of a second, presumably identical transistor, over wide variations in junction operating temperatures.

If the voltages dropped across the internal base, collector, and emitter resistances are small, the intrinsic emitter–base junction voltage, v_e, is approximately the indicated terminal voltage, v. Moreover, the intrinsic base–collector junction voltage, v_c, is essentially zero. It follows that for $v > v_\gamma$, the transistor in the diode connection operates in its linear regime.

In the subject diagram, the terminal voltage v is depicted as a superposition of a static voltage, V_Q, and a signal component, v_s. The resultant diode current, i, is a superposition of a quiescent current, I_Q, and a signal current, i_s. The quiescent components of diode voltage and current arise from static power supplied to the diode circuit to ensure that the diode-connected device operates in its linear regime. On the other hand, the signal components are established by a time-varying signal applied to the input port of the circuit in which the diode-connected transistor is embedded. In order to achieve reasonably linear processing of the applied input signal, the value of V_Q must be such as to ensure that $v = V_Q + v_s > v_\gamma$ for all values of the time-varying signal voltage v_s. Since v_s can be positive or negative at any instant of time, the requirement $V_Q + v_s > v_\gamma$ mandates that the amplitude of v_s be sufficiently small.

The immediate impact of the small-signal condition corresponding to the linearity requirement $V_Q + v_s > v_\gamma$ is that the small-signal volt–ampere characteristics of the diode are linear. And since the diode is a two-terminal element, these characteristics can be modeled at low-signal frequencies by a simple resistance, say R_d, as suggested by the single-element macromodel offered in Fig. 56.14(b). The resistance in the latter figure can be determined by using the small-signal transistor model of Fig. 56.13(a) to construct the small-signal equivalent circuit of the diode-connected transistor show in Fig. 56.14(c). In this figure, the ratio of the test voltage, V_{test}, to the test current, I_{test}, is the desired resistance, R_d. A straightforward KVL analysis confirms that

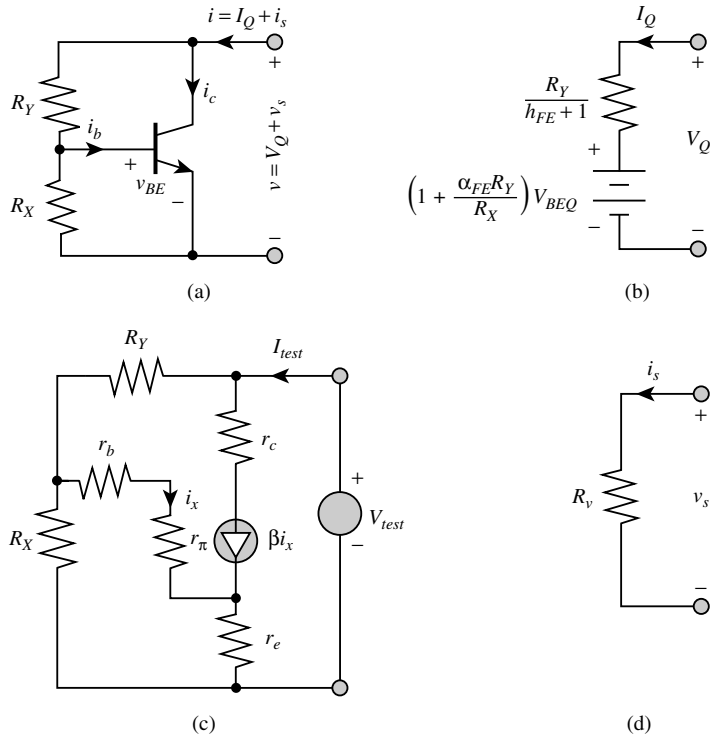

FIGURE 56.15 (a) Schematic diagram of V_{BE} multiplier. (b) DC macromodel of the multiplier in (a). (c) Low-frequency small-signal equivalent circuit of the Y_{BE} multiplier. (d) The small-signal equivalent resistance at the terminals of the V_{BE} multiplier.

$$R_d = \frac{V_{\text{test}}}{I_{\text{test}}} = r_e + \frac{(r_o + r_c) \| (r_b + r_\pi)}{1 + \dfrac{\beta r_o}{r_o + r_c + r_b + r_\pi}} \tag{56.31}$$

Typically, r_o is 25 kΩ or larger, r_c is smaller than 75 Ω, r_b is of the order of 100 Ω, and r_π is in the range of 1 kΩ for a minimal geometry device. It follows that $r_o \gg (r_c + r_b + r_\pi)$, and R_d can be approximated as

$$R_d \approx r_e + \frac{r_b + r_\pi}{\beta + 1} \tag{56.32}$$

Note that this terminal resistance is of the order of the low tens of ohms. For example, if $r_b = 100$ Ω, $r_\pi = 1.2$ kΩ, $r_e = 1$ Ω, and $\beta = 100$, $R_d = 13.9$ Ω. It is instructive to note that the approximation, $r_o \gg (r_c + r_b + r_\pi)$, collapses the model in Fig. 56.14(c) to the structure in Fig. 56.14(d), from which (56.32) follows immediately.

A variation of the diode scheme is the so-called V_{BE} *multiplier* depicted in Fig. 56.15(a). This circuit finds extensive use in regulator and level shifting applications that require either a series interconnection of more than one diode or a circuit branch voltage drop whose requisite value is a nonintegral multiple of the base–emitter terminal voltage of a single diode.

The circuit under consideration establishes a static terminal voltage, V_Q, whose value is a designable multiple of the static base–emitter terminal voltage, V_{BEQ}. To confirm this contention, observe that for static operating conditions, V_Q is

© 2003 by CRC Press LLC

$$V_Q = R_Y\left(I_Q - I_{CQ}\right) + V_{BEQ} \tag{56.33}$$

where the voltage component V_{BEQ} of the net base-emitter terminal voltage v_{be} is

$$V_{BEQ} = R_X\left[I_Q - \left(\frac{h_{FE}+1}{h_{FE}}\right)I_{CQ}\right] \tag{56.34}$$

The current, I_{CQ}, is the static component of the net collector current, i_c, and h_{FE} is the collector current to base current transfer ratio defined by (56.23). An elimination of I_{CQ} from the foregoing two expressions leads to

$$V_Q = \left(1 + \frac{\alpha_{FE}R_Y}{R_X}\right)V_{BEQ} + \left(\frac{R_Y}{h_{FE}+1}\right)I_Q \tag{56.35}$$

where

$$\alpha_{FE} = \frac{h_{FE}}{h_{FE}+1} \tag{56.36}$$

is known as the **static common-base current gain** (often referred to as the **DC alpha**) of a BJT. Equation (56.35) suggests that the static electrical behavior of the V_{BE} multiplier approximates a battery, whose voltage is controllable by the resistive ratio R_Y/R_X. The internal resistance of this effective battery is inversely dependent on $(h_{FE} + 1)$, and is therefore small. The macromodel in Fig. 56.15(b) reflects the foregoing electrical interpretation. Note the for $R_Y = 0$ and R_X infinitely large, the circuit in Fig. 56.15(a) collapses to the diode-connected transistor of Fig. 56.14(a), and V_Q understandably reduces to V_{BEQ}, the quiescent base–emitter terminal voltage of a diode-connected transistor.

For $V_Q + v_s > v_\gamma$, the transistor in the V_{BE} multiplier operates linearly. Accordingly, the pertinent small-signal terminal characteristics emulate a resistance, say R_v, which can be determined by applying the model of Fig. 56.13(a) to the circuit in Fig. 56.15(a). The resultant equivalent circuit, simplified to reflect the realistic assumption of large r_o, is shown in Fig. 56.15(c) while Fig. 56.15(d) postulates the small-signal macromodel. An analysis of the circuit in Fig. 56.15(c) reveals that

$$R_v \approx R_X \| R_d + R_Y\left[1 - \frac{\alpha R_X}{R_X + R_d}\right] \tag{56.37}$$

where

$$\alpha = \frac{\beta}{\beta+1} \tag{56.38}$$

is the *low-frequency, small-signal, common-base, short-circuit current gain* (more simply referred to as the **ac alpha**) of the transistor, and R_d is the resistance given by (56.31). For $R_Y = 0$, $R_X = \infty$ reduces R_v to the expected result, $R_v \approx R_d$. Note further that for $\beta \gg 1$ (which makes $\alpha \approx 1$) and $R_d \gg R_X$, R_v is essentially the small-signal resistance presented at the terminals of a diode-connected transistor.

Common Emitter Amplifier

The most commonly used single-ended canonic gain cell is the *common-emitter amplifier*, whose NPN and PNP AC schematic diagrams are shown in Fig. 56.16(a) and (b), respectively. The AC schematic diagram delineates only the signal paths of a circuit. Thus, the biasing subcircuits required for linear operation of the transistors are not shown, thereby affording topological and analytical simplification.

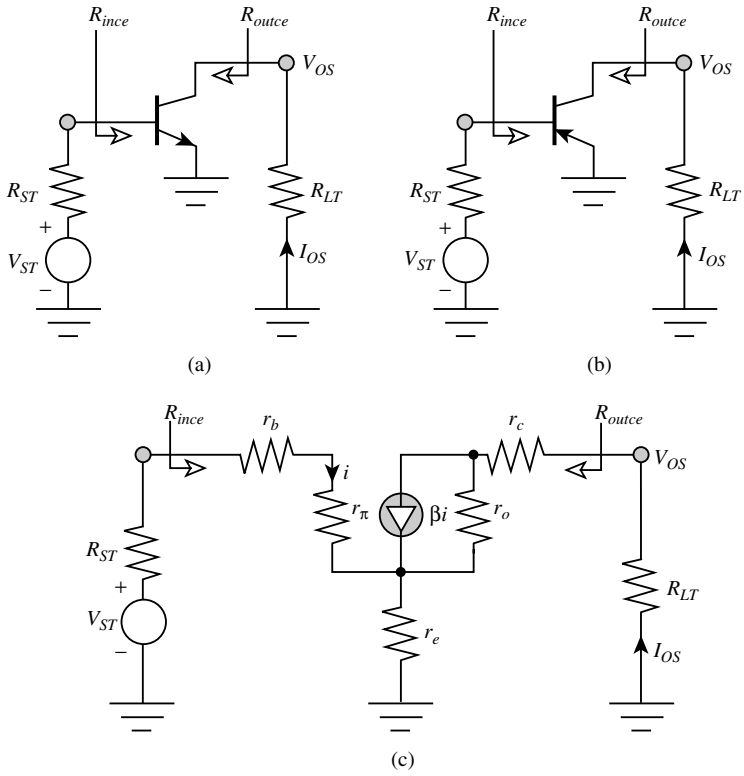

FIGURE 56.16 (a) AC schematic diagram of an NPN common-emitter amplifier. (b) AC schematic diagram of a PNP common-emitter amplifier. (c) Small-signal, low-frequency equivalent circuit of the common-emitter amplifier.

This simplification is accomplished without loss of engineering generality, for the results produced by an analysis of the AC schematic diagram reveal all salient performance traits of the common-emitter configuration.

The common-emitter amplifier is distinguished by the facts that signal is applied to the base of the transistor, and the resultant response is extracted as either the voltage, V_{OS}, or the current, I_{OS}, at the collector port. The effective load resistance terminating the collector to ground is indicated as R_{LT}, while the signal source is represented as a traditional Thévenin equivalent circuit. Alternatively, a Norton representation of the input source can be used, with the understanding that the Norton equivalent signal current, say I_{ST}, is simply the ratio of the Thévenin signal voltage, V_{ST}, to the Thévenin source resistance, R_{ST}.

The common-emitter amplifier is capable of large magnitudes of voltage and current gains, moderately large input resistance, and very large driving point output resistance. An analytical confirmation of these contentions begins by drawing the small-signal equivalent circuit of the amplifier. This structure is given in Fig. 56.16(c) and is valid for either the NPN or the PNP versions of the amplifier. An analysis of the small-signal model yields a voltage gain,

$A_{vce} = V_{OS}/V_{ST}$, of

$$A_{vce} = -\left\{ \frac{\left(\beta - \frac{r_e}{r_o}\right)\left(\frac{r_o}{r_o + r_c + r_e + R_{LT}}\right) R_{LT}}{R_{ST} + r_b + r_\pi + \left(\frac{\beta r_o}{r_o + r_c + R_{LT}} + 1\right)\left[r_e \| \left(r_o + r_c + R_{LT}\right)\right]} \right\} \tag{56.39}$$

© 2003 by CRC Press LLC

This relationship can be simplified by exploiting the fact that the internal resistance r_e of a transistor is small. Thus, $\beta \gg r_e/r_o$ and $r_e \gg (r_o + r_c + R_{LT})$, thereby implying

$$A_{vce} \approx -\frac{\beta_{\text{eff}} R_{LT}}{R_{ST} + r_b + r_\pi + (\beta_{\text{eff}} + 1) r_e} \tag{56.40}$$

where

$$\beta_{\text{eff}} \triangleq \beta \left[\frac{r_o}{r_o + r_c + R_{LT}} \right] \tag{56.41}$$

is an attenuated version of the AC beta for the utilized transistor. This effective beta approximates β itself, since $r_o \gg (r_c + R_{LT})$ is typical.

In concert with earlier arguments, (56.40) confirms a diminished magnitude of gain for large internal device resistances. Note also that phase inversion, as inferred by the negative sign in either (56.39) or (56.40) prevails between the Thévenin source voltage, V_{ST}, and the voltage signal response, V_{OS}. Finally, observe that large magnitudes of voltage gain are possible in the common-emitter orientation when β_{eff} is sufficiently large.

The driving point input resistance, R_{ince}, of the common-emitter amplifier can be determined as the ratio V_x/I_x for the test structure depicted in Fig. 56.17(a). It is easily shown that

$$R_{ince} = r_b + r_\pi + (\beta_{\text{eff}} + 1)\left[r_e \| (r_o + r_c + R_{LT}) \right] \tag{56.42}$$

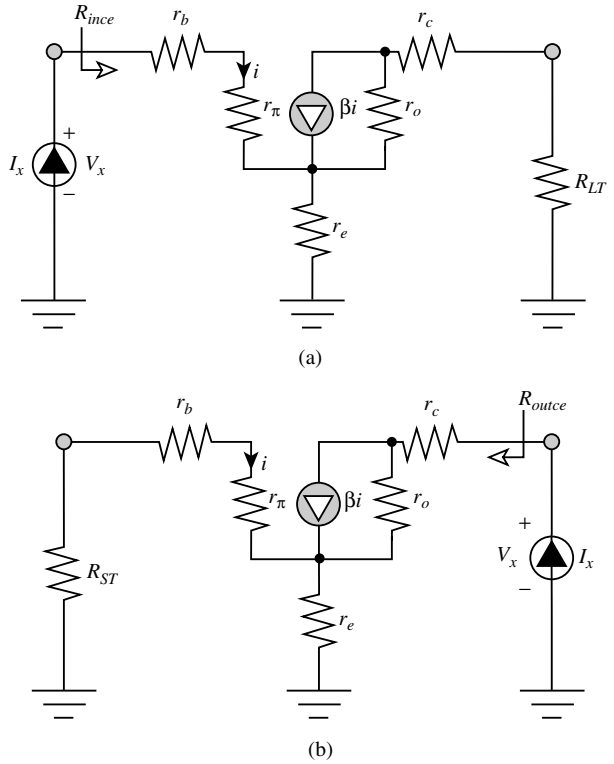

FIGURE 56.17 (a) Small-signal test structure used to determine the driving point input resistance of the common-emitter amplifier. (b) Small-signal test structure used to determine the driving point output resistance of the common-emitter amplifier.

© 2003 by CRC Press LLC

Since $r_e \lll (r_o + r_c + R_{LT})$, (56.42) collapses to

$$R_{ince} \approx r_b + r_\pi + (\beta_{\text{eff}} + 1) r_e \tag{56.43}$$

Similarly, the driving point output resistance, R_{outce}, is derived as the V_x/I_x ratio of the equivalent circuit offered in Fig. 56.17(b). In particular,

$$R_{outce} = r_c + r_e \left\| \left(r_\pi + r_b + R_{ST} \right) + \left(\frac{\beta r_e}{r_e + r_\pi + r_b + R_{ST}} + 1 \right) r_o \right. \tag{56.44}$$

Since the model resistance r_π varies inversely with collector bias current, R_{ince} is moderately large when the common-emitter transistor is biased at low currents. On the other hand, R_{outce} is very large since (56.44) confirms $R_{outce} > r_o$.

When the foregoing results are simplified to reflect the practical special case of a very large forward Early resistance, r_o, the cumbersome small-signal equivalent circuit of Fig. 56.16(c) reduces to a *small-signal macromodel* useful for design-oriented circuit analysis of multistage amplifiers. To this end, note that a large r_o produces a driving point common-emitter input resistance that is independent of the terminating load resistance. Such independence implies no internal feedback from the output to input ports. It follows that the small-signal volt–ampere characteristics at the input port of a common-emitter amplifier can be modeled approximately by a simple resistance of value, R_{ince}, as defined by (56.43). On the other hand, the large driving point output resistance R_{outce} suggests that a prudent output port model of a common emitter stage is a Norton equivalent circuit. The Norton, or short-circuit, output current is proportional to the applied input signal voltage, V_{ST}, as depicted in Fig. 56.18(a). Alternatively, it can be expressed as a proportionality of the Norton input signal current, I_{ST}, as suggested in Fig. 56.18(b). In the former figure, the Norton current is

$$G_{fce} V_{ST} = \lim_{R_{LT} \to 0} I_{OS} = \lim_{R_{LT} \to 0} \left(-\frac{V_{OS}}{R_{LT}} \right) = \lim_{R_{LT} \to 0} \left(-\frac{A_{vce} V_{ST}}{R_{LT}} \right) \tag{56.45}$$

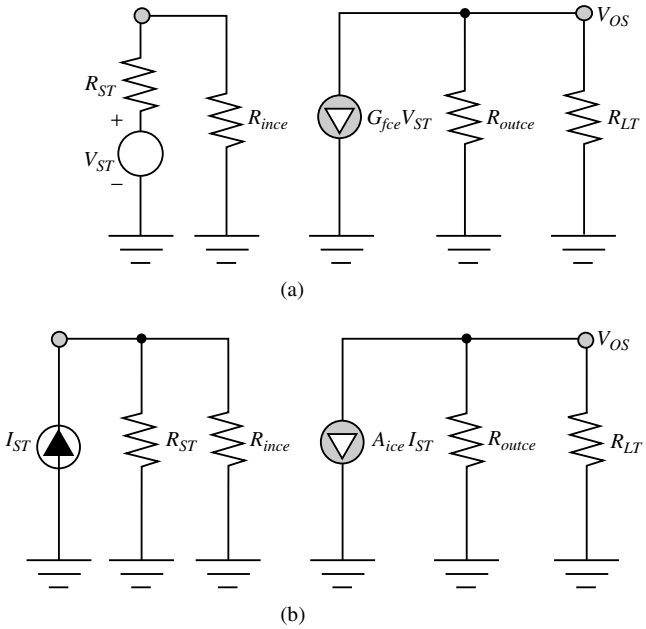

FIGURE 56.18 (a) Small-signal macromodel of a common-emitter amplifier in which the Norton output port circuit uses a voltage-controlled current source. (b) Small-signal macromodel of a common-emitter amplifier in which the Norton output port circuit uses a current-controlled current source.

© 2003 by CRC Press LLC

Subject to the assumption of large r_o,

$$G_{fce} = \lim_{R_{LT}\to 0}\left(-\frac{A_{vce}}{R_{LT}}\right) \approx \frac{\beta}{R_{ST} + r_b + r_\pi + (\beta+1)r_e} \tag{56.46}$$

Recalling (56.28), this effective forward transconductance of the amplifier can be expressed in terms of the transconductance, g_m of the transistor utilized in the amplifier. Specifically,

$$G_{fce} \approx \frac{g_m}{1 = g_m r_e + \dfrac{r_e + r_b + R_{ST}}{r_\pi}} \tag{56.47}$$

In the macromodel of Fig. 56.18(a), R_{outce} is very large by virtue of large r_o. Accordingly, the parallel combination of R_{outce} and R_{LT} is essentially R_{LT}, thereby implying an approximate common-emitter voltage gain of

$$A_{vce} \approx -G_{fce}R_{LT} \tag{56.48}$$

For the alternative macromodel in Fig. 58.18(b), the Norton current is

$$A_{ice}I_{ST} = A_{ice}\left(\frac{V_{ST}}{R_{ST}}\right) = \lim_{R_{LT}\to 0} I_{OS} = G_{fce}V_{ST} \tag{56.49}$$

Since $V_{ST} = R_{ST}I_{ST}$, it follows that A_{ice} is, for large r_o,

$$A_{ice} = G_{fce}R_{ST} \approx \beta\left[\frac{R_{ST}}{R_{ST} + r_b + r_\pi + (\beta+1)r_e}\right] \tag{56.50}$$

Note that the Norton current proportionality A_{ice}, which is, in fact, the approximate ratio of the indicated output current, I_{OS}, to the Norton source current, I_{ST}, in the common-emitter configuration, is always smaller than β.

Example 1. Transistor Q_1 in the amplifier depicted in Fig. 56.19(a) is fundamentally a common-emitter configuration since input signal is applied to its base terminal and the output voltage signal response is extracted at its collector. The amplifier uses coupling capacitors C_i and C_o at its input and output ports. The input coupling capacitor, C_i, blocks the flow of static current in the source signal branch consisting of the series interconnection of the voltage, V_S, and the Thévenin source resistance, R_S. Accordingly, C_i, precludes R_S from affecting the biasing of both transistors used in the amplifier. Similarly, the output coupling capacitor, C_o, blocks the flow of static current in the external load resistance, R_L. Thus, both C_i and C_o can be viewed as open circuits for dc considerations. But simultaneously, these capacitors can be rendered transparent for AC situations by choosing them sufficiently large so that they emulate short circuits at the lowest frequency, say f_l, of signal-processing interest. In this problem, it is tacitly assumed that C_i and C_o, which are perfect DC open circuits, behave as good approximations of AC short circuits.

The subject amplifier utilizes a diode-connected transistor ($Q2$) for temperature compensation of the static collector current conducted by transistor $Q1$. For simplicity, assume that these two transistors have identical small-signal parameters of r_b = 90 Ω, r_c = 55 Ω, r_π = 970 Ω, r_o = 42 kΩ, and β = 115. Let the indicated circuit parameters be R_1 = 2.2 kΩ, R_2 = 1.3 kΩ, R_{EE} = 75 Ω, R_{CC} = 3.9 kΩ, R_L = 1.0 kΩ, and R_S = 300 Ω. Assuming that these circuit variables ensure linear operation of both devices, determine the small-signal voltage gain, $A_v = V_{OS}/V_S$, the driving point input resistance, R_{in}, and the driving point output

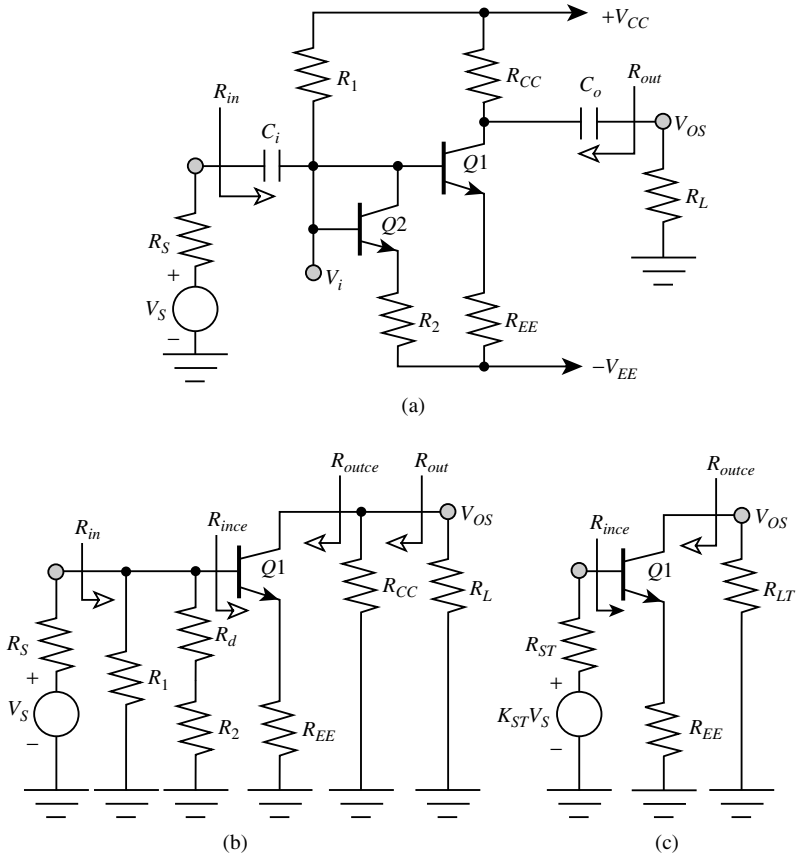

FIGURE 56.19 (a) Common-emitter amplifier with capacitively coupled input and output signal ports. (b) AC schematic diagram of the amplifier in (a). (c) Simplified AC schematic diagram of the amplifier in (a).

resistance, R_{out}, of the amplifier. Finally, calculate the requisite minimum values of the input and output coupling capacitors, C_i and C_o, such that the lowest frequency f_l of interest is 500 Hz.

Solution.

1) The first step of the solution process entails drawing the AC schematic diagram of the subject amplifier. By casting this diagram in the form of the canonic cell shown in Fig. 56.16(a), the gain and resistance expressions provided above can be exploited directly to assess the small-signal performance of the circuit at hand. Such a solution tack maximizes design-oriented understanding by avoiding the algebraic tedium implicit to an analysis of the entire small-signal equivalent circuit of the amplifier.

To the foregoing end, observe that transistor $Q2$ operates in its linear regime as a diode. It can therefore be viewed as the two terminal resistance R_d, given by (56.31) or (56.32). Since the Early resistance is large, the latter expression can be used to arrive at $R_d = 10.64\ \Omega$.

Since the power supply voltage, V_{EE}, is presumed ideal in the sense that it contains no signal component, the resultant series combination of R_d and R_2 returns base of transistor $Q1$ to ground, as depicted in Fig. 56.19(b). Similarly, R_1 appears in shunt with the series interconnection of R_d and R_2, since V_{CC}, like V_{EE}, is also presumed to be an ideal constant (zero signal component) source of voltage. The AC schematic diagram of the input port is completed by noting that the AC short-circuit nature of the coupling capacitance C_i effectively connects the Thévenin representation of the signal source directly between the base of $Q1$ and ground.

© 2003 by CRC Press LLC

At the output port of the amplifier, R_{CC} connects between the collector and ground since, as already exploited, V_{CC} is an AC short circuit. Moreover, the external load resistance, R_L, shunts R_{CC}, as shown in Fig. 56.19(b), because C_o behaves as an AC short circuit. The AC schematic diagram is completed by inserting the emitter degeneration resistance R_{EE} as a series element between ground and the emitter of transistor $Q1$.

2) The diagram in Fig. 56.19(b) can be straightforwardly collapsed to the simplified topology of Fig. 56.19(c). In the latter circuit, the effective load resistance, R_{LT} is

$$R_{LT} = R_{CC} \| R_L = 795.9\ \Omega$$

At the input port, the Thévenin resistance seen by the base of $Q1$ is

$$R_{ST} = R_1 \| \left(R_d + R_2\right) \| R_S = 219.7\ \Omega$$

while the corresponding Thévenin signal voltage can be expressed as $K_{ST}V_S$, where the voltage divider K_{ST} is

$$K_{ST} = \frac{R_1 \| \left(R_d + R_2\right)}{R_1 \| \left(R_d + R_2\right) + R_S} = 0.733$$

The implication of this calculation is that insofar as the active transistor $Q1$ is concerned, the biasing resistance R_1 and R_2 cause a loss of more than 25 percent of the applied input signal.

3) The resultant AC schematic diagram in Fig. 56.19(c) is virtually identical to the canonic topology in Fig. 56.16(a). Indeed, if the circuit resistance R_{EE} is absorbed into $Q1$, where it appears in series with the internal emitter resistance r_e, the diagram is identical to the AC schematic diagram of the canonic common-emitter cell. Since $(r_e+R_{EE}) = 76.5\ \Omega$, is better than 560 times smaller than the resistance sum, $(r_o+r_c+R_{LT}) = 42.85\ \text{k}\Omega$, and $\beta = 115$ is more than 63,000 times larger than the resistance ratio $(r_e+R_{EE})/r_o = 0.00182$, the simplified expression in (56.40) can be used to evaluate the voltage gain $V_{OS}/K_{ST}V_S$ in Figure 56.19(c). From (56.41), the effective small-signal beta is $\beta_{\text{eff}} = 112.7$. Then, with r_e replaced by $(r_e + R_{EE}) = 76.5\ \Omega$ (56.40) gives

$$A_{vce} = \frac{V_{OS}}{K_{ST}V_S} = -8.99\ \text{V/V}$$

It follows that the actual voltage gain of the amplifier in Fig. 56.19(a) is

$$A_v = \frac{V_{OS}}{V_S} = K_{ST}A_{vce} = -6.59\ \text{V/V}$$

A better design, in the sense of achieving an adequate desensitization of circuit transfer characteristics with respect to parametric uncertainties, entails the use of a slightly larger emitter degeneration resistance R_{EE} selected to ensure that $(\beta_{\text{eff}}+1)(r_e+R_{EE}) \approx \beta_{\text{eff}}\, R_{EE} \gg (R_{ST}+r_b+r_\pi)$. For such a design, (56.40) produces

$$A_v \approx -\frac{K_{ST}R_{LT}}{R_{EE}}$$

which is nominally independent of transistor parameters.

© 2003 by CRC Press LLC

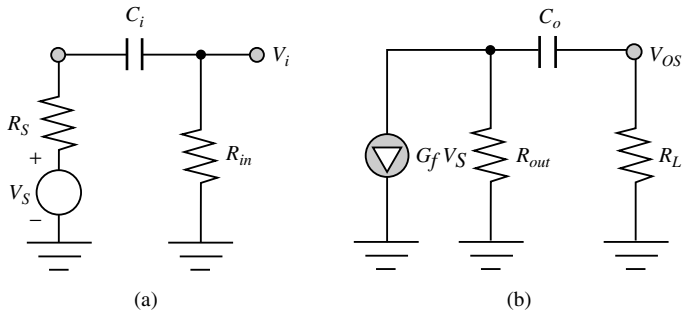

FIGURE 56.20 (a) Input port macromodel used in the calculation of the input coupling capacitor C_i. (b) Output port macromodel used to calculate the output coupling capacitor C_o.

4) With r_e replaced by $(r_e + R_{EE}) = 76.5\ \Omega$, (56.43) gives for the input resistance seen looking into the base of transistor $Q1$ in Fig. 56.19(c), $R_{ince} = 9.76\ \text{k}\Omega$. It follows that the driving point input resistance seen by the source circuit in Fig. 56.19(b) is

$$R_{\text{in}} = R_1 \| (R_d + R_2) \| R_{ince} = 757.6\ \Omega$$

5) The output resistance, R_{outce}, seen looking into the collector of transistor $Q1$ in the diagram of Fig. 56.19(c) is derived from (56.44). With r_e replaced by $(r_e + R_{EE}) = 76.5\ \Omega$, $R_{outce} = 2.49\ \text{M}\Omega$. The resultant driving point output resistance seen by the load circuit in Fig. 56.19(b) is

$$R_{\text{out}} = R_{CC} \| R_{outce} = 3{,}894\ \Omega$$

The circuit output resistance is only a scant 6 Ω smaller than the collector biasing resistance R_{CC}, owning to the large value of R_{outce}. In turn, the value of the latter resistance is dominated by the last term on the right-hand side of (56.44), which is proportional to the large forward Early resistance, r_o.

6) The input coupling capacitance, C_i, can be calculated with the help of the input port macromodel of Fig. 56.20(a). In this model, the subcircuit to the right of C_i in Fig. 56.19(a) is replaced by its Thévenin equivalent circuit, which consists of the driving point input resistance, R_{in}, calculated previously. The voltage transfer function of this input port is

$$\frac{V_i(j\omega)}{V_S(j\omega)} = \left(\frac{R_{\text{in}}}{R_{\text{in}} + R_S}\right)\left[\frac{j\omega(R_{\text{in}} + R_S)C_i}{1 + j\omega(R_{\text{in}} + R_S)C_i}\right]$$

An inspection of the foregoing relationship confirms that the dynamical effect of C_i on the voltage transfer function response is minimized if $\omega(R_{\text{in}} + R_s)C_i \gg 1$. At $\omega = 2\pi f_l$, the value of C_i that makes the left-hand side of this inequality equal to one is $C_i = 0.30\ \mu\text{F}$. Observe that at $\omega_l(R_{\text{in}} + R_S)C_i = 1$,

$$\left|\frac{V_i(j\omega_l)}{V_S(j\omega_l)}\right| = \left(\frac{R_{\text{in}}}{R_{\text{in}} + R_S}\right)\left|\frac{j}{1+j}\right| = \frac{1}{\sqrt{2}}\left(\frac{R_{\text{in}}}{R_{\text{in}} + R_S}\right)$$

that is, the magnitude of the input port voltage transfer function is a factor of the square root of two, or 3 dB, below the transfer function value realized at signal frequencies that are significantly higher than f_l. If this 3-dB attenuation is acceptable, $C_i = 0.30\ \mu\text{F}$ is appropriate to the design requirement.

© 2003 by CRC Press LLC

7) The output coupling capacitance, C_o, is calculated analogously by exploiting the macromodel concepts overviewed in Figure 56.18(a). To this end, the output port macromodel is offered in Fig. 56.20(b), where the effective forward transconductance, G_f, is such that $-G_f(R_{out}\|R_L) = A_v$, as calculated in step 3. The voltage gain is seen to be

$$A_v(j\omega) = \frac{V_{OS}(j\omega)}{V_S(j\omega)} = -\left[G_f\left(R_{\text{out}}\|R_L\right)\right]\left[\frac{j\omega\left(R_{\text{out}}+R_L\right)C_o}{1+j\omega\left(R_{\text{out}}+R_L\right)C_o}\right]$$

which has an algebric form that is similar to the foregoing transfer relationship for the amplifier input port Thus, C_o is

$$C_o \geq \frac{1}{2\pi f_l\left(R_{\text{out}}+R_L\right)} = 0.065\ \mu\text{F}$$

Since the 0.30 μF input capacitor and the 0.065 μF output capacitor establish identical input and output port left-half-plane poles at the same frequency (f_1), the resultant attenuation at f_1 is actually larger than 3 dB. If this enhanced attenuation is unacceptable, the smaller of the two coupling capacitances can be made larger by a factor of three or so, thereby translating the associated pole frequency downward by a factor of three. In the present case, a plausible value of C_o is $C_o \geq (3)(0.065\ \mu\text{F}) = 0.2\ \mu\text{F}$.

It should be noted that the requisite two coupling capacitances are orders of magnitude too large for monolithic realization. Accordingly, if the subject amplifier is an integrated circuit, C_i and C_o are necessarily off-chip elements.

Example 2. When very large magnitudes of voltage gains are required, the output port of a common-emitter configuration can be terminated in an active load, as opposed to the passive resistive load encountered in the preceding example. Consider, for example, the complementary, NPN-PNP transistor amplifier whose schematic diagram appears in Fig. 56.21(a). The subcircuit containing transistors $Q1$ and $Q2$ is identical to that of the amplifier in Fig. 56.19(a). Indeed, for the purpose of this example, let the resistances, R_1, R_2, R_{EE}, and R_S, as well as small-signal parameters of transistors $Q1$ and $Q2$, remain at the values respectively stipulated for them in the preceding example. In the present diagram, the PNP transistor $Q3$, along with its peripheral biasing resistances R_3, R_4, and R_5, supplants the resistance R_{CC} in the previously addressed common-emitter unit. Since no signal is applied to the base of $Q3$, the subcircuit consisting of $Q3$, R_3, R_4, and R_5 serves only to supply the appropriate biasing current to the collector of transistor $Q1$. To the extent that this static current is invariant with temperature and the voltage signal response, V_{os}, established at the collector of $Q1$, the $Q1$ load circuit functions as a nominally constant current source. As a result, the effective load resistance, indicated as R_L in the subject figure, seen by the collector of $Q1$ is very large. In view of the absence of an external load appended to the output port, the resultant voltage gain of the amplifier is commensurately large.

Let $R_3 = 1.8\ \text{k}\Omega$, $R_4 = 3.3\ \text{k}\Omega$, and $R_5 = 100\ \Omega$. Moreover, let the small-signal parameters of the PNP transistor be $r_{bp} = 40\ \Omega$, $r_{cp} = 70\ \Omega$, $r_{ep} = 9\ \Omega$, $r_{\pi p} = 1100\ \Omega$, $r_{op} = 30\ \text{k}\Omega$, and $\beta_p = 60$. Assuming linear operation of all devices, determine the small-signal voltage gain $A_v = V_{OS}/V_S$, the driving point input resistance R_{in}, and the driving point output resistance R_{out} of the amplifier. As in the preceding example, the input coupling capacitance C_i can be presumed to act as an ac short circuit for the signal frequencies of interest.

Solution.

1) The ac schematic diagram of the amplifier in Figure 56.21(a) is given in Fig. 56.21(b), where the PNP transistor load subcircuit is represented as an effective two terminal load resistance, R_L. This representation is rendered possible by the fact that no signal is applied to the PNP load, which therefore acts only to supply biasing current to the collector of transistor $Q1$. In the diagram, K_{ST}, R_{ST}, and R_{EE} (which

© 2003 by CRC Press LLC

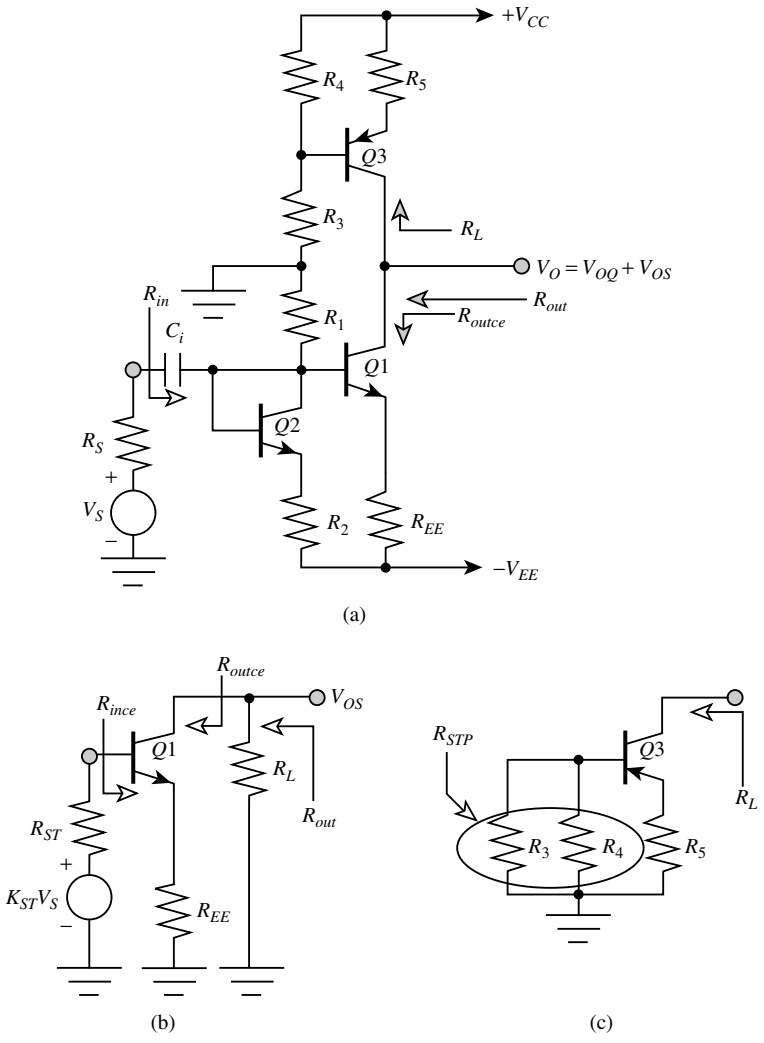

FIGURE 56.21 (a) Common-emitter amplifier with active current source load. (b) AC schematic diagram of the common-emitter unit. (c) AC schematic diagram of the active PNP transistor load.

effectively appears in series with r_e, the internal emitter resistance of $Q1$) remain the same as in Example 1, namely, $K_{ST} = 0.733$, $R_{ST} = 219.7\ \Omega$, and $R_{EE} = 75\ \Omega$.

2) The AC schematic diagram of the $Q3$ subcircuit alone appears in Fig. 56.21(c). A comparison of this figure with that shown in Fig. 56.21(b) suggests that the subject diagram represents a PNP common-emitter amplifier under zero signal conditions. In particular, the Thévenin source resistance seen by the base of the PNP unit is $R_{STP} = R_3 \| R_4 = 1165\ \Omega$, while the emitter degeneration resistance of this subcircuit is $R_5 = 100\ \Omega$. It follows that the effective AC load resistance R_L terminating the collector port of $Q1$ is the driving point output resistance of a common-emitter stage. With $r_c \triangleq r_{cp} = 70\ \Omega$, $r_b \triangleq r_{bp} = 40\ \Omega$, $r_e \triangleq (r_{ep} + R_5 = 109\ \Omega$, $r_\pi \triangleq r_{\pi p} = 1.1\ \text{k}\Omega$, $R_{ST} \triangleq R_{STP} = 1165\ \Omega$, $r_o \triangleq r_{op} = 30\ \text{k}\Omega$, and $\beta \triangleq \beta_p = 60$, (56.44) yields $R_{outce} \triangleq R_L = 111.5\ \text{k}\Omega$.

3) The voltage gain, input resistance, and output resistance of the actively loaded common-emitter amplifier can now be computed. For $r_c \triangleq r_{cn} = 55\ \Omega$, $r_b \triangleq r_{bn} = 90\ \Omega$, $r_e \triangleq (r_{en} + R_{EE} = 76.5\ \Omega$, $r_\pi \triangleq r_{\pi n} = 970\ \text{k}\Omega$, $R_{ST} \triangleq R_{STN} = 219.7\ \Omega$, $r_o \triangleq r_{on} = 42\ \text{k}\Omega$, $R_{LT} \triangleq R_L = 111.5\ \text{k}\omega$, and $\beta \triangleq \beta_n = 115$, (56.41) gives an

© 2003 by CRC Press LLC

effective NPN transistor beta of $\beta_{\text{eff}} = 31.46$, and (56.40) yields a voltage gain of $A_{vce} = V_{OS}/K_{ST}V_{ST} = -931.9$. It follows that the small-signal voltage gain of the stage at hand is $A_v = V_{OS}/V_S = K_{ST}A_{vce} = -682.6$ V/V. It should be noted that this voltage gain is the ratio of only the signal component, V_{OS}, of the net output voltage, V_O (which contains a quiescent component of V_{OQ}) to the source signal voltage, V_S.

(4) From (56.42), the driving point input resistance seen looking into the base of transistor $Q1$ in Fig. 56.19(b) is $R_{ince} = 3.54$ kΩ. Then,

$$R_{\text{in}} = R_1 \| \left(R_d + R_2\right) \| R_{ince} = 666.7\ \Omega$$

This input resistance differs slightly from the corresponding calculation in the preceding example owing to the reduction in the effective forward AC beta caused by the large active load resistance.

(5) The resistance R_{outce} seen looking into the collector of transistor $Q1$ remains the same as calculated in Example 1, namely $R_{outce} = 2.49$ MΩ. It follows that the driving point output resistance of the amplifier under investigation is

$$R_{\text{out}} = R_L \| R_{outce} = 106.7\ \text{k}\Omega$$

This large output resistance means that the actively loaded common-emitter configuration is a relatively poor voltage amplifier. In particular, an output buffer is mandated to couple virtually any practical external load resistance to the amplifier output port. In addition to reducing the output resistance, such a properly designed and implemented output buffer can reliably establish and stabilize the quiescent output voltage, V_{OQ}.

Common Base Amplifier

The second of the canonic linear bipolar gain cells in the *common-base amplifier,* whose NPN and PNP AC schematic diagrams and corresponding small-signal equivalent circuit appear in Fig. 56.22(a) and (b), respectively. As is confirmed below, the input resistance, R_{incb}, of this stage is very small and the output resistance, R_{outcb}, is very large. Accordingly, the common-base unit comprises a relatively poor voltage amplifier in the sense that its voltage gain, though potentially large, is a sensitive function of both the Thévenin source resistance R_{ST} and the Thévenin load resistance R_{LT}.

Although the common-base amplifier is not well suited for general voltage gain applications, it is an excellent *current buffer*, which is ideally characterized by zero input resistance, infinitely large output resistance, and unity current gain. When used for current buffering purposes, the common-base amplifier rarely appears as a stand alone single-stage amplifier, since signal excitations, particularly at the input and output ports of an electronic system are invariably formatted as voltages. Instead, it is invariably used in conjunction with an input voltage to current converter and/or an output current to voltage converter to achieve desired system performance characteristics.

The small-signal analysis of the common-base stage is considerably simplified if the assumption of large r_o is exploited at the outset. To this end, the equivalent circuit shown in Fig. 56.22(b) reduces to the structure of Fig. 56.23(a). In the latter equivalent circuit, observe a signal emitter current i_{es} that relates to the indicated signal base current i in accordance with the Kirchhoff's current law (KCL) constraint

$$i_{es} = -\left(\beta + 1\right) i \tag{56.51}$$

The signal component of the output current I_{OS} is therefore expressible as

$$I_{OS} = -\beta_i = \left(\frac{\beta}{\beta + 1}\right) i_{es} = \alpha i_{es} \tag{56.52}$$

where (56.51) and (56.52) are used. The last result suggests the alternative model in Fig. 56.23(b), which is slightly more convenient version of the model in Fig. 56.23(a) in that the current-controlled current

© 2003 by CRC Press LLC

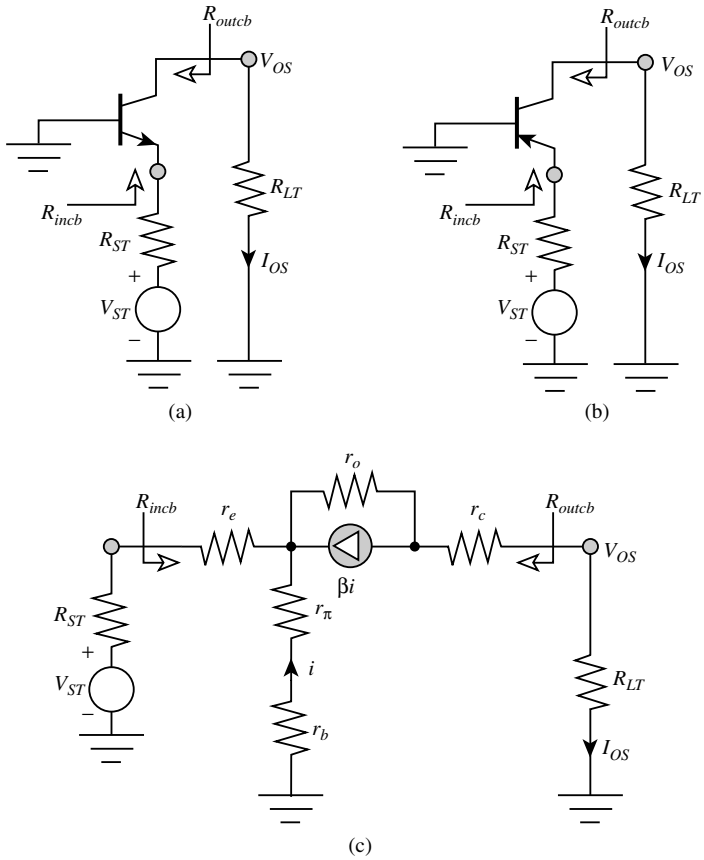

FIGURE 56.22 (a) AC schematic diagram of an NPN common-base amplifier. (b) AC schematic diagram of a PNP common-base amplifier. (c) Small-signal, low-frequency equivalent circuit of the common-base amplifier.

source, αi_{es}, is dependent on the signal input port current i_{es}, as opposed to the signal current, i, that flows in the grounded base lead.

By inspection of the equivalent circuit in Fig. 56.23(b), the small-signal voltage gain A_{vcb} of the common-base cell is

$$A_{vcb} = \frac{\alpha R_{LT}}{R_{ST} + r_e + (1-\alpha)(r_\pi + r_b)} = \frac{\alpha R_{LT}}{R_{ST} + R_d} \tag{56.53}$$

where (56.38) is used once again and R_d is the diode resistance defined by (56.32). In contrast to the common-emitter cell, the common-base stage has no voltage gain phase inversion. But like the common-emitter configuration, the common-base voltage gain is directly proportional to the effective load resistance. It is also almost inversely proportional to the effective source resistance, given that the diode resistance R_d is small.

Although the voltage gain is vulnerable to uncertainties in the terminating load and source resistances, the common-base current gain, A_{icb}, is virtually independent of R_{LT} and R_{ST}. This contention follows from the fact that A_{icb}, which is the ratio of I_{OS} to the Norton equivalent source current, V_{ST}/R_{ST}, is

$$A_{icb} = \left(\frac{R_{ST}}{R_{LT}}\right) A_{vcb} = \frac{\alpha R_{ST}}{R_{ST} + R_d} \tag{56.54}$$

© 2003 by CRC Press LLC

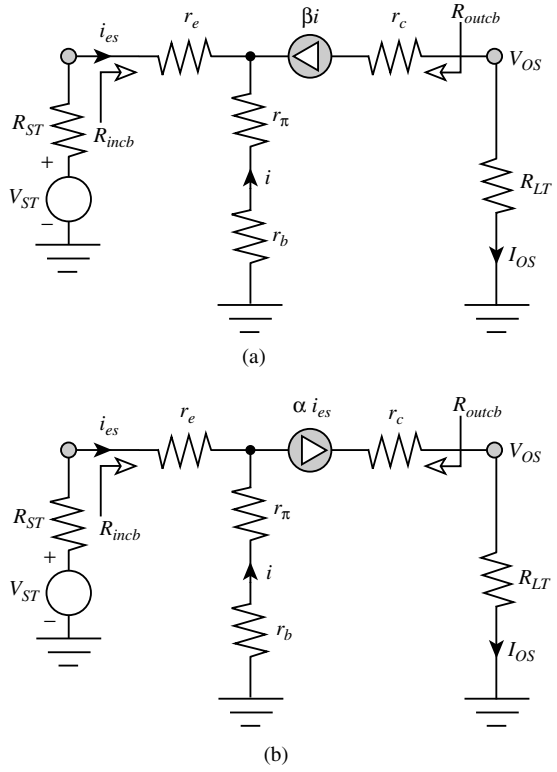

FIGURE 56.23 (a) The equivalent circuit of Fig. 56.22(c), simplified for the case of very large Early resistance r_o. (b) Modification of the circuit in (a) in which the current-controlled current source is rendered dependent on the input signal current i_{es}.

which is independent of R_{LT} (to the extent that the Early resistance r_o can indeed be ignored). Since the signal in a current-drive amplifier is likely to have a large source resistance, $R_{ST} \gg R_d$, which implies $A_{icb} \approx \alpha$, independent of R_{LT} and R_{ST}. Note that this approximate current gain is essentially unity, since α as introduced by (56.38) approaches one for the typically encountered circumstances of large β.

The input and output resistances of the common-base amplifier follow immediately from an analysis of the model in Fig. 56.23(b). In particular, the driving point input resistance, R_{incb}, is

$$R_{incb} = \left(\frac{V_{ST}}{i_{es}}\right)\Bigg|_{R_{ST}=0} = r_e + (1-\alpha)(r_\pi + r_b) = R_d \tag{56.55}$$

where the numerical value is of the order of only a few tens of ohms. On the other hand, the driving point output resistance, R_{outcb}, is infinitely large since $V_{ST} = 0$ constrains i_{es}, and thus αi_{es}, to zero. In turn, αi_{es}, $= 0$ means that R_{LT} in Fig. 56.23(b) faces an open circuit, whence $R_{outcb} = \infty$.

To the extent that the common-base amplifier is excited from a signal current source and that the forward Early resistance of the utilized transistor is very large, the common-base amplifier is seen to have almost unity current gain, very low input resistance, and infinitely large output resistance. Its transfer characteristics therefore approximate those of an ideal current buffer. Of course, the finite nature of the forward Early resistance renders the observable driving point output resistance of a common-base cell large, but nonetheless finite. The actual output resistance can be determined as the V_x to I_x ratio in the ac schematic diagram of Fig. 56.24(a). The requisite analysis is algebraically cumbersome owing to the presence of r_o in shunt with the current-controlled current source in the equivalent circuit of Fig. 56.22(c).

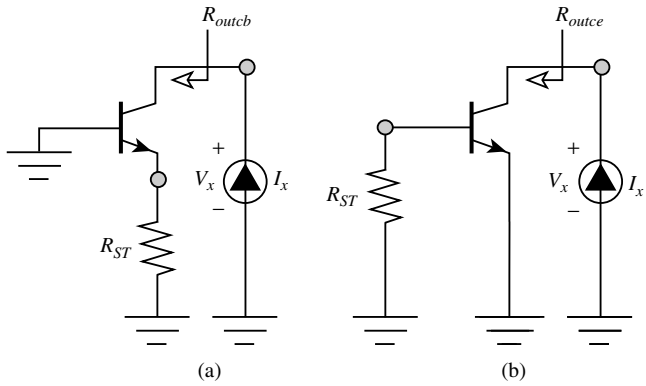

FIGURE 56.24 (a) AC schematic diagram appropriate to the computation of the driving point output resistance of a common-base amplifier. (b) AC schematic diagram pertinent to computing the driving point output resistance of a common-emitter amplifier.

Fortunately, however, an actual circuit analysis can be circumvented by a proper interpretation of cognate common emitter results formulated earlier.

In order to demonstrate the foregoing contention, consider Fig. 56.24(b), which depicts the AC schematic diagram for determining the driving point output resistance R_{outce} of a common-emitter amplifier. The only difference between the two AC schematic diagrams in Fig. 56.24 is the topological placement of the effective source resistance, R_{ST}. In the common-base stage, this source resistance is in series with the emitter of a transistor with a base that is grounded. On the other hand, R_{ST} appears in the common emitter configuration as an element in series with the base of a transistor whose emitter is ground. It follows that (56.44) can be used to deduce an expression for R_{outcb}, provided that in (56.44) R_{ST} is set to zero and r_e is replaced by (r_e+R_{ST}).

The result is

$$R_{outcb} = r_c + \left(r_e + R_{ST}\right) \left\| \left(r_\pi + r_b\right) + \left[\frac{\beta\left(r_e + R_{ST}\right)}{r_e + R_{ST} + r_\pi + r_b} + 1\right] r_0 \tag{56.56}$$

For large R_{ST} and large r_o, (56.46) reduces to

$$R_{outcb} \approx \left(\beta + 1\right) r_o \tag{56.57}$$

which is an extremely large output resistance.

The common-base stage is generally used in conjunction with a common-emitter amplifier to form the *common-emitter-common base cascode,* whose schematic diagram is shown in Fig. 56.25. In this application, the common-emitter stage formed by transistor $Q1$, the emitter degeneration resistance, R_{EE}, and the biasing elements, R_1 and R_2, serves as a transconductor that converts the input signal voltage, V_S, to a collector current whose signal component is i_{1s}. Note that such conversion is encouraged by the fact that the effective load resistance, R_{Leff}, terminating the collector of $Q1$, is the presumably low input resistance of the common-base stage formed by transistor $Q2$ and the biasing resistances, R_3 and R_4. Since the current gain of a common-base stage is essentially unity, $Q2$ translates the signal current in its emitter to an almost identical signal current flowing through the collector load resistance, R_L. The latter element acts as a current to voltage convert to establish the signal component, V_{OS}, of the net output voltage V_O.

The analysis of the common-emitter-common-base cascode begins by representing the collector port of the common-emitter configuration by its Norton equivalent circuit. Assuming that the input coupling capacitor, C_1, is sufficiently large to enable its replacement by a short circuit over the signal frequency range of interest, the pertinent AC schematic diagram is the circuit in Fig. 56.26(a), where I_{ns} symbolizes

© 2003 by CRC Press LLC

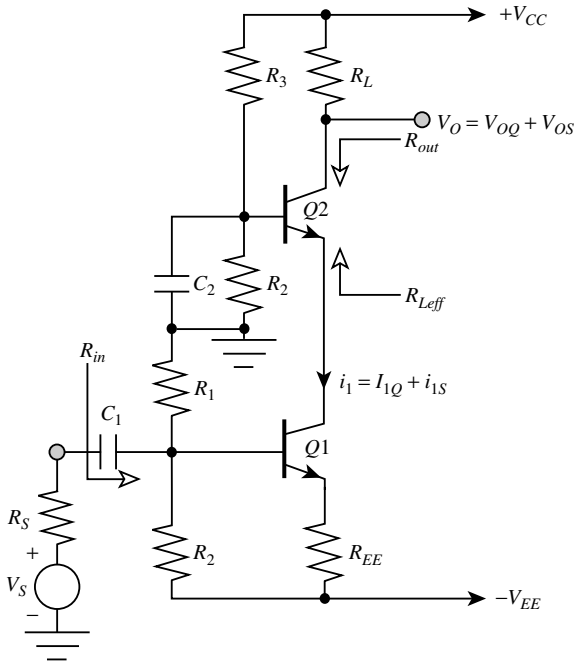

FIGURE 56.25 Schematic diagram of a common-emitter–common-base cascode. The common-emitter stage formed by transistor Q1 and its peripheral elements acts as a voltage to current converter. Transistor Q2 and its associated biasing elements functions as a current amplifier, while the load resistance, R_L, acts as a current to voltage converter.

the Norton, or short-circuit signal current conducted by the collector of transistor $Q1$. The corresponding small-signal equivalent circuit appears in Fig. 56.26(b), where the Early resistance is tacitly ignored, the effective source resistance, R_{ST}, seen by the base of $Q1$ is

$$R_{ST} = R_S \| R_1 \| R_2 \tag{56.58}$$

and the voltage divider K_{ST} is

$$K_{ST} = \frac{R_1 \| R_2}{R_1 \| R_2 + R_S} \tag{56.59}$$

Using the model in Fig. 56.26(b) it is a simple matter to show that

$$I_{ns} = \beta i = G_{ns} V_S \tag{56.60}$$

where G_{ns}, which can be termed the **Norton transconductance** of the common-emitter stage, is

$$G_{ns} = \frac{\beta K_{ST}}{R_{ST} + r_b + r_\pi + (\beta + 1) r_e} \tag{56.61}$$

The Norton output resistance R_{ns} is infinitely large by virtue of the assumption of infinitely large Early resistance.

The foregoing results permit drawing the AC schematic diagram of the common-base component of the common-emitter–common-base cascode in the topological form depicted in Fig. 56.27(a). From the

© 2003 by CRC Press LLC

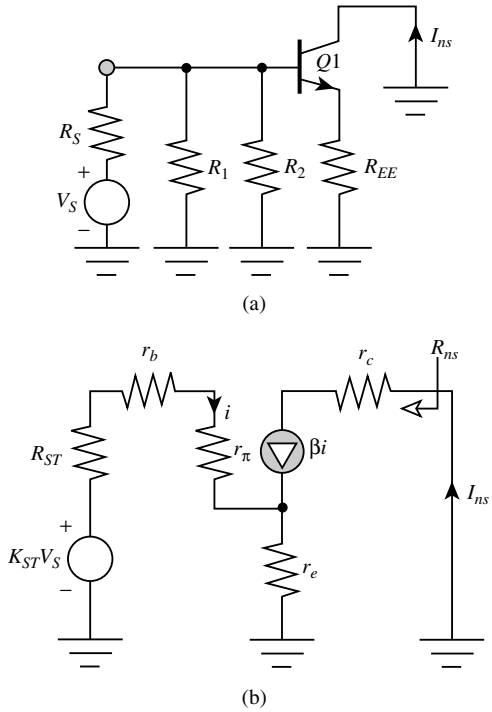

FIGURE 56.26 (a) AC schematic diagram used to calculate the Norton equivalent output circuit of the common-emitter subcircuit in the cascode configuration of Fig. 56.25. (b) Small-signal model of the AC circuit in (a).

corresponding small-signal equivalent circuit in Fig. 56.27(b), which assumes that the capacitor, C_2, behaves as an AC short circuit and which once again ignores transistor Early resistance, the voltage gain, say A_v, follows immediately as

$$A_v = \frac{V_{OS}}{V_S} = -\alpha G_{ns} R_L = -\frac{\alpha\beta K_{ST} R_L}{R_{ST} + r_b + r_\pi + (\beta + 1) r_e} \tag{56.62}$$

The driving point output resistance R_{out}, like the Norton output resistance of the common-emitter stage, is infinitely large. In fact, R_{out} is a good approximation of infinity. Its numerical value approaches $(\beta + 1)r_o$, since the terminating resistance, R_{ns}, seen in the emitter circuit of transistor $Q2$ is of the order of r_o.

Equation (56.62) is similar in form to (56.40) which defines the voltage gain of a simple common-emitter amplifier. A careful comparison of the two subject relationships suggests that the voltage gain of the common-emitter–common-base cascode of Fig. 56.25 is equivalent to the voltage gain achieved by a simple common-emitter stage, whose output port is loaded in an effective load resistance of αR_L. Although α is close to unity, but nonetheless always less than one, an effective load of αR_L implies that the voltage gain of the cascode is slightly less than that achieved by the common-emitter stage alone, provided, of course, that the transistors utilized in both configurations have identical small-signal parameters. A question therefore arises as to the prudence of incorporating common-base signal processing in conjunction with a common-emitter unit stage.

In fact, no practical purpose is served by a common-emitter–common-base cascode if the load resistance R_L driven by the amplifier is very small. But if the load resistance imposed on the output port of a simple common-emitter amplifier is large, as it is when the load itself is realized actively, as per Example 2, the effective transistor beta defined by (56.41) is appreciably smaller than the actual small-signal beta. The result is a degraded common-emitter amplifier voltage gain. In this situation, the insertion of a common-base stage between the output port of the common-emitter amplifier and R_L, as diagrammed in Fig. 56.25,

© 2003 by CRC Press LLC

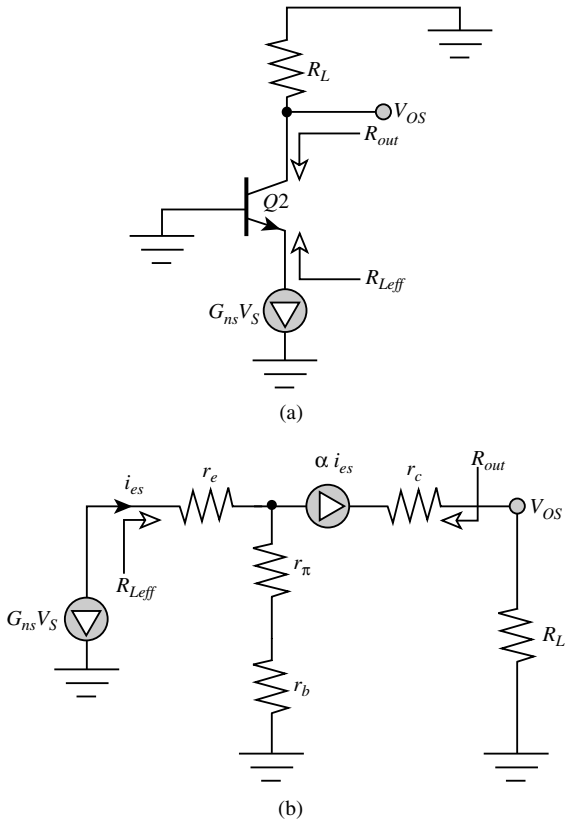

FIGURE 56.27 (a) The effective AC schematic diagram of the common-base component of the common-emitter–common-base cascode of Fig. 56.25. (b) Small-signal model of the AC circuit in (a).

increases the degraded gain of the common-emitter amplifier alone by restoring the effective beta of the common emitter transistor to a value that approximates the actual small-signal beta of the transistor. This observation follows from the fact that the effective load resistance, R_{Leff}, seen by the collector of the common emitter transistor in the cascode topology is of the order of only a small diode resistance. It follows from (56.41) that β_{eff} for $R_{LT} = R_{Leff}$ is likely to significantly larger than the value of β_{eff} that derives from the load condition, $R_{LT} = R_L$.

The reason for using common-base circuit technology in conjunction with a common-emitter amplifier is circuit broadbanding. In particular, a carefully designed common-emitter–common-base cascode configuration displays a 3-dB bandwidth and a gain–bandwidth product that are significantly larger than the bandwidth and gain–bandwidth product afforded by a common-emitter stage of comparable gain. The primary reason underlying this laudable attribute is the low effective load resistance presented to the collector of the common-emitter stage by the emitter of the common-base structure. This low resistance attenuates the magnitude of the phase-inverted voltage gain of the common-emitter circuit, thereby reducing the deleterious effects of Miller multiplication of the base-collector junction depletion capacitance implicit to the common-emitter transistor [8].

Common Collector Amplifier

While the common-base configuration functions as a current buffer, the *common-collector amplifier,* or *emitter follower,* with AC schematic diagrams that appear in Fig. 56.28(a) and (b) operates as a voltage buffer. It offers high input resistance, low output resistance, a voltage gain approaching unity, and a moderately large current gain. The small-signal model of the emitter follower is the circuit in Fig. 56.28(c).

© 2003 by CRC Press LLC

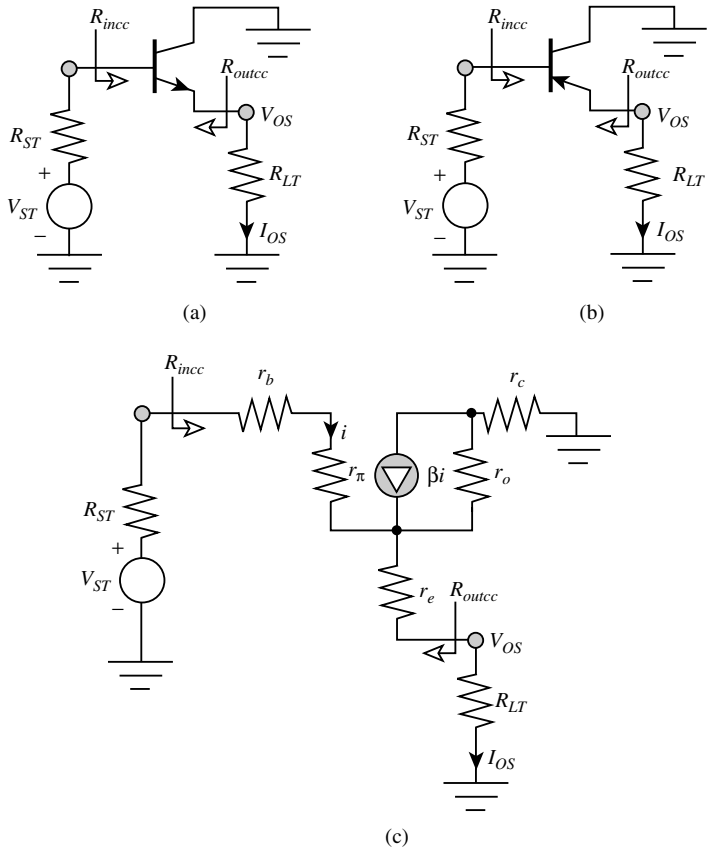

FIGURE 56.28 (a) AC schematic diagram of an NPN common-collector amplifier. (b) AC schematic diagram of PNP common-collector amplifier. (c) Small-signal low-frequency equivalent circuit of the common-collector amplifier, assuming that the Early resistance is sufficiently large to ignore.

Assuming infinitely large Early resistance, r_o, a straightforward analysis of the subject model reveals an emitter-follower voltage gain A_{vcc} of

$$A_{vcc} = \frac{V_{OS}}{V_S} = \frac{R_{LT}}{R_{LT} + R_d + (1-\alpha)R_{ST}} \tag{56.63}$$

where R_d is the diode resistance given by (56.32). Observe that A_{vcc} is a positive less than unity number. The indicated gain approaches one for $R_{LT} \gg R_d + (1 - \alpha)R_{ST}$. Although the voltage gain is less than one, the corresponding current gain, which is simply the voltage gain scaled by a factor of (R_{ST}/R_{LT}), can be substantially larger than one.

It is simple to confirm that the driving point input resistance R_{incc} and the driving point output resistance R_{outcc} of the emitter follower are, respectively,

$$R_{incc} = r_b + r_\pi + (\beta+1)(r_e + R_{LT}) = (\beta+1)(R_d + R_{LT}) \tag{56.64}$$

and

$$R_{outcc} = r_e + \frac{r_\pi + r_b + R_{ST}}{(\beta+1)} = R_d + (1-\alpha)R_{ST} \tag{56.65}$$

© 2003 by CRC Press LLC

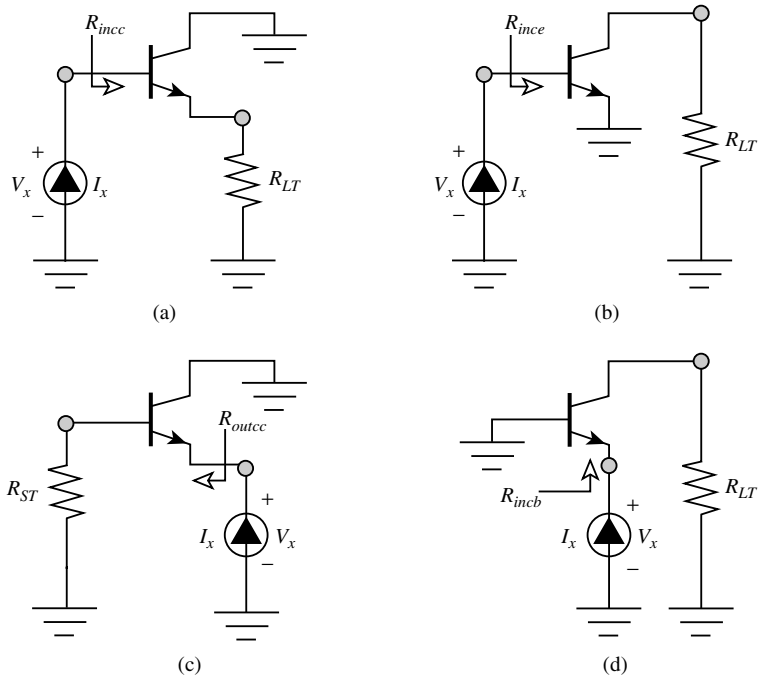

FIGURE 56.29 (a) Test circuit for determining the driving point input resistance R_{incc} of a common-collector amplifier. (b) Test circuit for determining the driving point input resistance R_{ince} of a common-emitter amplifier. Note that $R_{incc} = R_{ince}$ if R_{LT} in the common collector unit is zero. (c) Test circuit for determining the driving point output resistance R_{outcc} of a common-collector amplifier. (d) Test circuit for determining the driving point input resistance R_{incb} of a common-base amplifier. Note that $R_{outcc} = R_{incb}$ if R_{ST} in the common-collector unit is zero.

It is interesting and instructive to note that the driving point input resistance R_{incc}, of an emitter follower is of the same form as the driving point input resistance R_{incc}, of a common-emitter stage. Indeed, if R_{LT} in the emitter follower is zero, $R_{incc} \equiv R_{ince}$. This result is reasonable in view of the fact that for both the emitter-follower and common-emitter configurations, the input resistance is, as suggested by the test circuits in Figs. 56.29(a) and (b), the Thévenin resistance presented to the source circuit by the base of the subject transistor. Moreover, the common-collector output resistance R_{outcc} mirrors the driving point input resistance R_{incb} for the common-base amplifier. In fact, $R_{incb} \equiv R_{outcc}$ if the base of a common-base amplifier is terminated to ground in a resistance of value R_{ST}. Once again, the latter observation is intuitively correct, for, as depicted in Figs. 56.29(c) and (d), the emitter of the transistor comprises the input terminal for the common-base amplifier and the output terminal of an emitter follower.

An inspection of (56.63) confirms a common-collector voltage gain that tends toward unity for progressively larger Thévenin load resistances, R_{LT}. Correspondingly, the driving point input resistance of an emitter follower increases dramatically with increasing R_{LT}. These observations are often pragmatically exploited by supplanting the passive load in the schematic diagram of Fig. 56.28(a) with an active load, as suggested in Fig. 56.30(a). Since the effective AC load resistance must be large to achieve a near unity voltage gain, this active load must function as a sink of nominally constant current. To this end, the active load in question is shown conducting a net current that consists of a static current component I_{CS} and a signal current component I_{OS}, where the constant current sink nature of the load implies $I_{CS} \gg I_{OS}$.

The subject active load can be represented by its Norton equivalent circuit, as diagrammed in Fig. 56.30(b), where I_{CS} is depicted as a constant current source and I_{OS} is made to flow through a resistance, R_{cs}. The latter branch element represents the dynamic resistance presented to the emitter-follower output port by the two terminal active termination. Note that $R_{cs} = \infty$ yields $I_{os} = 0$, which implies an active load that behaves as an ideal constant current sink. The corresponding AC schematic

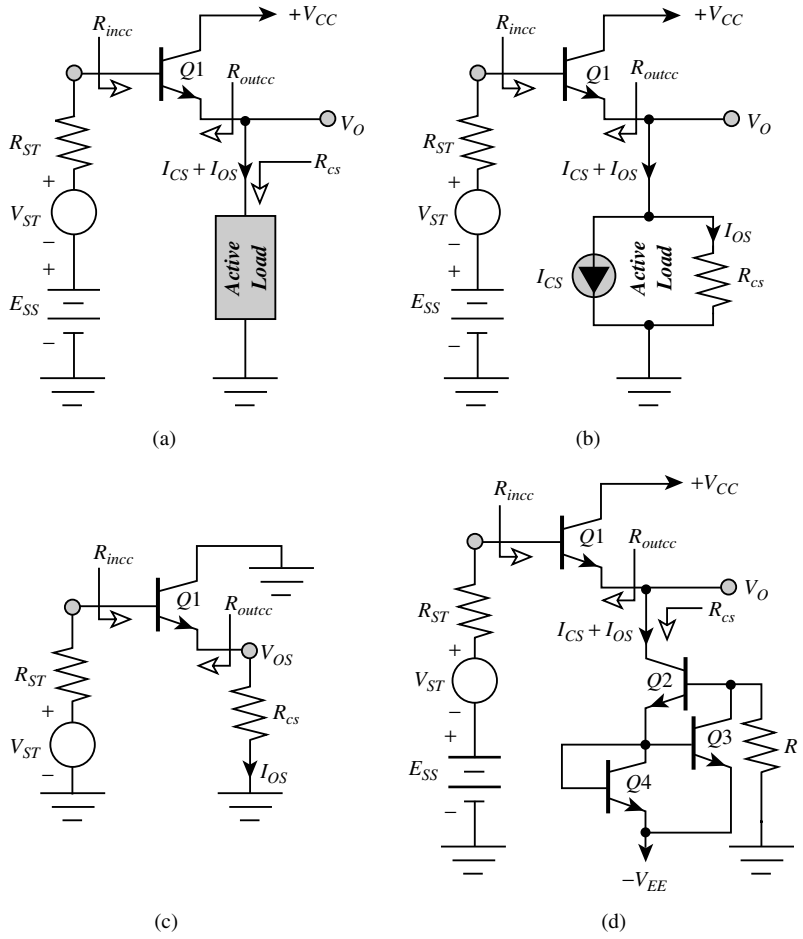

FIGURE 56.30 (a) Emitter follower with active load that conducts a static current I_{CS} and a signal component I_{OS}. (b) The Norton equivalent circuit of the active load. (c) AC schematic diagram of the actively loaded emitter follower. (d) Wilson current mirror realization of the active load.

diagram, which is offered in Fig. 56.30(c), is derived from Fig. 56.30(b) by setting I_{CS} to zero, since I_{CS} itself is a constant current that is devoid of any signal component. Additionally, the biasing sources, V_{CC}, V_{EE}, and E_{SS} are presumed ideal and are therefore set to zero as well.

The AC schematic diagram in Fig. 56.30(c) is identical to that in Fig. 56.28(a), subject to the proviso that $R_{LT} = R_{cs}$. But since R_{cs} is presumably a large resistance, substituting $R_{LT} = R_{cs}$ into (56.63) to evaluate the voltage gain of the actively loaded emitter follower is at least theoretically inappropriate because the subject gain equation is premised on the assumption of a large Early resistance, r_o; specifically (56.63) reflects the assumption $R_{LT} \ll r_o$. A voltage gain expression, more accurate than (56.63), derives from an analysis of the model in Fig. 56.28(c). If r_o is included in this analysis, but if r_e and r_c are sufficiently small to justify their neglect, the result for $R_{LT} = R_{cs}$ is

$$A_{vcc} = \frac{V_{OS}}{V_S} \approx \frac{r_o \| R_{cs}}{\left(r_o \| R_{cs}\right) + R_d + \left(1-\alpha\right)R_{ST}} \tag{56.66}$$

where the algebraic form collapses to (56.63) if $R_{cs} \ll r_o$. Similarly, the revised expression for the driving point input resistance is

© 2003 by CRC Press LLC

$$R_{incc} \approx r_b + r_\pi + (\beta + 1)\left(r_o \| R_{cs}\right) \tag{56.67}$$

The output resistance R_{outcc} remains as stipulated by (56.65).

The active load appearing in Fig. 56.30(a) can be realized as any one of a variety of NPN current sources [9]. Figure 56.30(d) offers an examples of such a realization in the form of the Wilson current mirror formed of transistors $Q2$, $Q3$, and $Q4$, and the current setting resistor, R [10]. This subcircuit establishes an extremely high dynamic resistance between the collector of transistor $Q2$ and the signal ground. In particular, if β_2 and r_{o2} symbolize the AC beta and forward Early resistance, respectively, of transistor $Q2$, it can be shown that

$$R_{cs} \approx \frac{\beta_2 r_{o2.}}{2} \tag{56.68}$$

Note further that the static current, I_{CS}, conducted by the Wilson mirror flows through the emitter lead of the emitter-follower transistor $Q1$. Thus, the biasing stability of $Q1$ is determined by the thermal sensitivity of the static current that flows in the Wilson subcircuit.

Example 3. In order to dramatize the voltage buffering property of an emitter follower, return to the amplifier addressed analytically in Example 1 and drawn schematically in Fig. 56.19(a). Let the two coupling capacitors remain large enough to approximate them as AC short circuits over the signal frequency range of interest, and let the small-signal parameters of the two transistors remain at $r_b = 90\ \Omega$, $r_c = 55\ \Omega$, $r_e = 1.5\ \Omega$, $r_\pi = 970\ \Omega$, $r_o = 42\ \text{k}\Omega$, and $\beta = 115$. The circuit parameters also remain the same; namely, $R_1 = 2.2\ \text{k}\Omega$, $R_2 = 1.3\ \text{k}\Omega$, $R_{EE} = 75\ \Omega$, $R_{CC} = 3.9\ \text{k}\Omega$, and $R_{S=} 300\ \Omega$. But instead of $R_L = 1.0\ \text{k}\Omega$, consider an external load termination of $\text{R}_\text{L} = 300$. Reevaluate the small-signal voltage gain, $A_v = V_{OS}/V_S$, for the subject amplifier. Compare this result to the voltage gain achieved when an emitter follower is inserted between the collector of transistor $Q1$ and the 300 Ω load termination, as depicted in Fig. 56.31(a). Assume that the small-signal parameters of the emitter-follower transistor $Q3$ and those of the two transistors that comprise the diode-compensated current sink load of the follower are identical to the model parameters of transistors $Q1$ and $Q2$.

Solution.

1) With reference to Fig. 56.19 and Example 1, the Thévenin load resistance R_{LT} is now

$$R_{LT} = R_{CC} \| R_L = 278.6\ \Omega$$

The parameters R_{ST} and K_{ST} in Fig. 56.19 (c) remain unchanged at the previously computed values of $R_{ST} = 219.7\ \Omega$ and $K_{ST} = 0.733$. Then, ignoring the effects of the finite, but large, Early resistance r_o, the voltage gain is

$$A_v = \frac{V_{OS}}{V_S} \approx -\frac{\beta K_{ST} R_{LT}}{R_{ST} + r_b + r_\pi + (\beta + 1)\left(r_e + R_{EE}\right)}$$

whence $A_v = -2.31$ V/V.

2) Consider now the amplifier modification shown in Fig. 56.31(a). Transistor $Q3$ functions as an emitter follower to buffer the terminating load resistance R_L effectively seen by the gain stage formed of transistor $Q1$ and its peripheral elements. Transistors $Q3$ and $Q4$ form a diode-compensated current sink that comprises the active load presented to the emitter-follower output port under static operational conditions. To the extent that r_o can be tacitly ignored, this current sink comprises an infinitely large dynamic

(b)

FIGURE 56.31 (a) The amplifier of Fig. 56.19, but with an emitter-follower buffer inserted between the gain stage and the terminating load resistance. (b) AC schematic diagram of the amplifier in (a).

resistance. Accordingly, the AC schematic diagram seen to the right of the collector of transistor $Q1$ is the structure identified in Fig. 56.31(b).

3) The source circuit that drives the base of transistor $Q3$ in Fig. 56.31(b) is the Thévenin equivalent circuit established at the collector of transistor $Q1$ in Fig. 56.31(a). The signal voltage associated with this source circuit is the open circuit voltage developed at the $Q1$ collector; that is, it is the voltage at the $Q1$ collector with the load formed of transistor $Q3$ and its peripheral elements removed. Since the circuit to the left of the base of transistor $Q3$ is a linear network, this Thévenin voltage is necessarily proportional to the input signal V_S. The indicated constant of proportionality in Fig. 56.31(b), A_{v1}, can rightfully be termed the open-circuit voltage gain of the first stage of the subject amplifier. This is to say that A_{v1} is A_v, as determined in step 1) above, but with R_L removed and therefore, R_{LT} set equal to R_{CC}. It follows that

$$A_{v1} = -\frac{\beta K_{ST} R_{CC}}{R_{ST} + r_b + r_\pi + (\beta + 1)(r_e + R_{EE})}$$

or $A_{v1} = -32.38$ V/V. Since r_o is taken to be infinitely large, the resistance seen looking into the collector of transistor $Q1$ is likewise infinitely large. As a result, the Thévenin resistance associated with the source circuit in the AC diagram of Fig. 56.31 (b) is $R_{CC} = 3.9$ kΩ.

© 2003 by CRC Press LLC

4) Recalling (56.63), the voltage gain of the circuit in Fig. 56.19(b) is

$$A_{vcc} = \frac{V_{OS}}{A_{v1}V_S} = \frac{R_L}{R_L + R_d + (1-\alpha)R_{CC}} = 0.871 \text{ V/V}$$

The resultant overall circuit gain is

$$A_v = \frac{V_{OS}}{V_S} = A_{v1}A_{vcc}$$

or A_v = –28.21 V/V. Recalling the results of step 1) of this computational procedure, the effect of the emitter follower is to boost the gain magnitude of the original configuration by a factor of about 12.2.

5) From (56.65), the driving point output resistance of the buffered amplifier is

$$R_{\text{out}} = R_d + (1-\alpha)R_{CC}$$

or R_{out} = 44.3 Ω. Note that for the original nonbuffered case, the output resistance is R_{CC} = 3.9 kΩ.

Darlington Connection

In the **Darlington connection**, whose basic schematic diagram is abstracted in Fig. 56.32(a), the emitter of one transistor *Q*1 is incident with the base of a second transistor *Q*2 and the two transistor collector leads are connected. The output signal is extracted as either the current flowing in the collector of transistor *Q*2 or the voltage developed at the emitter of *Q*2. In the former case, the indicated Darlington connection functions as a transconductance amplifier. In the latter case, an output signal voltage at the emitter of *Q*2 renders the connection functional as a voltage follower, or buffer. In both applications, the small-signal driving point input resistance, R_{ind}, seen looking into the base of transistor *Q*1 is large. On the other hand, the driving point output resistance, R_{outed}, seen at the emitter is small and virtually independent of the source resistance R_S. The output resistance, R_{outcd}, presented to the node at which the two transistor collectors are incident is large. At the expense of forward transconductance, R_{outcd} can be enhanced by returning the collector of *Q*1 to the $+V_{CC}$ bus, instead of to the collector of transistor *Q*2. For a nonzero collector load resistance, R_{LC}, this alternate connection, which is diagrammed in Fig. 56.32(b) eliminates Miller multiplication of the base–collector junction capacitance of transistor *Q*1, thereby resulting in an improved transconductance frequency response.

A fundamental problem that plagues both of the foregoing Darlington connections is the fact that the static emitter current conducted by *Q*1 is identical to the static base current drawn by *Q*2. Accordingly, the emitter current of *Q*1 is likely to be much smaller than the biasing current commensurate with optimal gain–bandwidth product in this device. Moreover, this emitter current cannot be predicted accurately since it is inversely proportional to the *Q*2 static beta, whose numerical value is an unavoidable uncertainty. This poor biasing translates into an unreliable delineation of the static and small signal parameters for *Q*1. In turn, potentially significant uncertainties shroud the forward transfer and driving point resistance characteristics of the Darlington configuration.

To remedy the situation at hand, an additional current path, usually directed to signal ground, is provided at the junction of the *Q*1 emitter and the *Q*2 base, as suggested in Fig. 56.32(c) and (d). The appended current path can be a simple two terminal resistance, although care must be exercised to ensure that this resistance is sufficiently large to avoid seriously compromising the large driving point input resistance afforded by the basic Darlington connection in either of the preceding diagrams. Since large resistance and realistic biasing currents may prove to be conflicting design requirements, the appended current path is often an active current sink, such as the Wilson mirror load explored earlier in conjunction with the common-collector amplifier. Note in the latter two diagrams that the current, indicated as *I*,

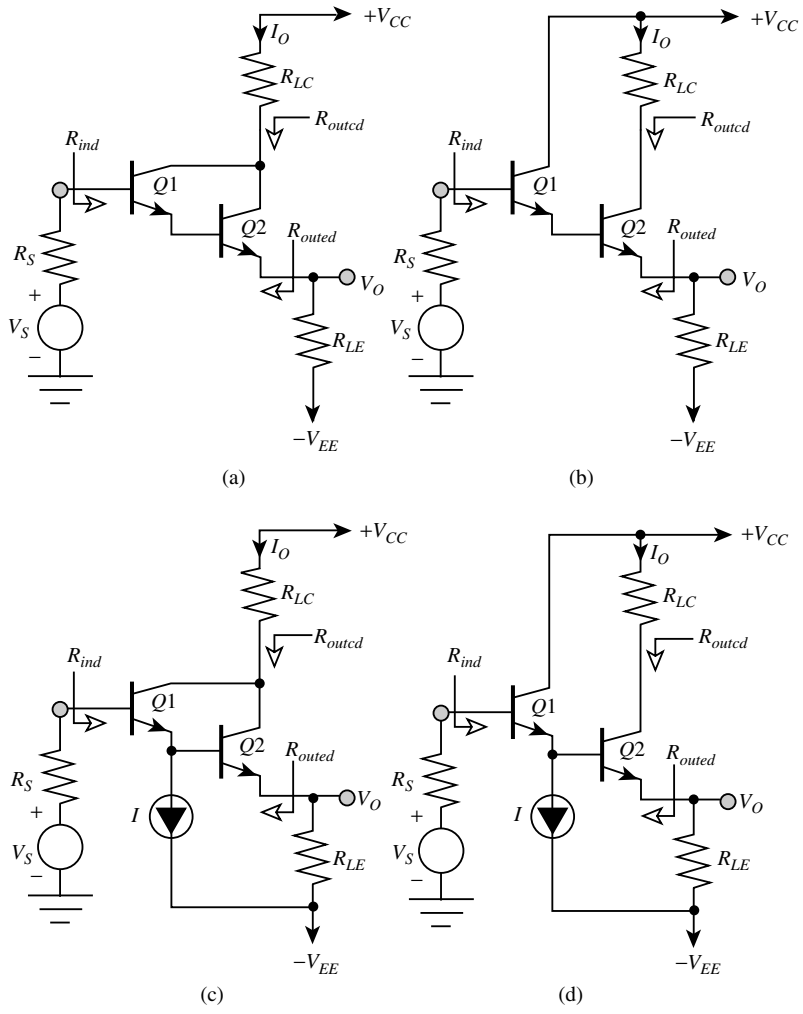

FIGURE 56.32 (a) The basic Darlington connection. (b) Alternative Darlington connection for wide-band transconductance response. (c) Darlington connection with input transistor current compensation. (d) Alternative Darlington connection with input transistor current compensation.

conducted by the appended passive or active current path is essentially the emitter current of transistor $Q1$, provided that I is much larger than the base currents of $Q2$.

The small-signal bipolar junction transistor equivalent circuit of Fig. 56.13(a) can be used to deduce the transfer and driving point resistance characteristics of any of the Darlington connections depicted in Fig. 56.32. An analysis is provided herewith for only the configuration in Fig. 56.32(c), since this topology is the most commonly encountered Darlington circuit and the others are amenable to very straightforward analyses. To this end, the model for the subject structure is offered in Fig. 56.33, where it is assumed that both transistors are biased so that their corresponding small-signal parameters are nominally identical. Moreover, the Early resistance of each transistor is presumed to be sufficiently large to warrant its neglect, and a resistance, R_{is} is included to account for the terminal resistance of the appended current path discussed above. Letting

$$k_{is} \triangleq \frac{R_{is}}{R_{is} + (\beta + 1)(R_d + R_{LE})} \tag{56.69}$$

© 2003 by CRC Press LLC

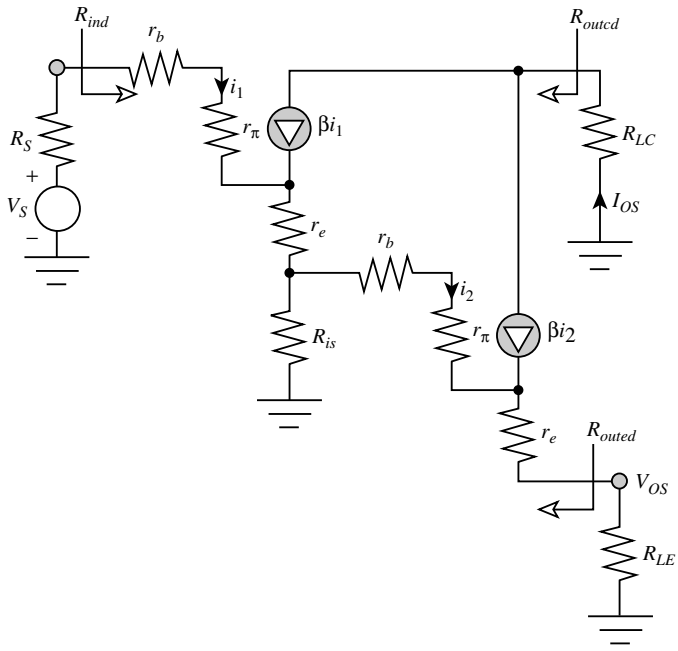

FIGURE 56.33 The small-signal equivalent circuit of the Darlington connection in Fig. 56.32(c). The Early resistance is ignored, and both transistors are presumed to have identical corresponding small-signal parameters. The resistance, R_{is}, represents the terminal AC resistance associated with the appended current path conducting current I in Fig. 56.32(c).

denote the small-signal current divider between the appended current path and the base circuit of transistor $Q2$, it can be shown that the driving point input resistance R_{ind} is

$$R_{ind} = (\beta+1)\left[R_d + (\beta+1)k_{is}\left(R_d + R_{LE}\right)\right] \tag{56.70}$$

For large ac beta,

$$R_{ind} \approx (\beta+1)^2 k_{is}\left(R_d + R_{LE}\right) \tag{56.71}$$

which is maximal for $k_{is} \approx 1$. From (56.69), the latter constraint mandates that the appended current path be designed so that its small-signal terminal resistance satisfies the inequality $R_{is} \gg (\beta+1)(R_d+R_{LE})$. The voltage gain, A_{vd}, from the signal source to the emitter port is

$$A_{vd} = \frac{V_{OS}}{V_S} = \frac{(\beta+1)^2 k_{is} R_{LE}}{R_S + (\beta+1)R_d + (\beta+1)^2 k_{is}\left(R_d + R_{LE}\right)} \tag{56.72}$$

where V_{OS} is the signal component of the net output voltage V_O. Equation (56.52) reduces to

$$A_{vd} \approx \frac{R_{LE}}{R_d + R_{LE}} \tag{56.73}$$

for large ac beta. The corresponding driving point output resistance, R_{outed}, is

$$R_{outed} = R_d + \frac{R_d}{(\beta+1)k_{is}} + \frac{R_S}{(\beta+1)^2 k_{is}} \approx R_d \tag{56.74}$$

© 2003 by CRC Press LLC

At the collector port, the driving point output resistance R_{outcd} is infinitely large to the extent that the Early resistance r_o of both transistors can be ignored. For finite r_o this resistance is of the order of, and slightly larger than, $(r_o/2)$. Finally, the model in Fig. 56.33 yields a forward transconductance, G_{fd}, from the signal source to the collector port of

$$G_{fd} = \frac{I_{OS}}{V_S} = \frac{\beta\left[1+(\beta+1)k_{is}\right]}{R_S+(\beta+1)R_d+(\beta+1)^2 k_{is}\left(R_d+R_{LE}\right)} \tag{56.75}$$

where I_{OS} is the signal component of the net output current I_O. Equation (56.75) collapses to

$$G_{fd} \approx \frac{\alpha}{R_d+R_{LE}} \tag{56.76}$$

for large AC beta.

Differential Amplifier

The **differential amplifier** is a four-port network, as suggested in Fig. 56.34(a). Source signals represented by the voltages, V_{S1} and V_{S2}, which have Thévenin resistances of R_{S1} and R_{S2}, respectively, are applied to the two amplifier input ports. The two output ports are terminated in three load resistances. Two of these loads, R_{L1} and R_{L2}, are **single-ended terminations** in that they provide a signal path to ground from each of the two output terminals. A third load resistance, R_{LL}, is differentially connected between the two output terminals. In response to the two applied source signals, two *single-ended output* voltages, V_{O1} and V_{O2}, are generated across R_{L1} and R_{L2}, and a *differential output voltage*, V_{DO}, is established across R_{LL}. This third output response is the difference between V_{O1} and V_{O2}; that is,

$$V_{DO} = V_{O1} - V_{O2} \tag{56.77}$$

The salient features of a differential amplifier are unmasked by the concepts of *differential- and common-mode* excitation and response. To this end, let the *differential input source voltage,* V_{DI}, be defined as

$$V_{DI} \triangleq V_{S1} - V_{S2} \tag{56.78}$$

and let the *common-mode input voltage,* V_{CI}, be

$$V_{CI} \triangleq \frac{1}{2}\left(V_{S1}+V_{S2}\right) \tag{56.79}$$

The differential input voltage is seen as the difference between the two applied source excitations. On the other hand, the common-mode input voltage is the arithmetic average of the two source voltages.

When solved for V_{S1} and V_{S2} (56.78) and (56.79) give

$$V_{S1} = V_{CI} + \frac{1}{2}V_{DI} \tag{56.80a}$$

$$V_{S2} = V_{CI} - \frac{1}{2}V_{DI} \tag{56.80b}$$

The preceding two expressions allow the diagram of Fig. 56.34(a) to be drawn in the form shown in Fig. 56.34(b). This alternative representation underscores the fact that the Thévenin voltage applied to either input port is the superposition of a common-mode source voltage and a component proportional

© 2003 by CRC Press LLC

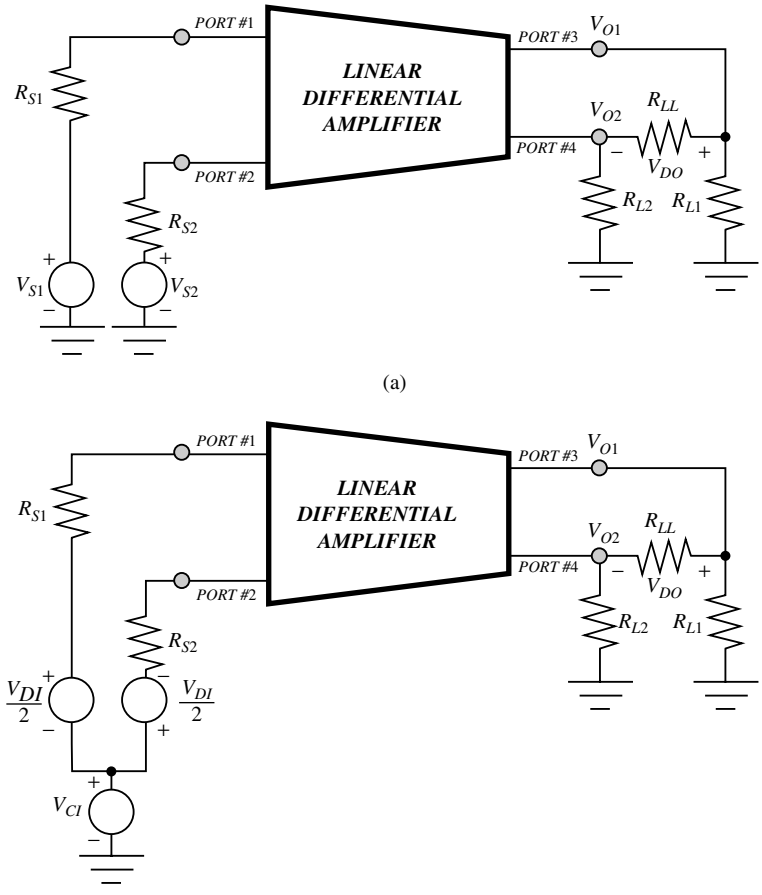

FIGURE 56.34 (a) System-level diagram of a differential amplifier. (b) System-level diagram that depicts the electrical implications of the common-mode and the differential-mode input source voltages.

to the differential-mode source voltage. The common-mode component raises both of the open-circuit input terminals to a voltage that lies above ground by an amount, V_{CI}. Superimposed with V_{CI} at the open circuit terminals of port 1 is a differential-mode voltage, $V_{DI}/2$. Simultaneously, a voltage of $-V_{DI}/2$ superimposes with V_{CI} at the open-circuit terminals of port 2.

The fact that two general source excitations applied to a four-port system can be separated into a voltage component that appears only differentially across the two system input ports and a single-ended common-mode voltage component that is simultaneously incident with both of the system input ports makes it possible to achieve signal discrimination in a differential circuit. In particular, a differential amplifier can be designed so that it amplifies the differential component of two source signals while rejecting (in the sense of amplifying with near zero gain) their common-mode component. Signal discrimination is useful whenever an electronic system must process low-level electrical signals that are contaminated by spurious inputs, such as the voltage ramifications of electromagnetic interference or the biasing perturbations induced by temperature. If the two input ports of a differential amplifier are geometrically proximate and have matched driving point input impedances, these spurious excitations impact the two input ports identically. The undesired inputs are therefore common-mode excitations that can be rejected by a differential amplifier that is well designed in the sense of producing output port responses that are sensitive to only differential inputs.

© 2003 by CRC Press LLC

If the differential amplifier in Fig.56.34 is linear, superposition theory gives

$$V_{O1} = A_{11}V_{S1} + A_{12}V_{S2} \tag{56.81a}$$

$$V_{O2} = A_{21}V_{S1} + A_{22}V_{S2} \tag{56.81b}$$

where the A_{ij} are constants, independent of V_{S1} and V_{S2}. When (56.80a) and (56.80b) are inserted into the last two relationships, the single-ended output voltages are expressible as

$$V_{O1} = \left(A_{11} + A_{12}\right)V_{CI} + \left(A_{11} - A_{12}\right)\frac{V_{DI}}{2} \tag{56.82a}$$

$$V_{O2} = \left(A_{22} + A_{21}\right)V_{CI} - \left(A_{22} - A_{21}\right)\frac{V_{DI}}{2} \tag{56.82b}$$

It follows that the differential output voltage is

$$V_{DO} = \left(A_{11} - A_{22} + A_{12} - A_{21}\right)V_{CI} + \left(A_{11} + A_{22} - A_{12} - A_{21}\right)\frac{V_{DI}}{2} \tag{56.83}$$

Since the common-mode output voltage is

$$V_{CO} \triangleq \frac{1}{2}\left(V_{O1} + V_{O2}\right) \tag{56.84}$$

(56.82a) and (56.82b) yield

$$V_{CO} = \left(\frac{A_{11} + A_{22} + A_{12} + A_{21}}{2}\right)V_{CI} + \left(\frac{A_{11} - A_{22} - A_{12} + A_{21}}{2}\right)\frac{V_{DI}}{2} \tag{56.85}$$

The ability of a differential amplifier to process differential excitations is measured by the **differential-mode voltage gain**, A_D. This performance index is defined as the ratio of the differential output voltage to the differential input voltage, under the condition of zero common-mode input voltage. From (56.83),

$$A_D \triangleq \left[\frac{V_{DO}}{V_{DI}}\right]\Bigg|_{V_{CI}=0} = \frac{A_{11} + A_{22} - A_{12} - A_{21}}{2} \tag{56.86}$$

On the other hand, the *common-mode voltage gain,* A_C, is a measure of the common-mode signal rejection characteristics of a differential amplifier. It is the ratio of the common-mode output voltage to the common-mode input voltage, under the condition of zero differential input voltage. Using (56.85),

$$A_C \triangleq \left[\frac{V_{CO}}{V_{CI}}\right]\Bigg|_{V_{DI}=0} = \frac{A_{11} + A_{22} + A_{12} + A_{21}}{2} \tag{56.87}$$

A measure of the degree to which a differential amplifier rejects common-mode excitation is the **common-mode rejection ratio** ρ, which is the ratio of the differential-mode voltage gain to the common-mode voltage gain. From (56.86) and (56.87)

$$\rho \triangleq \frac{A_D}{A_C} = \frac{A_{11} + A_{22} - A_{12} - A_{21}}{A_{11} + A_{22} + A_{12} + A_{21}} \tag{56.88}$$

© 2003 by CRC Press LLC

A common-mode gain of zero indicates that no common-mode output results from the application of common-mode input signals. Therefore, a practical design goal is the realization of a differential amplifier that has the largest possible magnitude of common-mode rejection ratio.

Balanced Differential Amplifier

Most differential amplifiers are *balanced.* Two operating requirements are satisfied by balanced differential systems. First, with zero common-mode input voltage, the two single-ended output voltages are mutually phase inverted, but otherwise identical. By (56.82a) and (56.82b), the balance requirement implies the parametric constraint.

$$A_{11} - A_{12} = A_{22} - A_{21} \tag{56.89}$$

Second, equal single-ended output voltages result when the differential-mode input voltage is zero. Using (56.82a) and (56.82b) once again, this stipulation requires

$$A_{11} + A_{12} = A_{22} + A_{21} \tag{56.90}$$

Equations (56.89) and (56.90) combine to deliver the balanced operating requirement

$$\left.\begin{aligned} A_{11} &= A_{22} \\ A_{12} &= A_{21} \end{aligned}\right\} \tag{56.91}$$

From (56.86) through (56.88), the differential-mode voltage gain, the common-mode voltage gain, and the common-mode rejection ratios of a balanced differential amplifier are

$$A_D = A_{11} - A_{12} \tag{56.92}$$

$$A_C = A_{11} + A_{12} \tag{56.93}$$

$$\rho = \frac{A_{11} - A_{12}}{A_{11} + A_{12}} \tag{56.94}$$

Moreover, the single-ended output voltages in (56.82a) and (56.82b) become

$$V_{O1} = A_C V_{CI} + A_D \frac{V_{DI}}{2} = \frac{A_D}{2}\left(1 + \frac{2V_{CI}}{\rho V_{DI}}\right)V_{DI} \tag{56.95a}$$

$$V_{O2} = A_C V_{CI} - A_D \frac{V_{DI}}{2} = -\frac{A_D}{2}\left(1 - \frac{2V_{CI}}{\rho V_{DI}}\right)V_{DI} \tag{56.95b}$$

which give rise to a differential response of

$$V_{DO} = V_{O1} - V_{O2} = A_D V_{DI} \tag{56.96}$$

Equations (56.95a) and (56.95b) show that a balanced differential amplifier having a very large common-mode rejection ratio produces single-ended outputs that are nominally phase-inverted versions of one another and approximately independent of the common-mode input voltage. On the other hand, the differential output voltage of a balanced system is independent of the common-mode input signal, regardless of the value of the common-mode rejection ratio.

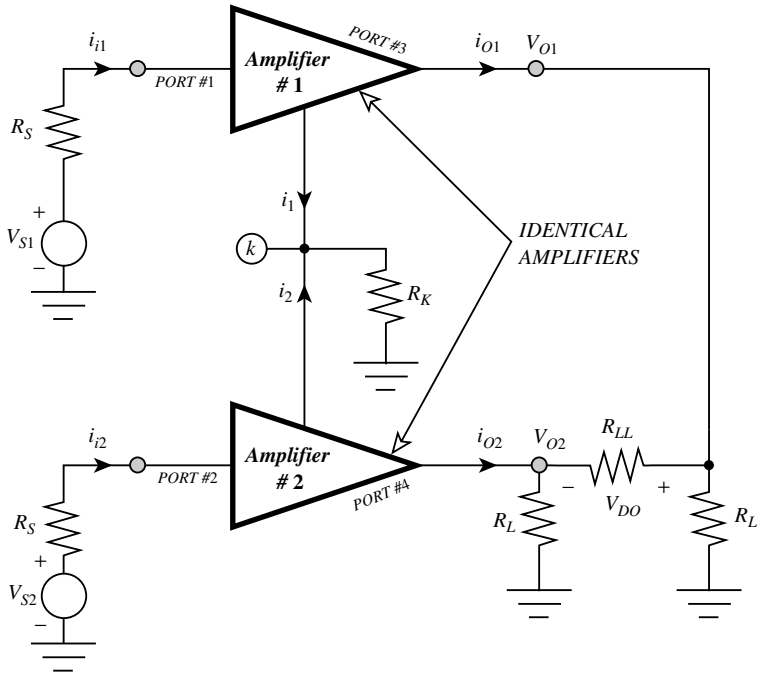

FIGURE 56.35 Generalized system diagram of a balanced differential system. The topology is an AC schematic diagram in that requisite biasing subcircuits of either amplifier are not shown.

Figure 56.35 depicts the most straightforward way to implement balance in a differential configuration. In this abstraction, two identical single-ended amplifiers, such as those discussed in earlier subsections, are interconnected to establish signal flow paths between single-ended input and single-ended output ports. This topology boasts integrated circuit practicality, since it exploits the inherent ability of a mature monolithic fabrication process to produce well-matched equivalent components. The two single-ended amplifiers in the subject figure are topologically identical, and they incorporate matched active devices that are biased at the same quiescent operating points. Thus, amplifiers 1 and 2 have small-signal two-port equivalent circuits that are reflective of one another. In order to ensure balanced operation, the single-ended output ports of each amplifier are terminated to ground in equal load resistances R_L. Similarly, the Thévenin source resistances are equivalent. Observe that balance implies that the upper half of the circuit in Fig. 56.35 is a mirror image of the lower half of the system schematic diagram. This interpretation begets the common reference to a balanced differential amplifier as a **differential pair**.

The balance condition entails the following engineering constraints.

1. Under the case of differential-mode excitation, which implies $V_{S1} = -V_{S2} = V_{DI}/2$ and hence, $V_{CI} = 0$, the currents indicated in Fig. 56.35 are such that $i_{i1} = -i_{i2}$, $i_{01} = -i_{02}$, and $i_1 = -i_2$. Since the resistance, R_K, conducts a current equal to the sum of i_1 and i_2, $i_1 = -i_2$ clamps node k to signal ground potential for exclusively differential-mode inputs. Moreover, (56.95a) and (56.95b) confirm $V_{01} = -V_{02} = A_D\, V_{DI}/2$, which produces a signal current through the differential load resistance R_{LL} of

$$\frac{V_{O1} - V_{O2}}{R_{LL}} = \frac{V_{O1}}{R_{LL}/2}$$

Since the single-ended response voltage, V_{O1}, is referred to signal ground, the midpoint of the differential load resistance is effectively grounded for differential inputs.

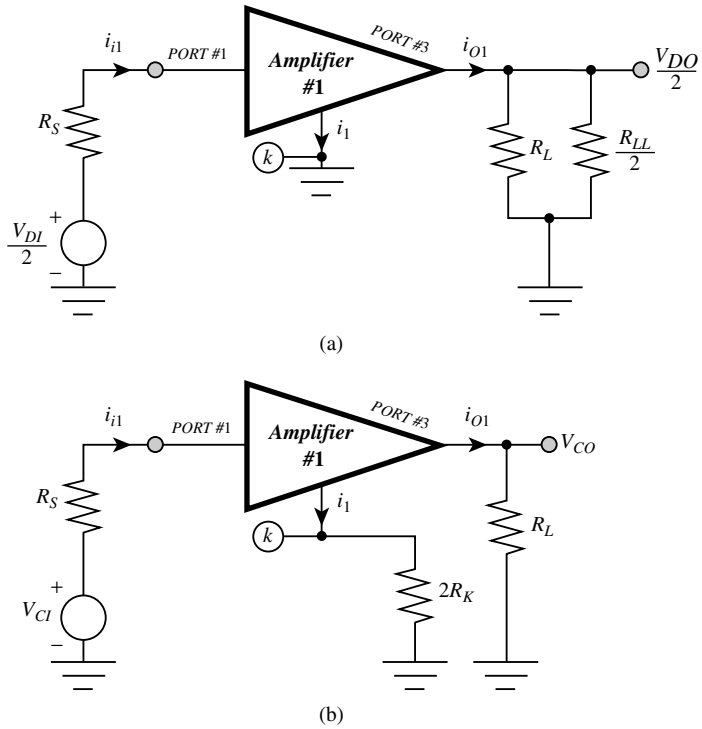

FIGURE 56.36 (a) Differential-mode half-circuit equivalent of the balanced differential amplifier. (b) Common-mode half-circuit equivalent of the balanced differential amplifier.

The foregoing disclosures imply the circuit diagram of Fig. 56.36(a), which is the so-called **differential-mode half-circuit equivalent** [11], [12] of the differential amplifier. For a balanced differential pair driven by exclusively differential inputs, the branch currents, branch voltages, and node voltages computed from an analysis of the structure in Fig. 56.36(a) are precisely the negative of the corresponding circuit variables in the remaining half of the system.

2. Under the case of common-mode inputs, which implies $V_{SI} = V_{S2} = V_{CI}$ and hence, $V_{DI} = 0$, the currents delineated in Fig. 56.35 satisfy the constraints, $i_{i1} = i_{i2}$, $i_{01} = i_{02}$, and $i_1 = i_2$, Since the resistance, R_K, conducts a current equal to the sum of i_1 and i_2, $i_1 = i_2$ establishes a voltage at node k of

$$R_K\left(i_1 + i_2\right) = \left(2R_K\right)i_1$$

that is, the signal voltage developed at node k corresponds to an amplifier 1 current of i_1 flowing through a resistance whose value is twice R_K. Additionally, $V_{O1} = V_{O2} = V_{CO}$, which means that no signal current flows through R_{LL} under exclusively common-mode excitation.

It follows that the *common-mode half-circuit equivalent* of the differential amplifier is as drawn in Fig. 56.36(b). For a balanced differential pair driven by exclusively common-mode input signals, the branch currents, branch voltages, and nodal voltages computed for the structure in Fig. 56.36(b) are identical to the corresponding circuit variables in the other half of the circuit.

Thévenin Equivalent I/O Circuits

Because the two input ports of a differential amplifier electrically interact with one another, the Thévenin equivalent circuit seen by the two signal sources in Fig. 56.34(a) is itself a two-port network. The branch elements of the Thévenin model are defined in terms of a *differential-mode input resistance,* R_{DI}, and a *common-mode input resistance,* R_{CI}.

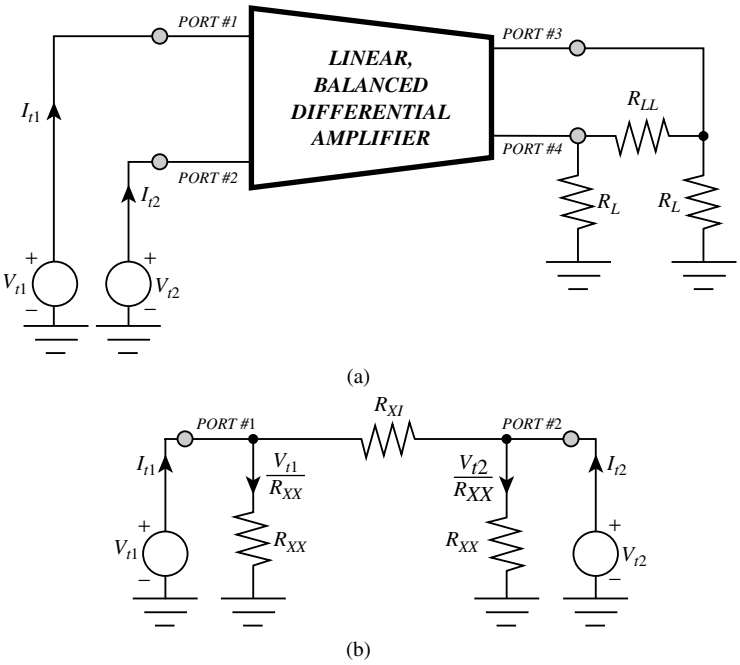

FIGURE 56.37 (a) Test circuit used to evaluate the Thévenin input equivalent circuit of a balanced differential amplifier. Note the connection of balanced loads at ports 3 and 4. (b) Hypothesized Thévenin equivalent input circuit.

Consider the test circuit of Fig. 56.37(a), which is configured to formulate the Thévenin equivalent input circuit. This structure is analogous to that of Fig. 56.34(a), except that the linear differential unit is presumed balanced. Furthermore, the original source circuits are supplanted by the test voltages, V_{t1} and V_{t2}, which establish the input port currents I_{t1} and I_{t2}. Because no signals other than V_{t1} and V_{t2} are applied to the differential pair, the Thévenin equivalent circuit seen between ports 1 and 2 is a resistance, say R_{XI}. Similarly, a second resistance, R_{XX}, is introduced to terminate port 1 to ground. System balance implies that a resistance of the same value terminates the second input port. The hypothesized Thévenin equivalent input circuit is given in Fig. 56.37(b).

The application of Kirchhoff's current and voltage laws to the model is Fig. 56.37(b) produces

$$I_{t1} - \frac{V_{t1}}{R_{XX}} = \frac{V_{t2}}{R_{XX}} - I_{t2} \tag{56.97a}$$

$$V_{t1} - V_{t2} = R_{XI}\left(I_{t1} - \frac{V_{t1}}{R_{XX}}\right) \tag{56.97b}$$

If the test voltages V_{t1} and V_{t2}, are decomposed into their differential (V_{Dt}) and common mode (V_{Ct}) components in accordance with

$$V_{t1} = V_{Ct} + \frac{V_{Dt}}{2} \tag{56.98a}$$

$$V_{t2} = V_{Ct} - \frac{V_{Dt}}{2} \tag{56.98b}$$

© 2003 by CRC Press LLC

Equations (56.97a) and (56.97b) lead to

$$I_{t1} = \frac{V_{Ct}}{R_{XX}} + \frac{V_{Dt}}{R_{XI} \| (2R_{XX})} \tag{56.99a}$$

$$I_{t2} = \frac{V_{Ct}}{R_{XX}} - \frac{V_{Dt}}{R_{XI} \| (2R_{XX})} \tag{56.99b}$$

Equations (56.99a) and (56.99b) implicitly define the common-mode and differential-mode components of the currents I_{t1} and I_{t2} resulting from the test voltages V_{t1} and V_{t2}. Accordingly, the common-mode driving point input resistance, R_{CI}, is

$$R_{CI} = R_{XX} \tag{56.100}$$

On the other hand, the differential-mode driving point input resistance, R_{DI}, is

$$R_{DI} = R_{XI} \| (2R_{CI}) \tag{56.101}$$

where use has been made of (56.99a), (56.99b), and (56.100). Note that the model resistance, R_{XI}, is related to the differential input resistance, R_{DI}, of the amplifier by

$$R_{XI} = \frac{2R_{CI}R_{DI}}{2R_{CI} - R_{DI}} \tag{56.102}$$

The test circuits for measuring the common-mode and the differential-mode driving point input resistances derive directly from (56.99a) and (56.99b). For a differential input test voltage, V_{Dt} of zero, V_{t1} and V_{t2} are identical to the common-mode input test voltage V_{Ct}, whence

$$I_{t1} = \frac{V_{t1}}{R_{XX}} = \frac{V_{t1}}{R_{CI}} \equiv I_{t2} \tag{56.103}$$

It follows that the circuit of Fig. 56.38(a) is appropriate to the measurement (or calculation) of R_{CI} as the Ohm's law ratio of the common-mode test voltage to the resultant common-mode test current. Observe that half circuit analysis measures apply, wherein R_{CI} is the resistance seen looking into port 1, with port 3 terminated to ground in the resistance R_L. For differential testing, $V_{t1} = -V_{t2} = V_{Dt}/2$, whence

$$I_{t1} = \frac{2V_{t1}}{R_{XI} \| (2R_{CI})} = \frac{2V_{t1}}{R_{DI}} = -I_{t2} \tag{56.104}$$

The pertinent test cell is shown in Fig. 56.38(b). For half-circuit analysis, care should be exercised to recognize that the ratio of the test voltage, V_{t1}, to the corresponding test current, I_{t1}, is one-half of the driving point differential input resistance, R_{DI}. In addition, the subcircuit connecting port 2 to port 4 must be removed, and port 3 must be terminated to ground by the shunt interconnection of the resistances, R_L and $R_{LL}/2$.

Just as a Thévenin model can be constructed for the input ports of a balanced differential pair, a Thévenin equivalent circuit can be developed for the output ports. Under zero input conditions, this output model, which is presented in Fig. 56.39, is topologically identical to the equivalent circuit in Fig. 56.37(b). In a fashion that reflects the computation of the resistance parameters for the input equivalent circuit, Fig. 56.40(a) is the test circuit for evaluating the driving point common-mode output resistance, R_{CO}. Figure 56.40(b) is the test structure for calculating the driving point differential-mode output resistance, R_{DO}. Following (56.102), R_{XO} in Fig. 56.39 is given by

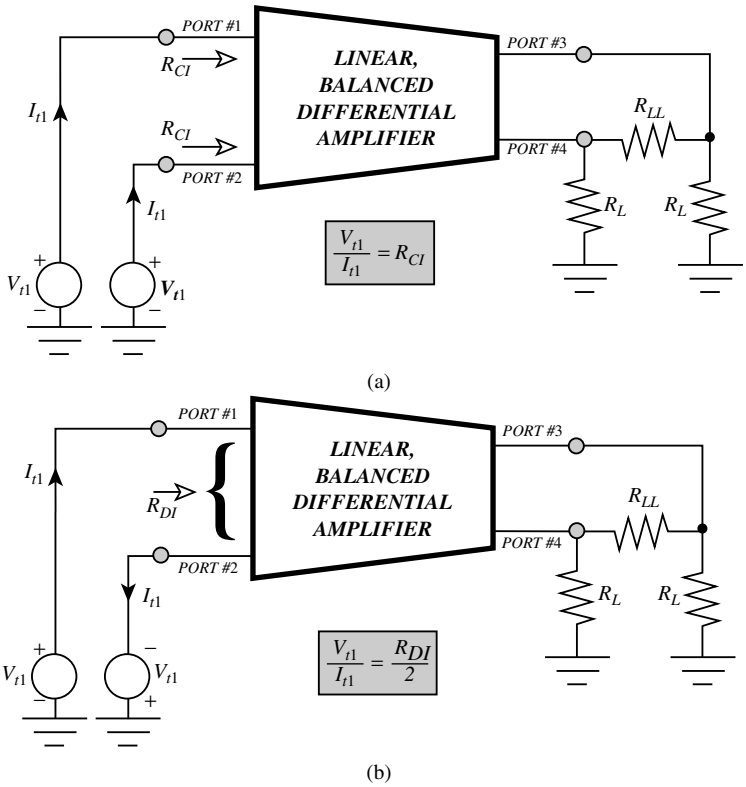

FIGURE 56.38 (a) Test circuit used to evaluate the driving point common-mode input resistance of a linear, balanced differential pair. (b) Test circuit used to evaluate the driving point differential-mode input resistance of a linear, balanced differential pair.

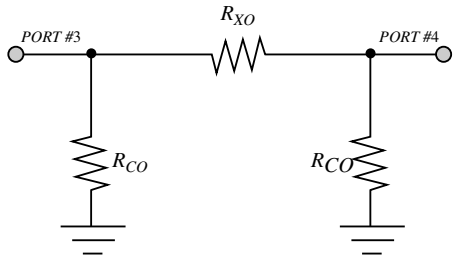

FIGURE 56.39 Thévenin equivalent output circuit of the balanced differential amplifier for the case of zero input signal excitation.

$$R_{XO} = \frac{2R_{CO}R_{DO}}{2R_{CO} - R_{DO}} \tag{55.105}$$

Two electrically interactive output ports are included in the differential system of Fig. 56.34(a). Thus, two Thévenin voltage V_{th1} and V_{th2}, each of which is linearly dependent on the differential-mode and the common-mode components of the applied source signals must be evaluated. These Thévenin output responses derive from open circuited load conditions, as indicated in Fig. 56.41(a). With $R_{S1} = R_{S2} \triangleq R_S$, balance prevails, and V_{th1} and V_{th2} are characterized by differential and common-mode components, analogous to the characterization of the terminated outputs, V_{O1} and V_{O2}.

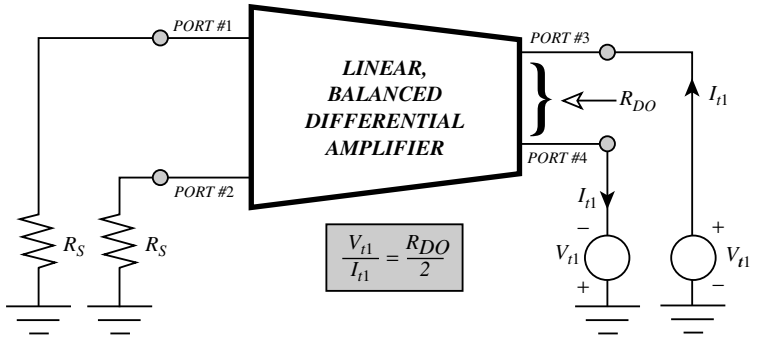
(a)



(b)

FIGURE 56.40 (a) Test circuit used to evaluate the driving point common-mode output resistance of a linear, balanced differential pair. (b) Test circuit used to evaluate the driving point differential-mode output resistance of a linear, balanced differential pair.

The Thévenin voltages in question derive from an analysis of the equivalent circuit in Fig. 56.41(b), which represents the model of Fig. 56.39 modified to account for nonzero source excitation. The proportionality constants, k_c and k_d, are related to the previously determined common-mode and differential-mode voltage gains. It is a simple matter to confirm that

$$V_{\text{thl}},\ V_{\text{th2}} = k_c V_{CI} \pm \left(\frac{k_d R_{XO}}{2R_{CO} + R_{XO}} \right) \frac{V_{DI}}{2} \tag{56.106}$$

The first term on the right-hand side of this relationship is the open-circuit common-mode output voltage, while the second term is the open-circuit differential-mode output voltage. It follows that k_c represents the open-circuit common-mode voltage gain, A_{CO}; that is,

$$k_c = \lim_{\substack{R_L \to \infty \\ R_{LL} \to \infty}} \left(A_C \right) \triangleq A_{CO} \tag{56.107}$$

On the other hand, the open-circuit differential-mode gain, A_{DO}, is

$$\frac{k_d\ R_{XO}}{2R_{CO} + R_{XO}} = \lim_{\substack{R_L \to \infty \\ R_{LL} \to \infty}} \left(A_D \right) \triangleq A_{DO} \tag{56.108}$$

© 2003 by CRC Press LLC

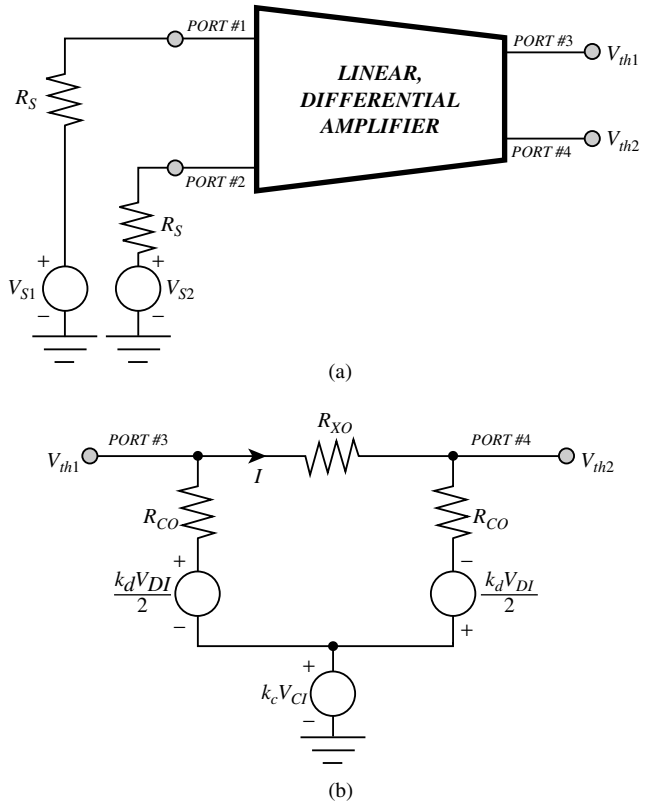


FIGURE 56.41 (a) System schematic diagram used to define the Thévenin voltages at the output ports of a balanced differential amplifier. (b) Thévenin equivalent circuit for the output ports of a balanced differential pair.

Using (56.52), the Thévenin model parameter, k_d, in the last expression can be cast as

$$k_d = \left(\frac{2R_{CO}}{R_{DO}}\right) A_{DO} \tag{56.109}$$

Fig. 56.42 summarizes the foregoing modeling results [13].

Example 4. Consider the balanced circuit of Fig. 56.43 which is operated as a single-ended input–single-ended output amplifier. The input voltage signal, which is capacitively coupled to the base of transistor $Q1$, is represented as a Thévenin equivalent circuit consisting of the source voltage, V_S, in series with a source resistance, R_S. In order to preserve electrical balance, the base of transistor $Q2$ is capacitively returned to ground through a resistance whose value is also equal to R_S. The capacitors can be presumed to act as AC short circuits over the signal frequency range of interest. For the parameters delineated in the inset to Fig. 56.43, a computer-aided circuit simulation of the subject amplifier indicates that both transistors have the small-signal parameters $r_b = 33.5\ \Omega$, $r_\pi = 1.22\ k\Omega$, and $\beta = 81.1$. Determine the small-signal voltage gain $A_v = V_{OS}/V_S$, driving point input resistance R_{in}, and driving point output resistance R_{out}.

Solution.

1) The AC schematic diagram of the differential-mode half circuit of the balanced amplifier in Fig. 56.43 is shown in Fig. 56.44(a). In concert with earlier arguments, note that the junction of the two emitter degeneration resistances, R_{EE}, is grounded, as are the mid-point of the resistance, R_{LL}, and the node at which R_1, R_2, and the two resistances labeled R are incident. Using the bipolar model of Fig. 56.13(a),

© 2003 by CRC Press LLC

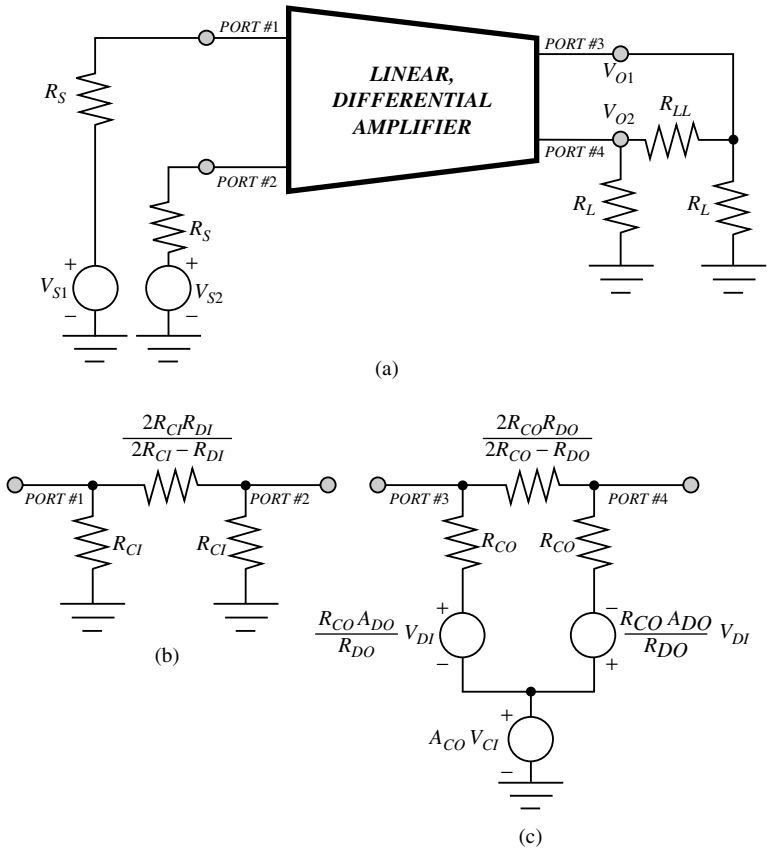

FIGURE 56.42 (a) System schematic diagram of a linear, balanced differential amplifier. (b) Thévenin equivalent input circuit. (c) Thévenin equivalent output circuit. The parameters, A_{DO} and A_{CO}, represent the open-circuit values of the differential- and common-mode voltage gains, respectively, of the balanced pair in (a).

with r_o and r_e ignored, the voltage gain of this structure is the differential-mode voltage gain of the differential pair. Moreover, the driving point input resistance of the circuit at hand is one-half of the differential input resistance of the original pair, while its driving point output resistance is one-half of the differential-mode output resistance. Analysis confirms

$$A_D = \frac{V_{DO}/2}{V_{DI}/2} = -\frac{\beta\left(\frac{R}{R+R_S}\right)\left(R_L \| \frac{R_{LL}}{2}\right)}{\left(R_S \| R\right) + r_b + r_\pi + \left(\beta+1\right)R_{EE}}$$

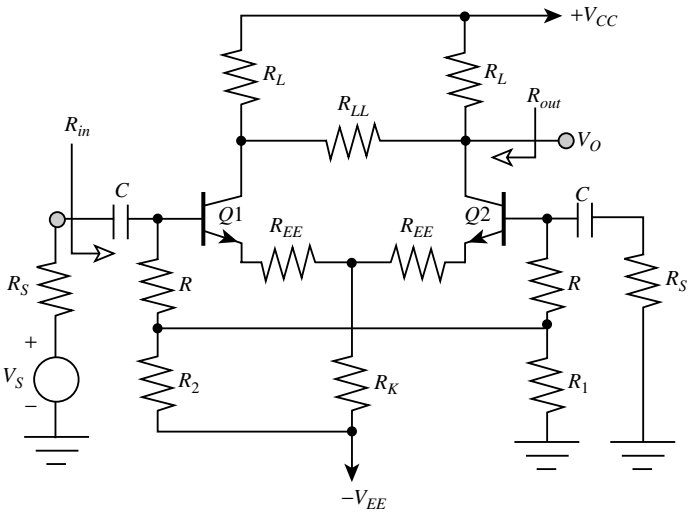
$$\frac{R_{DI}}{2} = R \| \left[r_b + r_\pi + \left(\beta+1\right)R_{EE}\right]$$

$$\frac{R_{DO}}{2} = R_L \| \frac{R_{LL}}{2}$$

Numerically, $A_D = -10.09$, $R_{DI} = 5971\ \Omega$, and $R_{DO} = 1875\ \Omega$.

2) The AC schematic diagram of the pertinent common-mode half circuit is given in Fig. 56.44(b). The input signal voltage is now the common-mode input voltage, V_{CI}, which produces the common-mode output response, V_{CO}. Using the bipolar model of Fig. 56.13(a), with r_o and r_e ignored, it is easily shown that

© 2003 by CRC Press LLC



$R_1 = 450\ \Omega$	$R_2 = 2000\ \Omega$	$R_K = 750\ \Omega$
$R_S = 50\ \Omega$	$R_{EE} = 75\ \Omega$	$R_L = 1500\ \Omega$
$R = 5000\ \Omega$	$R_{LL} = 5000\ \Omega$	$C = 1.5\ \mu f$
$V_{CC} = 5$ *volts*	$V_{EE} = 5$ *volts*	

FIGURE 56.43 A balanced bipolar differential amplifier used in a single-ended input–single-ended output mode.

$$A_C = \frac{V_{CO}}{V_{CI}} = -\frac{\beta\left(\dfrac{R + 2\left(R_1 \| R_2\right)}{R + 2\left(R_1 \| R_2\right) + R_S}\right) R_L}{\left\{R_S \left\| \left[R + 2\left(R_1 \| R_2\right)\right]\right\} + r_b + r_\pi + (\beta + 1)\left(R_{EE} + 2R_K\right)}$$

$$R_{CI} = \left[R + 2\left(R_1 \| R_2\right)\right] \left\| \left[r_b + r_\pi + (\beta + 1)\left(R_{EE} + 2R_K\right)\right]\right.$$

$$R_{CO} = R_L$$

Numerically, $A_C = -923.3\ (10^{-3})$, $R_{CI} = 5493\ \Omega$, and $R_{CO} = 1500\ \Omega$. The common-mode rejection ratio $p = A_D/A_C$ 10.93, is small owing to the relatively small value of the resistance R_K.

3) Since the output voltage is extracted at the collector of transistor $Q2$, (56.95b) is the applicable equation for determining the output signal voltage, V_{OS}. With only a single source voltage, V_S, applied, the differential input voltage is V_S, and the common-mode input voltage is $V_S/2$. It follows that

$$V_{OS} = A_C V_{CI} - \left(\frac{A_D}{2}\right) V_{DI} = \left(\frac{A_C - A_D}{2}\right) V_S$$

whence a voltage gain of

$$A_v = \frac{V_{OS}}{V_S} = \frac{A_C - A_D}{2}$$

© 2003 by CRC Press LLC

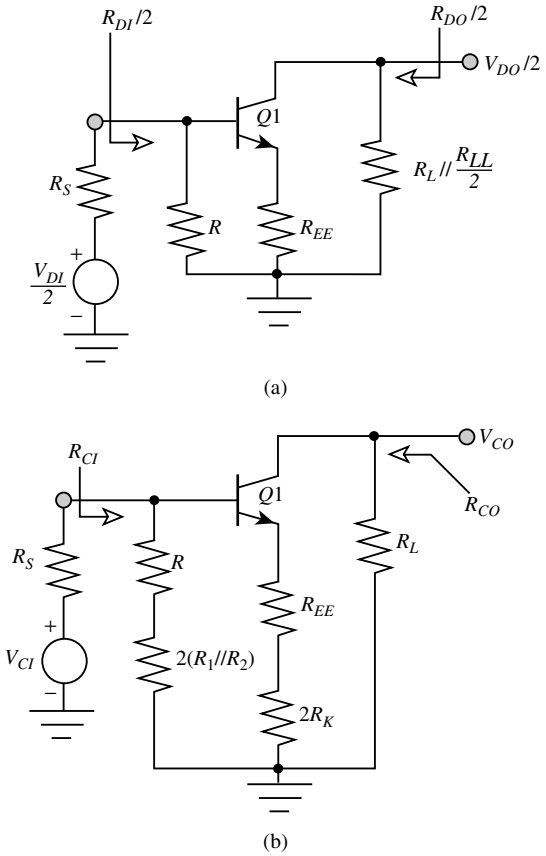


FIGURE 56.44 (a) Differential-mode half-circuit ac equivalent schematic of the differential amplifier shown in Fig. 56.43. (b) Common-mode half-circuit ac equivalent schematic of the differential amplifier shown in Fig. 56.43.

These analyses give $A_v = 4.583$.

4) In order to evaluate the driving point input and output resistances, the parameters, R_{XI} and R_{XO} must be calculated. From (56.102) and (56.105), $R_{XI} = 13.08$ kΩ, and $R_{XO} = 5.0$ Ω.

The two-port model for calculating the driving point input resistance R_{in} is given in Fig. 56.42(b). Recall that a circuit resistance, whose value is numerically equal to the internal signal source resistance, R_S, is connected between ground and the node to which the base of transistor $Q2$ is incident. By inspection,

$$R_{\text{in}} = R_{CI} \left\| \left[R_{XI} + \left(R_{CI} \| R_S \right) \right] \right.$$

or $R_{\text{in}} = 3.87$ kΩ.

The output port model that emulates the driving point output resistance is given in Fig. 56.42(c). This model is analogous to that of Fig. 56.42(a), except that no external loads are connected between signal ground and the node to which the collector of transistor $Q1$ is incident. Clearly,

$$R_{\text{out}} = R_{CO} \left\| \left(R_{XO} + R_{CO} \right) \right.$$

which produces $R_{\text{out}} = 1219$ Ω.

56.3 MOSFET Biasing Circuits

D. G. Haigh, B. Redman-White, and R. Akbari-Dilmaghani

Introduction

CMOS technology is finding a very wide range of applications in analog and analog-digital mixed-mode circuit implementations in addition to its traditional role in digital circuits. In mixed-mode circuits compatibility of analog circuits with digital VLSI is important, particularly in cost-sensitive areas and situations where low power consumption is required. Such CMOS circuits require a range of biasing circuits and it is this topic that is the main subject of this section, although the subject is mentioned elsewhere in this text, where particular designs are covered.

The requirements for biasing circuits in CMOS circuit design can be divided into the requirements for voltage and for current sources. These sources can be further subdivided into two additional categories, high precision and noncritical. High-precision voltage or current sources are essential components in data converters, both analog-to-digital and digital-to-analog and the precision required depends on the overall target precision of the data converter. For a large number of bits, the precision required could be very great indeed and would need to be maintained over a specified temperature and supply voltage range and in the presence of on-chip, chip-to-chip and wafer-to-wafer component parameter variations. Precision sources are also required in other applications such as dc pedestals for video signals in video systems.

© 2003 by CRC Press LLC

Noncritical voltage sources are generally required for setting up an internal analog ground or for biasing the gates of FETs in common-gate configuration, as in a cascode FET. In these cases, the sensitivity of overall circuit performance parameters to the bias voltage would generally not be high and moderate precision circuit techniques would be acceptable. The main considerations would be to maintain correct operation, especially in terms of signal headroom, overall variations in process, power supply, and temperature conditions. The requirement for current sources for biasing CMOS analog and mixed-mode circuits is very considerable. The reason for this is that most circuits, such as an operational amplifier, consist of several stages, each of which requires biasing. In discrete circuits, the tendency is to use resistors for biasing, for reasons of cost and the poor sample-to-sample tolerances on discrete active device parameters. In integrated circuit implementation, on the other hand, relatively well-matched devices on the same chip are available and the use of current source biasing minimizes gain loss due to loading effects. Furthermore, using a multioutput current mirror to supply different parts of the circuit allows stabilization of the current against temperature and power supply voltage variations to be performed at one location only (on or off the chip) and the stabilized current can be distributed throughout the chip or subcircuit using current mirror circuits. This also produces significant immunity to localized power supply fluctuation and noise. Full or partial stabilization of bias currents with operating and environmental changes is desirable in order to minimize the range of operating current for which design must be specified, allowing higher design performance targets to be achieved.

In many cases, CMOs circuits have their power supplies derived from an off-chip bipolar regulator (with its own internal bandgap). In these situations, a reasonable voltage reference can sometimes be obtained from the power supply voltage via a potential divider. A voltage obtained in this way can be applied to an external low tolerance resistor to obtain a current reference of moderate precision. The value of realizing a reference on chip is that the cost of the external reference can be avoided For example, in battery supplied equipment, a large degree of supply voltage immunity is required in the presence of a widely varying battery voltage. It is possible to use an on-chip voltage regulator or an on-chip, switched-mode power supply. In CMOS technology, high-precision voltage references are difficult to design, although a reference with good power supply rejection is possible. BiCMOS technology overcomes many of the problems experienced with CMOS technology since well-controlled bipolar devices for very high-precision references are available on-chip.

Many references to biasing appear in this text under the heading of the circuit concerned and only some general guidelines and principles, together with some example circuits will be given here. We begin this section on CMOS biasing circuits by considering the devices available for biasing in a CMOS integrated circuit including parasitically realized bipolar junction devices. Some useful simplified models of these devices and a brief examination of the variability of the relevant model parameters will be presented. We then consider different types of references and biasing circuits. Since voltage and current references are closely interrelated, they are dealt with concurrently. The material is presented according to a gradually increasing level of sophistication and achievable precision, starting with simple circuits with only minor supply voltage, temperature, and process independence and leading to fully curvature-compensated bandgap references. This is followed by a consideration of references based on less usual devices that may not be available or usable in every process but that offer potentially attractive solutions. We then illustrate the application of some biasing techniques in the context of simple operational amplifier circuits. Finally, we consider the biasing of amplifiers for very low supply voltages, where rail-to-rail optimized performance is required, and dynamic biasing techniques. The topic of CMOS biasing circuits is sufficiently large to warrant an entire book and we include a list of references that will help to provide the reader with more detailed information.

Device Types and Models for Biasing

Devices

The principal devices of CMOS technology are the enhancement-mode N-channel and P- channel MOSFET, which are shown schematically in Fig. 56.45(a) and (b) for N-well and P-well technologies,

© 2003 by CRC Press LLC

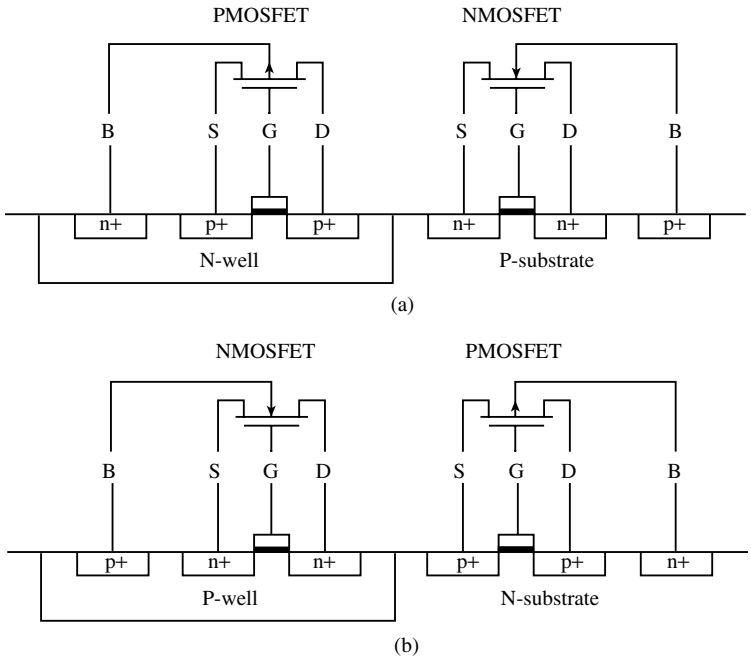

FIGURE 56.45 Realization of NMOS and PMOS FETs in COMS technology. (a) N-well process. (b) P-well process.

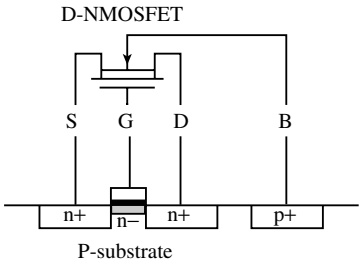

FIGURE 56.46 Realization of NMOS depletion-mode FET in N-well CMOS technology.

respectively. Currently, N-well technology is more widely available than P-well. Depletion-mode devices are not routinely provided in CMOS (in contrast with NMOS), but they are available in some processes [23] and they can be used to realize reference circuits [4], [5], [23]. They are produced by an additional implementation under the gate region (N-type for NMOS and P-type for PMOS). The NMOS depletion-mode symbol is shown schematically in Fig. 56.46.

In most processes, the MOSFET gate material is highly N-doped polysilicon. In some processes [8], P-doped gates are available, and these can be used to realize reference circuits. The symbol of an N-channel enhancement MOSFET with P-type doped base is shown in Fig. 56.47.

In order to realize temperature and process desensitized biasing of CMOS circuits, the special properties of bipolar junction transistors (BJTs) are advantageous. BJT devices can be realized in CMOS technology as parasitic devices with certain restrictions. Two classes of such device are available, namely vertical and lateral. For the vertical device [13], the restrictions are that an N-well process can realize PNP devices with the collectors connected to the substrate (most negative supply rail) and that a P-well process can realize NPN devices with the collectors connected to the substrate (most positive supply rail). The realization of these vertical devices in the case of N-well and P-well processes is shown schematically in Fig. 56.48(a) and (b), respectively. The devices can have typical current gains of around 100 and may have high leakage, and certain percautions have to be taken in the layout. One problem is that the control

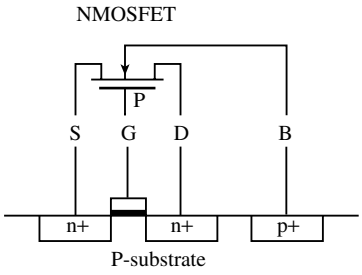

FIGURE 56.47 NMOS enhancement-mode FET with P-doped polysilicon gate.

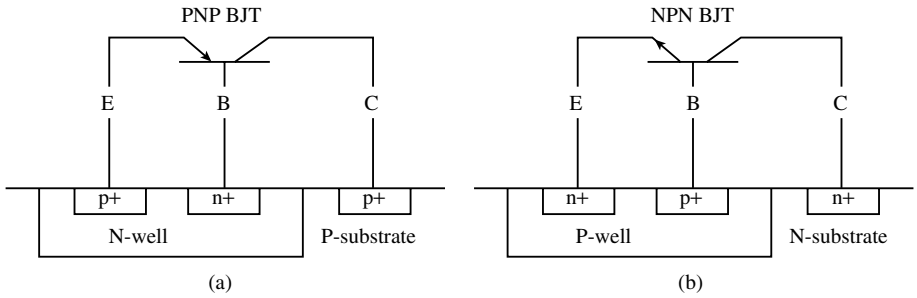

FIGURE 56.48 Realization of vertical BJT devices in CMOS technology. (a) N-well process. (b) P-well process.

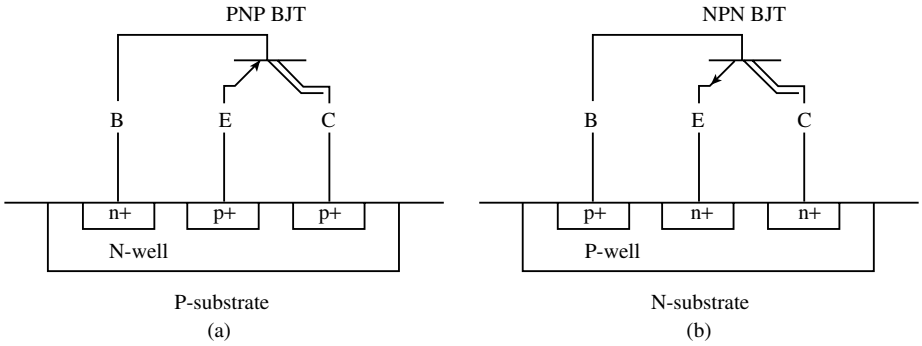

FIGURE 56.49 Realization of lateral BJT devices in CMOS technology. (a) N-well process. (b) P-well process.

on the parameters of these devices in production is minimal. Nevertheless, such devices are adequate to realize moderate to high precision bias and reference circuits.

The restriction on the collector connections of the vertical BJT devices in CMOS technology is effectively removed in lateral BJT devices [16]. The realization of these devices in the case of N-well and P-well processes is illustrated in Fig. 56.49(a) and (b), respectively. It should be noted that β_f for lateral bipolar transistors is not related to α_f in the usual way due to substrate currents. For both vertical and lateral parasitic bipolar devices, it is often the case that the foundry will not provide detailed characterization and models, and also that the parameters of the devices will not be well controlled.

Apart from MOSFETs and BJTs, the remaining component needed to realize bias circuits are resistors and in some cases capacitors. In the case of precision bias circuits, the realized variable (voltage or current) would be dependent on resistor ratios rather than on absolute values. On-chip resistors may be realized using polysilicon, or as N-well or P-well diffusion, as illustrated in Fig. 56.50. Diffused resistors are sensitive to substrate potential and thus they are not suitable for precision potential dividers. In some cases, voltages or currents on a chip that are required to have high stability are referred to an off-chip highly stable and accurate discrete resistor. In some advanced processes, film resistors (usually nichrome)

© 2003 by CRC Press LLC

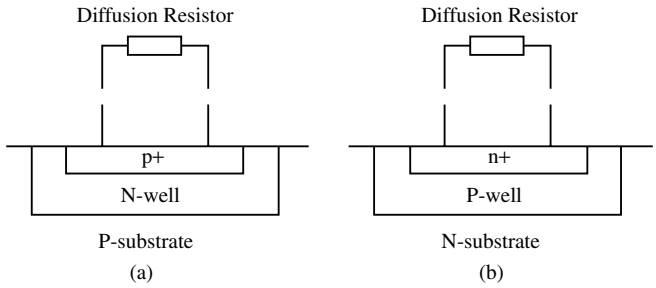

FIGURE 56.50 Realization of diffusion resistors in CMOS technology. (a) N-well process. (b) P-well process.

are available and they have excellent temperature stability, a wide range of values and can sometimes be laser-trimmed.

Capacitors, both on-chip and external, are used for decoupling bias and reference voltages and are especially valuable where low noise is critically important. On-chip capacitors also provide the basic components used for dynamic biasing.

Device Models and Parameter Variability

The MOSFETs in Fig. 56.45 may be very approximately described by [13], [15]

$$I_d = \beta\left(V_{gs} - V_t\right)^2\left(1 + \lambda V_{ds}\right) \tag{56.110}$$

where

$$\beta = \mu C_{ox} W/L \tag{56.111}$$

and

$$V_t = V_{to} + \gamma\left[\left(2\phi_{fb} - V_{bs}\right)^{0.5} - 2\phi_{fb}^{0.5}\right] \tag{56.112}$$

with

$$\phi_{fb} = \left(\frac{kT}{q}\right)\ln\left(\frac{N_{\text{sub}}}{n_i}\right) \tag{56.113}$$

and

$$\mu \propto T^{-\eta} \tag{56.114}$$

The parameters in (56.110)–(56.114) are defined in Table 56.1. As a result of (56.110)–(56.114), MOSFET parameters show considerable temperature dependence. In particular, threshold voltage varies with temperature according to

$$\frac{\partial V_t}{\partial T} = \frac{2}{T}\left(\phi_F - \frac{E_{go}}{2q}\right)\left(1 + \frac{\gamma}{2(2\phi_{fb} - V_{bs})}\right) \tag{56.115}$$

which amounts typically to about –2 mV/°C (Ego is the bandgap of silicon at 0°K) [15]. Transconductance varies according to

$$\frac{\partial g_m}{\partial T} = \frac{g_m}{2}\left(-\frac{\eta}{T} + \frac{1}{I_d}\frac{\partial I_d}{\partial T}\right) \tag{56.116}$$

ϕ_{GO}	Bandgap voltage for silicon at 0 K

The temperature and process dependencies of MOS devices have led to the exploitation of some properties of combinations of less usual MOS devices. It has been observed that the difference between the threshold voltages of an enhancement- and depletion-mode FET pair is relatively temperature independent. The threshold voltages for enhancement- and depletion-mode MOSFETs may be written

$$V_{t(\text{enh})} = V_{FB} - \frac{Q_{SS}}{C_{ox}} + 2|\phi_P| + \frac{|Qd|}{C_{ox}} \tag{56.117}$$

$$V_{t(\text{depl})} = V_{FB} - \frac{Q_{SS}}{C_{ox}} + \phi_{bi} + \left(|Q_d| - |Q_i|\right)\left(\frac{1}{C_{ox}} + \frac{1}{C_{\text{impl}}}\right) \tag{56.118}$$

where the meaning of the parameters is given in Table 56.1 [4]. Many of the parameters in (56.117) and (56.118) show considerable temperature dependence. The difference between the threshold voltages is given by

$$\begin{aligned} V_{t(\text{diff})} &= V_{t(\text{enh})} - V_{t(\text{depl})} \\ &= 2|\phi_P| - \phi_{bi} - |Q_i|\left(\frac{1}{C_{ox}} + \frac{1}{C_{\text{impl}}}\right) \end{aligned} \tag{56.119}$$

© 2003 by CRC Press LLC

assuming that $1/C_{ox} \gg 1/C_{\text{impl}}$, which is true in practice. In practice, it is also the case that $2|\phi_p| \approx \phi_{bi}$. Since the implanted charge Q_i is controllable and independent of temperature to first order [4], the threshold voltage difference exhibits temperature independence to first order.

The difference between the threshold voltages of two N-channel FETs with polysilicon gates of opposite doping polarity (P and N) also shows relative insensitivity to temperature variations [8]. To a first approximation, the threshold voltage difference is given by

$$\Delta V_G = \phi_G = 1.12 \text{ V} \quad (\text{room temperature}) \tag{56.120}$$

which is the bandgap voltage for silicon [8]. A more detailed analysis [1] gives

$$\Delta V_G(T) = \phi_{GO} - \frac{\alpha T^2}{T + \beta} \tag{56.121}$$

where $\alpha = 7.02 \cdot 10^{-4}$ V/K, $\beta = 1109$ K and the meaning of the remaining parameters is given in Table 56.1. In practice, the degree of temperature independence obtained provides useful reference circuits [8]. The exploitation of both the enhancement–depletion FET threshold difference and the N-P doped polysilicon gate threshold voltage difference for the design of references will be described later.

The strong temperature dependence of conventional MOS device parameters means that for stable biasing circuits, MOS devices are mainly useful where the critical variable depends on a ratio of parameters of similar devices. Even in this case, the matching is not as good as for bipolar devices. The matching of the gate–source voltages of two similar devices with nominally identical drain currents is inversely proportional to the square root of the gate area and is typically of the order of 10 mV, which limits the minimum offset voltage of a CMOS op amp. Since op amps form key components in many voltage and current reference circuits, this is a serious limitation.

In contrast to the rather complex dependence of MOS device parameters with temperature, the situation in the case of BJT devices is relatively straightforward [15], [17], [26]. The BJT may be described by

$$I_c = I_s e^{V_{be}q/kT} \tag{56.122}$$

where the additional parameters are defined in Table 56.1. Equation (56.122) may alternatively be written

$$V_{be} = \frac{kT}{q} \ln \frac{I_c}{I_s} \tag{56.123}$$

For two devices with an emitter area ratio of A

$$A = \frac{I_{s1}}{I_{s2}} \tag{56.124}$$

We have

$$\begin{aligned} \Delta V_{be} &= V_{be1} - V_{be2} \\ &= \frac{kT}{q} \ln \frac{I_{c1}}{I_{c2}} \frac{1}{A} \\ &= V_T \ln \frac{1}{A} \qquad (\text{for } I_{c1} = I_{c2}) \end{aligned} \tag{56.125}$$

Thus, the difference between the V_{be}'s of two BJTs with different current densities is proportional to the thermal voltage V_T, which is proportional to absolute temperature (PTAT). The positive temperature

© 2003 by CRC Press LLC

coefficient of V_T can be effectively used to cancel the negative temperature coefficient of V_{be} [13]. This is referred to as the bandgap principle.

Resistors are also key elements in MOS biasing circuits and they may be realized using diffusion, polysilicon and, in some advanced processes, using film techniques. Polysilicon and diffused resistors suffer from a high temperature coefficient that is positive for diffusion. The resistivity of gate polysilicon is typically rather low at about 20 Ω/square and its initial value tolerance is quite high. Film resistors have a very low temperature coefficient.

Voltage and Current Reference and Bias Circuits

Supply-Voltage-Referenced Voltage and Current References

When the supply voltages to a chip are well-regulated off-chip, then a voltage reference, acceptable in some cases, can be realized by a simple potential divider from the power supply voltage, as shown in Fig. 56.51. An external decoupling capacitor may be used if needed and the voltage dividing elements may be resistors [Fig. 56.51(a)] or MOSFETs [Fig. 56.51(b)]. If the power supply voltages are well-controlled off-chip, using an external regulator circuit, then a simple current reference can be realized by the arrangement in Fig. 56.52, where the reference current is defined by applying a well-defined fraction of the controlled supply voltage to a well-controlled external resistor.

A very simple biasing circuit proving multiple current sources and sinks, as required in CMOS analog signal-processing circuits is shown in Fig. 56.53(a) [13]. Assuming large FET W/L ratios, the voltage across the resistor is approximately $V_{dd} - V_{ss} - 2V_t$. The current in R is mirrored in the output MOSFETs where the W/L ratios may be chosen to provide required current magnitudes. The resistor R may have to be

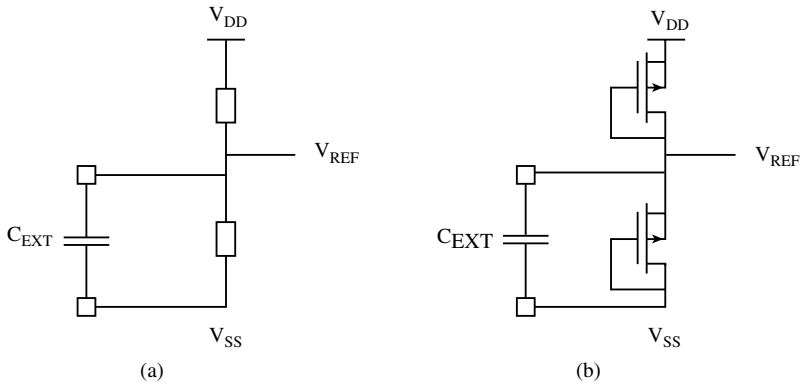

FIGURE 56.51 Voltage reference obtained via potential divider from regulated power supply: (a) using resistors; (b) using MOSFETs.

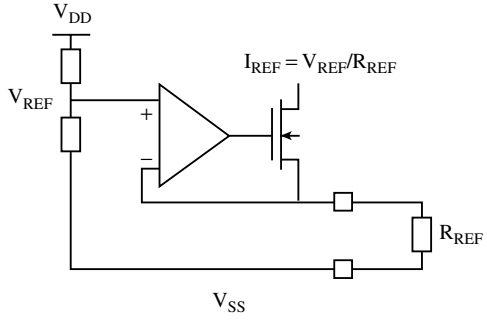

FIGURE 56.52 Current source realized using potential divider.

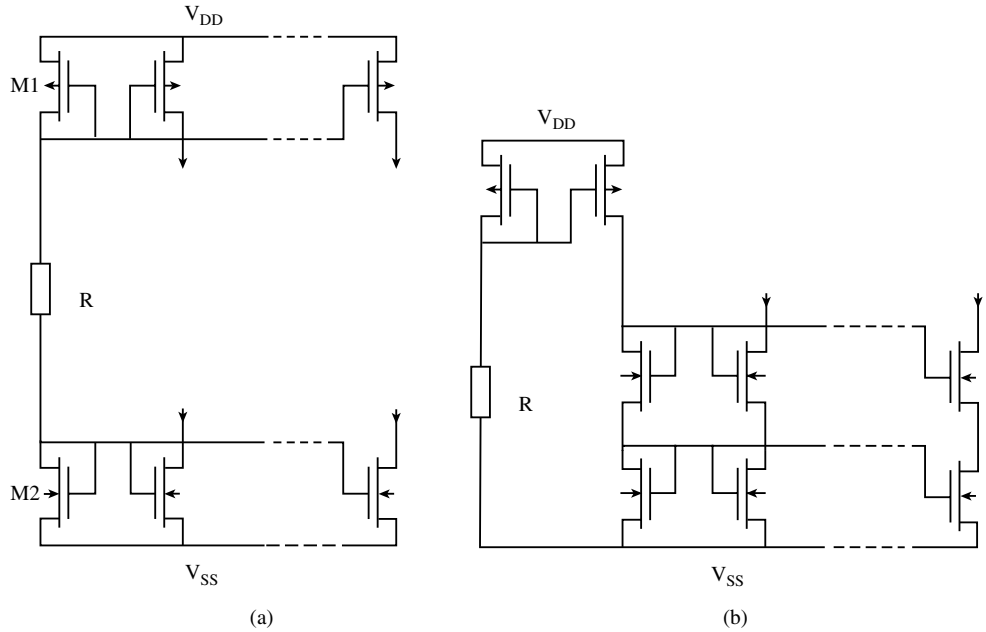

FIGURE 56.53 Resistor/current mirror bias circuits: (a) simple; (b) cascode.

realized off-chip as a precision film component with narrow tolerance and small temperature coefficient. In practice, the voltage across the diode-connected MOSFETs $M1$ and $M2$ will be greater than V_t and have some dependence on MOSFET β as well as V_t.

For the circuit in Fig. 56.53(a), the source conductance is equal to the MOSFET g_{ds}, which might not be sufficiently low for some applications. This disadvantage can be overcome by introducing cascode FETs as in Fig. 56.53(b). Nevertheless, the supply voltage dependence of the circuit in Fig. 56.53 remains.

For uncritical applications where the current source is to be realized entirely on-chip, the resistor R in Fig. 56.53(a) may be replaced by a chain of diode-connected P- and N-channel MOSFETs, as shown in Fig. 56.54 [13]. The number of these devices and their W/L ratios may be chosen according to the

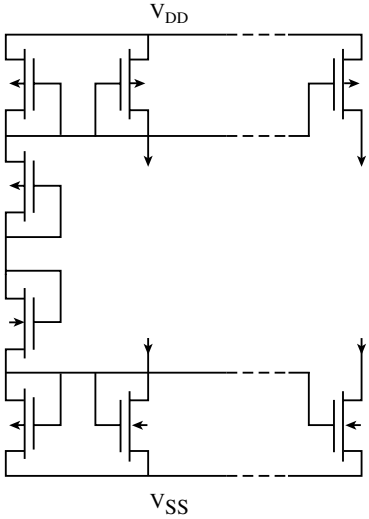

FIGURE 56.54 FET/current mirror bias circuit.

© 2003 by CRC Press LLC

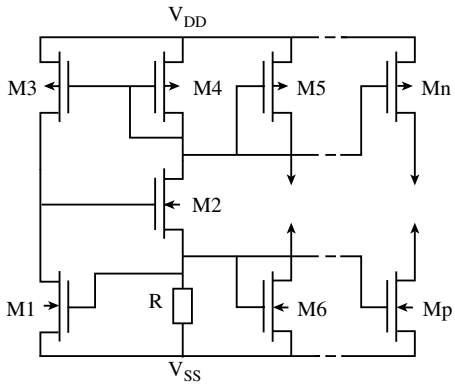

FIGURE 56.55 V_t-referenced current bias circuit.

supply voltage and the value of the current to be realized. Since the diode-connected MOSFETs are effectively realizing the resistor in the basic current source of Fig. 56.53(a), the power supply voltage dependence of the current remains. In addition, the effective resistance realized depends on MOSFET β and V_t, both of which have large tolerances and high temperature coefficients.

MOSFET Threshold Voltage-Based References

A current reference with reduced power supply voltage dependence is shown in Fig. 56.55 [13]. By choosing W/L for $M1$ to be large, the gate–source voltage of $M1$ can be made close to the device threshold voltage V_t. Since the gate–source voltage of $M1$ appears across the resistor R, the current in R is approximately V_t/R, which is ideally independent of power supply voltage. The W/L ratios of MOSFETs $M3$ and $M4$ chosen to define a fixed ratio for the currents in $M1$ and R. The combination of MOSFETs $M2$, $M3$, and $M4$ constitute a positive feedback loop and it is important to choose the W/L ratios so that the loop gain is less than unity to avoid oscillation. Many reference circuits have a stable state with all currents zero. In such cases, it is necessary to provide a start-up circuit [13] to prevent the reference circuit locking into an undesired operating point. A source follower can be introduced at the gate of $M2$ such that in this condition a current is injected into the circuit. The added components must be such that in the normal operating point, they are switched off and therefore do not influence operation. In practice, the currents realized by the circuit in Fig. 56.55 will have some supply voltage dependence due to channel length modulation in the MOSFETs. This effect can be reduced by introducing cascode devices appropriately. Although the currents realized can be made substantially independent of supply voltage, the dependence on resistance R remains. For high precision and temperature independence, R may need to be realized as an off-chip film resistor. It must be borne in mind that the device threshold voltage on which the current depends is rather variable (typically 0.5-0.8 V) and also rather temperature dependent. Solution of this problem requires the introduction of alternative techniques based on BJT or unconventional CMOS devices, which will be discussed.

An alternative circuit to that in Fig. 56.55 is shown in Fig. 56.56 [25]. This circuit regulates the MOSFET drain currents with the result that MOSFET transconductance is proportional to $1/R$. This circuit also relies on positive feedback and care must be taken in the design to avoid instability. It has been shown in [21] that a practical stable design results from the choice $(W/L)_4 = (W/L)_3$ and $(W/L)_2 = 4(W/L)_1$, giving $g_m = 1/R$. In processes where R can be realized as a film resistor on-chip, this circuit can stabilize transconductances to within 3 percent over a 100°C temperature range [25].

BJT V_{be}-Based References

The problem that MOSFET threshold voltage is not very well controlled from chip sample to chip sample leads to the idea of using the V_{be} of a parasitic bipolar transistor [13]. Such a V_{be}-referenced circuit is shown in Fig. 56.57 for the case of an N-well process, where the BJT is PNP [13]. The W/L ratios for $M1$

© 2003 by CRC Press LLC

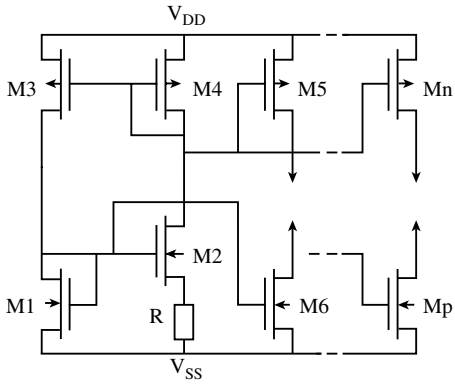

FIGURE 56.56 g_m-R tracking current reference circuit.

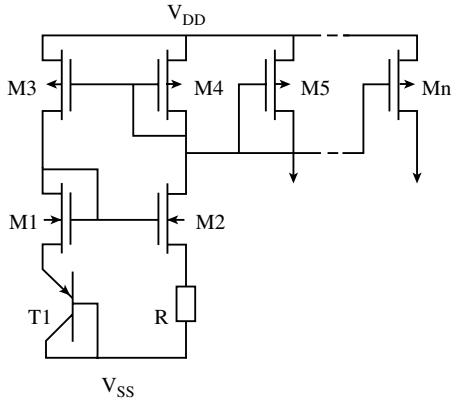

FIGURE 56.57 V_{be}-referenced current bias circuit.

and $M2$ are made large so that the V_{be} of $T1$ appears substantially across R. In order to achieve high precision and temperature independence, R would need to be an off-chip film resistor. However, the V_{be} has a process-dependent tolerance of about 5 percent and a dependence with temperature of about –2 mV/°C.

BJT V_T-Based References

The temperature dependence of V_{be} in the circuit of Fig. 56.57 can be overcome in the V_T-based circuit of Fig. 56.58 [13]. The emitter areas of the BJTs $Q1$ and $Q2$ are scaled in the ratio 1: n and the MOS current mirrors force the emitter currents to be equal. The difference between the V_{be} of $Q1$ and $Q2$ given by (56.120) appears across the resistor R, hence defining the current. The positive temperature coefficient of V_T can be used to counteract the positive temperature coefficient of the resistor R to obtain a stable current. In the circuit of Fig. 56.58, $M1$ and $M2$ must have large W/L to minimize the effect of MOSFET process variability. Also, cascoding of the current mirrors may be required to reduce the effect of channel length modulation.

Bandgap References

Precision voltage sources are key requirements for the realization of precision data converters and have received much attention [2], [3], [7], [10], [12]–[14], [20], [22]. The requirements for high precision and very low temperature and supply voltage dependence have led to the development of the bandgap principle [2], [3], [7], [10], [13]. The bandgap principle was originally developed for bipolar technology

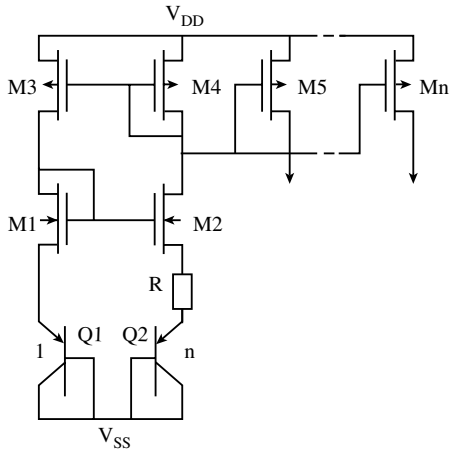

FIGURE 56.58 V_T-referenced current bias circuit.

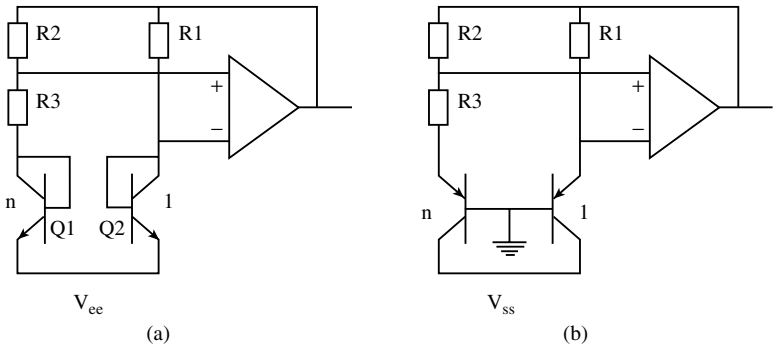

FIGURE 56.59 Basic bandgap circuits. (a) Classical bandgap circuit. (b) Modified form with grounded-collector PNP transistors, assuming an N-well process.

and a typical architecture is shown in Fig. 56.59(a). As described previously, the difference between the V_{be}'s of two BJTs with different current densities is proportional to the thermal voltage V_T and is PTAT. In Fig. 56.59(a), the difference between the V_{be}'s appears across $R3$ and in scaled form across $R2$. Thus the output voltage is equal to the V_{be} of $Q1$ plus the scaled version of ΔV_{be}. Thus $R2/R3$ may be chosen so that the opposite temperature coefficients of V_{be} and ΔV_{be} cancel. The ratio $R1/R2$ determines the ratio of the currents in $Q1$ and $Q2$. The circuit in Fig. 56.59(a) is incompatible with implementation using CMOS technology with vertical parasitic bipolar devices because the collectors are not grounded. This can be overcome using the architecture in Fig. 56.59(b). However, there is the further problem that the offset voltage of the operational amplifier is multiplied by the internal gain of the feedback loop and added to the output. Offset is worse for CMOS than for bipolar operational amplifiers. This problem has been overcome in various ways. In [12] and [22], use is made of a discrete time offset compensated differential amplifier, which can have very low offset. Another approach is to make use of lateral bipolar devices, which do not suffer from the topological restrictions of their vertical counterparts [16]. Thus the architecture of Fig. 56.59(a) or an equivalent topology may be implemented.

A typical example of a current reference based on a bandgap voltage reference is shown in Fig. 56.60 [13]. The current in the resistor xR is V_T-referenced as in Fig. 56.58 and therefore has a negative temperature coefficient (the BJTs are vertical parasitic devices). This current is converted to a voltage and weighted by the resistor xR before being added to the V_{be} of $Q3$, which has a negative temperature coefficient. The parameter x is chosen to obtain an overall zero temperature coefficient for the output

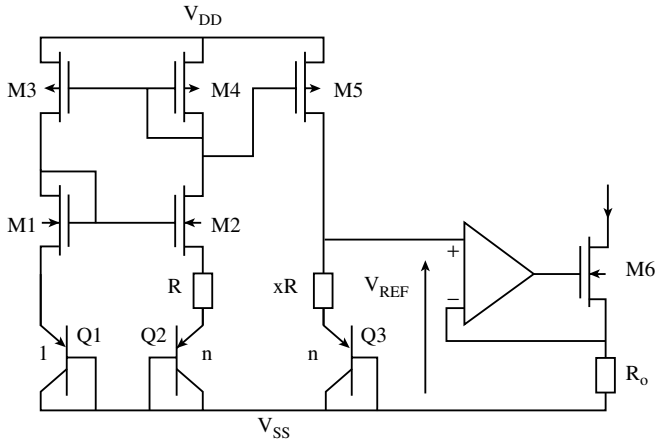

FIGURE 56.60 Bandgap current bias circuit.

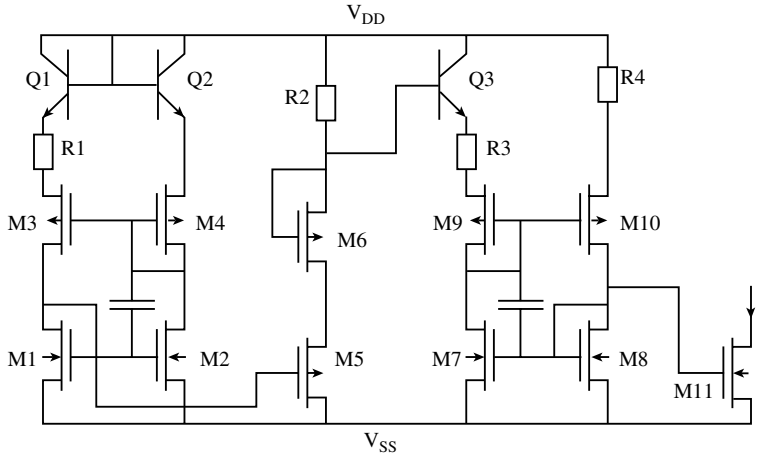

FIGURE 56.61 Curvature-compensated current bias circuit.

current, which is given by V_{ref}/R_0. Clearly, R_0 needs to be a high-precision resistor and could be external to the chip. The current mirrors need to be very well matched as any offset is amplified. The operational amplifier needs to have a low offset voltage since this is added to the reference voltage. Further current mirroring may be used to change the sign of the current or to increase the permissible range of the output voltage, referred to as compliance.

Curvature-Compensated Bandgap References

The bandgap reference principle can provide a zero temperature coefficient at a single temperature, leaving a temperature dependence that is dominated by a second-order temperature dependence. Very sophisticated techniques have been developed [12], [24] to eliminate this second-order dependence to leave a typically much smaller third-order dependence. This technique is referred to as curvature compensation. An example of a curvature-compensated current reference [24] is shown in Fig. 56.61. This circuit can achieve precisions of the order of 5 ppm/°C for supply voltages over 5 to 15 V.

Discrete Time Bandgap References

The voltage reference in [12] provides curvature compensation and achieves a drift of the order of 13 ppm/°C over the commercial temperature range. The design is based on a comprehensive analysis of

© 2003 by CRC Press LLC

nonideal effects in the basic bandgap circuit including finite β and base resistance of the bipolar devices, operational amplifier offset, and bias current variation. This leads to a system involving a very low offset switched capacitor differential amplifier and a system of injecting a differential pair of currents into the emitters of the bipolar devices to provide curvature compensation. The offset cancellation of the switched capacitor differential amplifier is accompanied by techniques for cancellation of the effect of base currents and base resistance in the bipolar devices. Base currents can sometimes be a severe problem due to the available current gains of parasitic bipolar devices. The design is fully compatible with a digital IC process and achieves an equivalent precision of 12 b. Room temperature trims are necessary for a zero temperature coefficient and for curvature compensation. Although low-frequency power supply rejection is good, it falls with increasing frequency.

In [22], a floating voltage reference for signal-processing applications with a good power supply rejection ratio of at least 85 dB maintained up to 500 MHz is realized. Over a temperature range of –40 to +85°C, voltage dependence is 40 ppm/°C and supply voltage dependence ±5 percent. The circuit has the important advantage that trimming is not required.

Voltage and Current References Based on Less Usual Devices

Use of Device in Subthreshold Region

An alternative approach to current reference making use of MOSFETs in the subthreshold region is reported in [19]. The principle of the approach is illustrated in Fig. 56.62(a), where for thermal stabilization the voltage source is required to be PTAT. The PTAT voltage source is realized as a cascade of 5 of the PTAT voltage sources shown in Fig. 56.62(b), which rely on the subthreshold mode operation of the devices. In practice, cascoding of the current mirrors and current sources is required and a start-up circuit is needed. A current accuracy of 3 percent with temperature stability of 3 percent over 0–80°C can be achieved with this approach [19].

Voltage Reference Circuits Using Lateral Bipolar Devices

The circuit diagram of a bandgap voltage reference making use of lateral bipolar devices is shown in Fig. 56.63 [16]. The circuit is designed to be insensitive to low β and α of the bipolar devices. It is also insensitive to offsets and mismatch. A single trim at room temperature is required and a high power supply rejection ratio, at least at low frequencies, is obtained. The output voltage is stable to within 2 mV over a wide temperature range.

Voltage References Based on Enhancement- and Depletion-Mode Threshold Voltage Difference

The topology restrictions and imperfections of the BJT devices available in CMOS technology have led to the development of alternative techniques for designing references without needing bipolar devices.

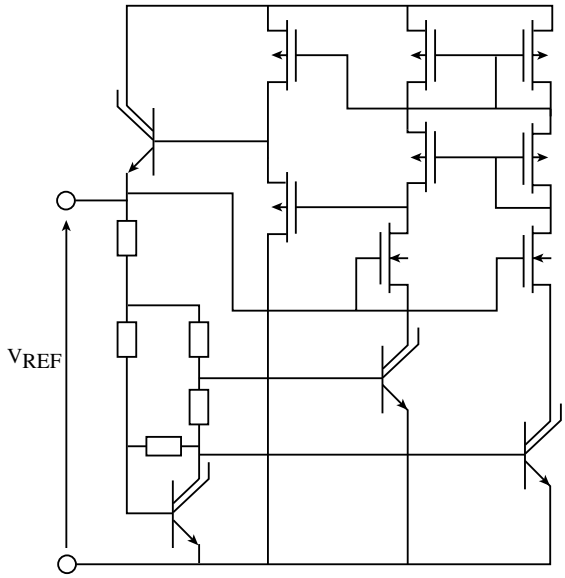

FIGURE 56.63 Voltage reference using lateral bipolar devices.

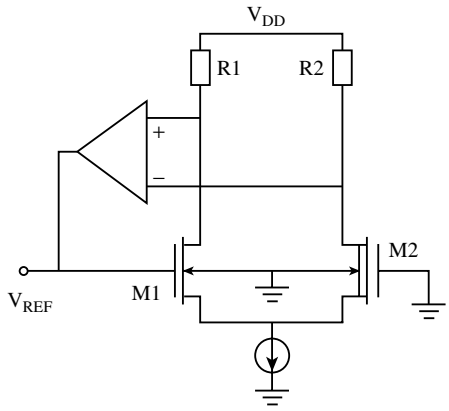

FIGURE 56.64 Basic reference based on enhancement–depletion threshold difference.

In one technique, the fact that the difference between the threshold voltage of depletion-mode and enhancement-mode devices is relatively temperature independent has been exploited [4], [5], [23].

The section on device models and parameter variability demonstrated that the difference in threshold voltages of an enhancement- and depletion-mode MOSFET is relatively insensitive to temperature. Since the threshold voltage of the depletion-mode device is negative, this approach leads to a reference voltage of the order of 2 V, which is higher than the bandgap voltage, and this can be an advantage. A basic scheme for exploiting this principle for a voltage reference is shown in Fig. 56.64. The op amp adjusts the gate voltage of the enhancement-mode FET to keep the drain voltages the same and the resistor values can be used to adjust the ratio of the currents in the two FETs. The operational amplifier may be implemented at device level [4]. The gate voltage of the depletion-mode FET may be connected to the output of a buffer amplifier whose output voltage may be adjusted using polysilicon fuses to typically 3.15 V ± 0.02 V [5].

Higher reference voltages may be obtained by replicating the enhancement- and depletion-mode MOSFETs. In Fig. 56.65, the reference voltage is the difference between the threshold voltages of the three enhancement-mode MOSFETs *M*1–*M*3 and the three depletion-mode MOSFETs *M*4–*M*6 [23]. *M*7–*M*10 are providing the necessary bias currents. In [23], the variation of V_{REF} with temperature is 1.5mV/°C,

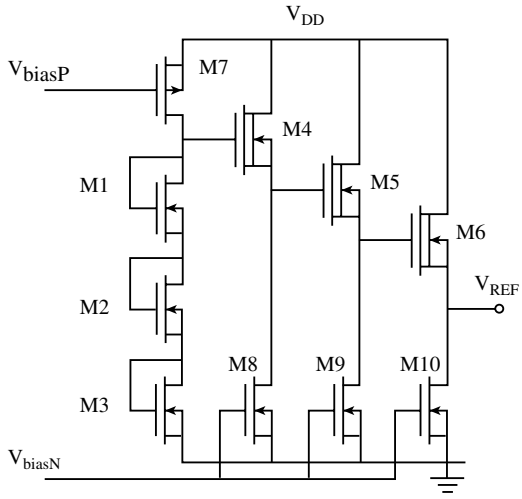

FIGURE 56.65 High-output enhancement–depletion threshold difference reference.

which is useful for many biasing situations and the reference voltage is of the order of 3 V in spite of low threshold voltage devices.

Voltage References Based on N- and P-Doped Polysilicon Gate Threshold Voltage Difference

In CMOS technology, the gate material is usually polysilicon with N-type doping. In some processes, selective doping to provide P-type doping of the polysilicon gate is also available and the presence of both types of doping has been exploited for reference circuit design [8].

The basic principle of a voltage reference based on the difference between the threshold voltages of N- and P-doped polysilicon gate MOSFETs is illustrated in Fig. 56.66. *M*1 has a P-doped gate and a higher threshold voltage than *M*2. *M*1 and *M*2 are in different P-wells but have the same effective dimensions and bias currents.

A full transistor-level implementation of the basic circuit in Fig. 56.66 is shown in Fig. 56.67 [8]. *M*1 and *M*2 are the reference MOSFETs. *M*3 has a very long channel and its current is the same as that in *M*1 by virtue of the current mirror *M*4: *M*5. Thus the current in *M*1 adjusts itself to the crosspoint of the characteristics of *M*1 and *M*3. *M*7, *M*8, and *M*9 ensure that the currents in *M*1 and *M*2 are identical. *M*6 is a start-up device. When the power supply is switched on, *M*6 comes on but within 1 ms is switched off by the reverse leakage resistance of the polysilicon diode *D*. In [8], *M*1 and *M*2 can have a *W*/*L* of 100 μm/20 μm; supply voltage sensitivity of $<10^{-3}$ is obtained for V_{DD} between 2 and 9 V [8]. Digital tuning using polysilicon fuses to reference voltages other than the polysilicon gate work function difference can be obtained and a further level of temperature compensation applied [8].

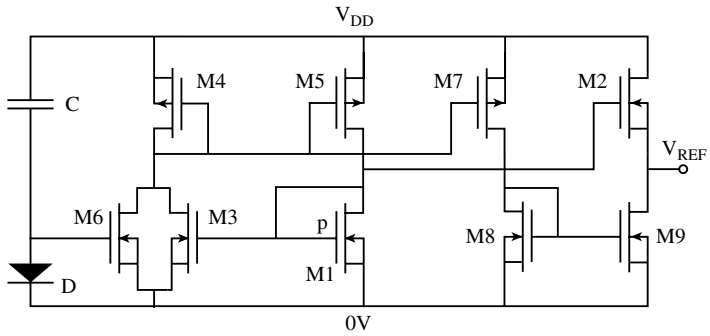

FIGURE 56.67 Example of reference based on polysilicon work function difference.

Biasing of Simple Amplifiers and Other Circuits

Simple Amplifiers

In traditional two-stage amplifier design, the bias for the whole circuit is easily set up from one reference current and no critical voltage differences have to be set up. It is only necessary to ensure that the operating currents, and hence the transconductance, of each device have a required value. A typical example of the biasing of a two-stage amplifier is shown in Fig. 56.68 [13]. The ratio of currents between the first- and second-stage controls the separation of the poles and also the systematic offset. The internal biasing circuit consists simply of a set of current mirrors.

Cascode Amplifiers

In cascode amplifiers [13], the idea is to raise the amplifier output impedance in order to increase the gain. An important requirement, especially in a low supply voltage environment, is to obtain maximum output voltage swing, or compliance, in the cascode amplifier. This requirement makes the biasing of the cascode devices critical.

A simple amplifier designed for cascode loads is shown in Fig. 56.69. Only a single current mirror from the main current reference is needed to control all the bias currents. For reasonable low-frequency gains of say >60 dB, the output impedance must be made high while keeping component parameters practical. Use of very long channel output FETs is undesirable because of poor bandwidth and the chip area requirement. Therefore, the cascode technique, as shown in Fig. 56.70, is the ideal solution. This

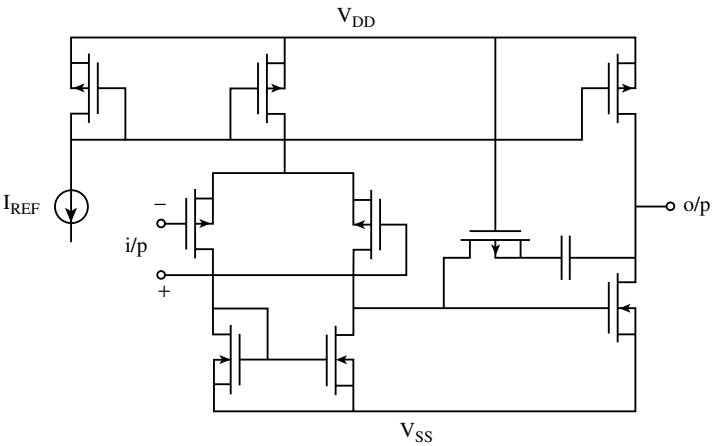

FIGURE 56.68 Two-stage amplifier.

© 2003 by CRC Press LLC

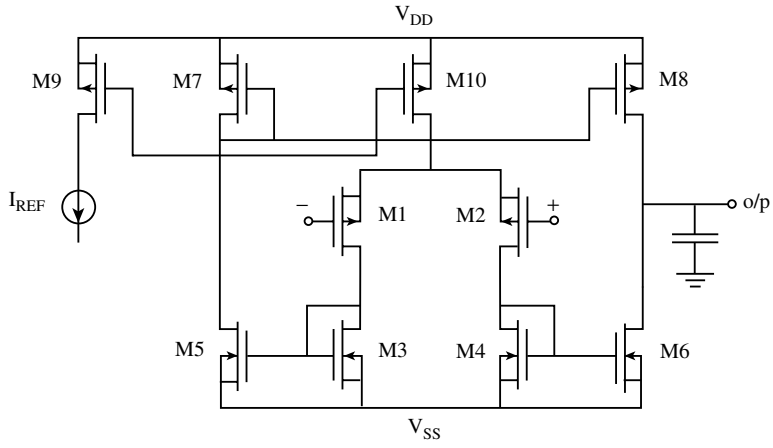

FIGURE 56.69 Simple single-stage amplifier.

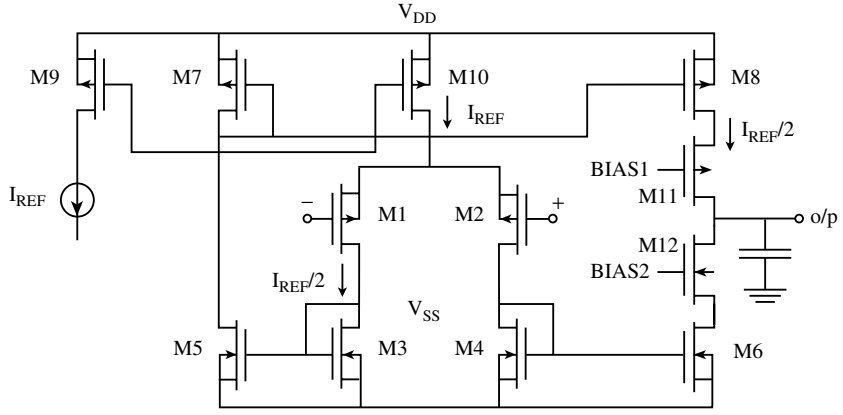

FIGURE 56.70 Simple single-stage amplifier with cascoded output FETs.

raises output impedance by approximately $g_{m(M11)}r_{ds(M11)}$ and $g_{m(M12)}r_{ds(M12)}$ on each side. However, the maximum output voltage swing, or compliance, of the circuit has now been reduced by at least the saturation voltages of *M*11 and *M*12. The cascode devices must be biased so that the voltage across *M*8 and *M*9 are just above V_{dsat}.

The usual way of achieving this is to arrange that a current is passed through an FET with a scaled width so that one obtains a voltage $V_{TN} + V_{Dsat(M6)}+V_{Dsat(M12)}$ for the N-channel side and $V_{TP} + V_{Dsat(M8)} + V_{Dsat(M11)}$ for the P-channel side. If the saturation voltage of the driver FET (*M*6) and the cascode FET (*M*12) are the same, then this requires a bias FET with a current density four times higher. In reality, the body effect in *M*12 and tolerance considerations mean that this factor will have to be somewhat higher than 4 [13].

Hence, there is a requirement for more replicas of the incoming reference current. The whole scheme develops to the configuration shown in Fig. 56.71, where the circuit is represented in its simplest ideal form. Note that all FET scaling is applied to device widths; the lengths are the same throughout. In practice, this circuit would have a large offset due to the unequal drain voltages in the various current mirrors, and balancing dummy FETs would be needed.

© 2003 by CRC Press LLC

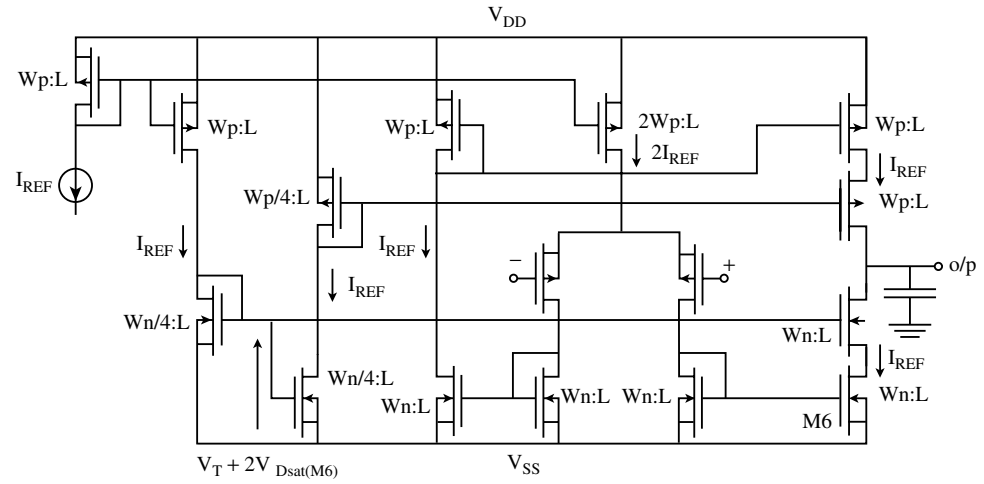

FIGURE 56.71 Cascode simple single-stage amplifier with biasing circuits.

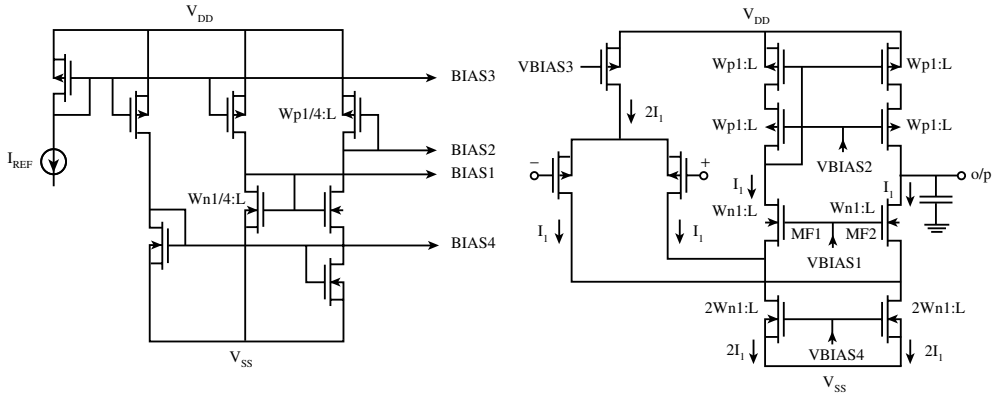

FIGURE 56.72 Folded cascode amplifier with biasing circuits.

Folded Cascode Amplifiers

A common problem in modern CMOS design is the basing of folded cascode amplifier stages [13]. Folded cascode amplifiers are much used to get reasonable common-mode and output range in low power supply voltage situations. A typical example of a folded cascode amplifier is shown in Fig. 56.72. The biasing of the folded cascode architecture is basically similar to that of a nonfolded cascode provided that correct current densities are maintained in the FETs. This is important because the folding current source (*MF*1, *MF* 2) and the cascode will have different current levels and the bias must allow for this and set the cascode FET to the minimum safe operating bias. A ratio of 1:4 in width for the same current density gives the ideal bias for equal saturation voltages. Differing values of saturation voltage must be summed and the bias FET scaled accordingly.

Current Mirrors

The folded cascode amplifier of Fig. 56.72 includes the current mirror of Fig. 56.73 [18]. This circuit is a high compliance current mirror featuring low input voltage and low minimum output voltage. The cascode devices embedded in it are biased from an FET of width ratio running at the same quiescent current as the mirror. A width ratio of 1:4 is predicted by simple theory for equal saturation voltages in the mirror.

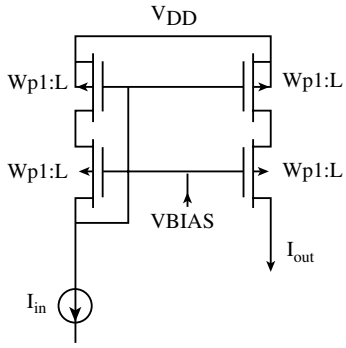

FIGURE 56.73 High-compliance current mirror.

Biasing of Circuits with Low Power Supply Voltage

The topic of low voltage analog MOS circuits is an important one because of the requirement for battery operation and also for compatibility with advanced digital IC processes with low power supply voltages. In order to maintain a reasonably high dynamic range in low supply voltage analog circuits, it is essential that the circuits operate with signal swings that are a very large fraction of the total supply voltage. Since operational amplifiers are key components in analog circuits, this has led to the design of operational amplifiers with "rail-to-rail" input common-mode voltage and output voltage capability. The design of such an input stage requires new approaches to biasing and we shall give brief details of an example of one such circuit [27].

A conventional differential pair of N- or P-channel MOSFETs would not provide sufficient input voltage common-mode range. This is because the input FET pair and the FET realizing the tail current source would tend to come out of saturation at one extreme of input common-mode voltage (negative for NMOS, positive for PMOS). This is overcome by combining an NMOS and PMOS differential pair as shown in Fig. 56.74. However, this circuit has the disadvantage that the effective transconductance varies widely with common-mode input voltage since in the middle range, both differential pairs are conducting but at the extremes, only one differential pair is conducting. This produces a common-mode voltage dependence of amplifier dynamic performance and makes it difficult to optimize the dynamic performance for all input conditions.

An elegant solution to this problem is reported in [27]. Assuming that the drain current of a MOSFET can be described by a square-law relationship, then transconductance is proportional to the square root of bias current. Since the overall effective transconductancce of the input stage in Fig. 56.74 is the sum

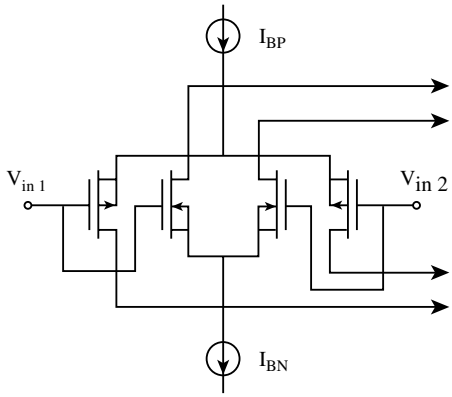

FIGURE 56.74 Op-amp input stage for rail-to-rail operation.

© 2003 by CRC Press LLC

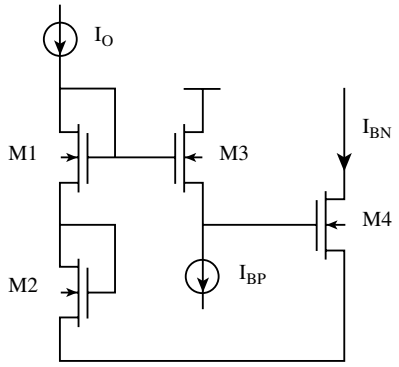

FIGURE 56.75 Bias circuit based on MOS translinear principle.

of the effective transconductance of each pair, it follows that the condition when the overall transconductance is independent of common-mode input voltage is

$$\sqrt{I_{BN}} + \sqrt{I_{BP}} = \text{constant} \tag{56.126}$$

Bias currents satisfying this relationship can be implemented using the MOS translinear circuit principle [27]. This principle applies to circuits where the gate–source ports of MOSFETs form a closed loop. Assuming that the devices are describable by a square-law drain–current relationship, the sum of the square roots of the drain currents of the MOSFETs whose ports are connected in a clockwise fashion equals the sum of the square roots of the drain currents of the counterclockwise-connected MOSFETs.

The application of the basic idea to implement bias currents according to (56.126) is shown in Fig. 56.75. Since the clockwise-connected MOSFETs $M1$ and $M2$ have a constant drain current I_o, the translinear principle implies that the drain current in $M3$ and $M4$ satisfy (56.126). The development of the schematic bias circuit in Fig. 56.75, the input stage in Fig. 56.74 and a class AB output stage into a fully operational amplifier is described in [27]. The circuit operates with a minimum power supply of 2.5 V.

Dynamic Biasing

Dynamic biasing is a technique that is applicable to amplifiers in sampled data systems, such as switched capacitor filters and data converters [6], [9]. Such amplifiers are required to meet two key requirements. These are fast settling time in order to allow high switching rates and high gain in order to obtain precision performance [13]. Fast settling time is obtained for maximum effective device transconductance and device transconductance g_m is approximately proportional to, $\sqrt{I_B}$, where I_B is bias current. Gain is given by g_m/g_o, where g_o is output conductance. Since g_o is proportional to bias current, gain is *inversely* proportional to $\sqrt{I_B}$. Thus maximum settling time requires a high bias current and maximum gain requires a low bias current. The dynamic bias technique reconciles these two requirements.

Figure 56.76 shows a typical switched capacitor integrator, which is a basic building block for implementing high-order switched capacitor systems. The switches are controlled by two-phase nonoverlapping clock signals ϕ and $\bar{\phi}$. The operational amplifier would generally have a first stage comprising a

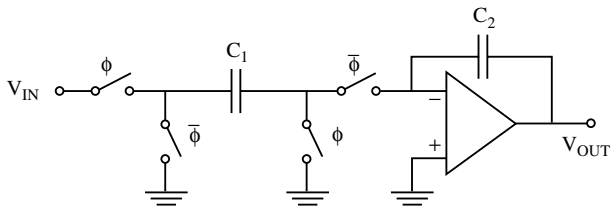

FIGURE 56.76 Typical switched capacitor integrator.

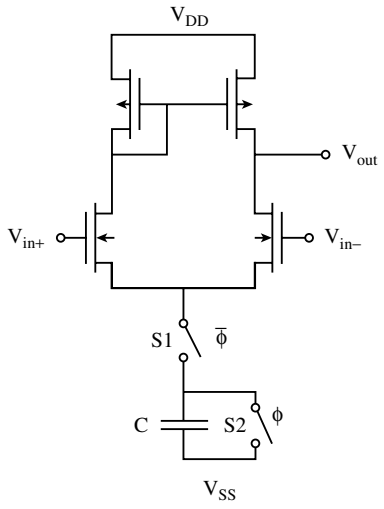

FIGURE 56.77 Simple op amp with dynamic biasing.

differential MOSFET pair with constant current source bias. The equivalent of this with dynamic biasing is shown in Fig. 56.77, where the constant current source has been replaced by the combination of capacitor *C* and switches *S*1 and *S*2. We refer to the integrator of Fig. 56.76. During phase ϕ, the capacitor C_1 is being charged up to the input voltage and the amplifier is inactive. Meanwhile, in the dynamically biased amplifier of Fig. 56.77, the capacitor *C* is being discharged. In phase $\bar{\phi}$, capacitor C_1 in Fig. 56.76 is connected to the input of the amplifier, where the output voltage is required to change to absorb the incoming charge. At the same time, capacitor *C* in Fig. 56.77 is connected to the differential pair and immediately starts to conduct a high current. The high current through the amplifier MOSFETs provides a high effective amplifier slew rate and fast initial settling time, although the gain of the amplifier during this initial part of the clock phase is low. As time progresses, capacitor *C* becomes charged and the current in the amplifier MOSFETs reduces. This increases the gain of the amplifier leading to a high precision of the amplifier output voltage. Eventually, the amplifier current falls to zero with the output voltage at this required level. If, as would usually be the case, it is required to sample the amplifier output voltage in both phases, then the dynamic current source comprising capacitor *C* and the two switches *S*1 and *S*2 in Fig. 56.77 would need to be duplicated with opposite switch phasing. This technique considerably increases the gain available from an amplifier since the effective gain depends on the low bias current condition and is very high. Dynamic biasing may, however, be easily applied to both stages of a two-stage amplifier if required [9]. Also, efficient schemes are available for the dynamic biasing of several amplifiers in a circuit.

Dynamic biasing is well worth considering in sampled date applications, such as switched capacitor filters and data converters. It can maximally exploit a given low power consumption to obtain good dynamic circuit performance. A variant of this approach [11] is adaptive biasing in which the input differential signal is sensed and the bias current is increased for large differential input signals to speed up the slewing response.

Conclusions

The task of designing voltage and current references and bias circuits is an important one. The requirements are very diverse, ranging from high precision, as required in data converters, to moderate, as required in general biasing situations. In these sections, space has been sufficient only to refer to some outstanding work in the area an briefly discuss some of the main principles. It is hoped that the reader will consult the references for more detailed information.

56.4 Canonical Cells of MOSFET Technology

M. Ismail, S.-C. Huang, C.-C. Hung, and T. Saether

Analog integrated circuits have long been designed in technologies other than CMOS. But modern analog and mixed-signal VLSI applications in areas such as telecommunications, smart sensors, battery-operated consumer electronics, and artificial neural computation require CMOS analog design solutions. In recent years, analog CMOS circuit design has shown signs of dramatic change. Field programmable analog arrays and modular analog VLSI circuits [1] are representatives of emerging analog design philosophies leading to a whole new generation of analog circuit and layout design methodologies.

This section discusses basic cells used in contemporary CMOS analog integrated circuits. The performance of a CMOS (bipolar) circuit can often be improved further by incorporating a limited number of bipolar (CMOS) transistors on the same substrate. The resulting circuits are called BiCMOS circuits. BiCMOS circuits that are predominantly CMOS will also be discussed. First, we discuss primitive analog cells. These cells may or may not require device matching for proper operation. Second, we introduce modern and simple circuit techniques to mitigate nonideal effects and significantly improve circuit performance, and finally, we discuss basic voltage amplifier circuits. The presented cells will help in the systematic design of analog integrated circuits and could constitute an efficient analog VLSI cell library. Throughout this section, MOS transistors are assumed to be biased in strong inversion.

Matched Device Pairs

Figure 56.78 shows basic MOS transistors pairs [2] operating in the saturation region, where only NMOS transistors pairs are shown. Figure 56.78(a} shows a differential pair with no direct connection between

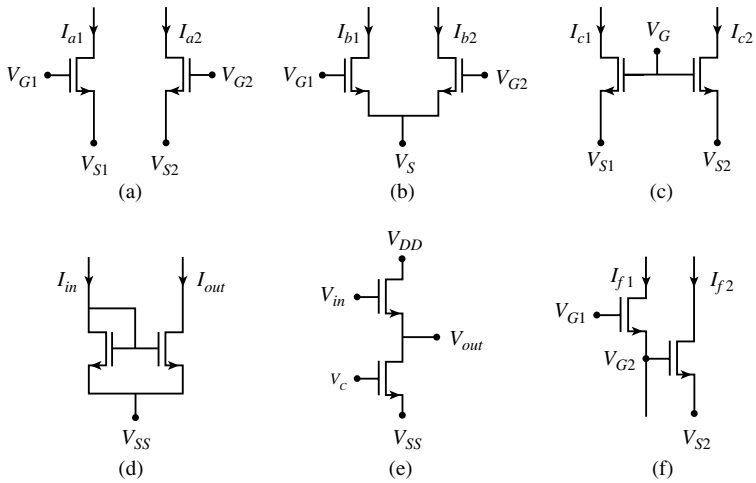

FIGURE 56.78 Matched primitive cells operating in the saturation region.

© 2003 by CRC Press LLC

the two transistors. The resultant differential pair is characterized by the difference in the drain currents (using the simple square-law equation); that is,

$$\begin{aligned} I_{a1} - I_{a2} &= \frac{K}{2}\left(V_{G1} - V_{S1} - V_T\right)^2 - \frac{K}{2}\left(V_{G2} - V_{S2} - V_T\right)^2 \\ &= \frac{K}{2}\left[\left(V_{G1} - V_{G2}\right) - \left(V_{S1} - V_{S2}\right)\right] \\ &\quad \times \left[\left(V_{G1} + V_{G2}\right) - \left(V_{S1} + V_{S2}\right) - 2V_T\right] \end{aligned} \tag{56.127}$$

where $K\ (=\mu C_{ox}W/L)$ and V_T are the transconductor parameter and the threshold voltage of the transistor respectively. Figure 56.78(b) is a common-source or source-coupled differential pair, a special case of circuit (a) with $V_{S1} = V_{S2} = V_S$, and the differential current is

$$I_{b1} - I_{b2} = \frac{K}{2}\left(V_{G1} - V_{G2}\right)\left[\left(V_{G1} + V_{G2}\right) - 2V_S - 2V_T\right] \tag{56.128}$$

Figure 56.78(c) is a common-gate differential pair with $V_{G1} = V_{G2} = V_G$ in circuit (a), and the differential current is obtained as

$$I_{c1} - I_{c2} = -\frac{K}{2}\left(V_{S1} - V_{S2}\right)\left[2V_G - \left(V_{S1} + V_{S2}\right) - 2V_T\right] \tag{56.129}$$

Differential pairs are essential building blocks of circuits such as op amps, differential difference amplifiers (DDAs) and operational transconductance amplifiers (OTAs). Several linear *V–I* converters built by these cells have been developed.

Current mirrors are usually used as loads for amplifier stages. Moreover, current mires are essential building blocks in modern current-mode analog integrated circuits. Figure 56.78(d) shows a well-known simple current mirror. Ideally, the input current I_{in} is equal to the output current I_{out} for matched transistors. In practice, a nonunity I_{out} to I_{in} ratio occurs due to finite output resistance resulting from channel length modulation effects. The output resistance can be increased by Wilson or cascode current mirrors at the expense of a limited output swing, which is not desired in low-voltage applications. A regulated current mirror can improve both the output resistance and swing but increase circuit complexity. Detail analysis and comparison are discussed in [3].

A voltage follower is shown in Fig. 56.78(e). Since the same current flows in both transistors, their gate–source voltages are the same. That is

$$V_{\text{in}} - V_{\text{out}} = V_C - V_{SS} \tag{56.130}$$

and therefore

$$V_{\text{out}} = V_{\text{in}} - V_C + V_{SS} \tag{56.131}$$

Alternatively, a transistor pair can be arranged as the circuit shown in Fig. 56.78(f), which is used as a basic cell for composite MOSFET (COMFET) circuits [4]. The differential current is given by

$$\begin{aligned} I_{f1} - I_{f2} &= \frac{K}{2}\left(V_{G1} - V_{G2} - V_T\right)^2 - \frac{K}{2}\left(V_{G2} - V_{S2} - V_T\right)^2 \\ &= \frac{K}{2}\left(V_{G1} - V_{S2} - 2V_T\right)\left(V_{G1} - 2V_{G2} + V_{S2}\right) \end{aligned} \tag{56.132}$$

With proper biasing, linear *V–I* conversion can be achieved by this transistor cell.

© 2003 by CRC Press LLC

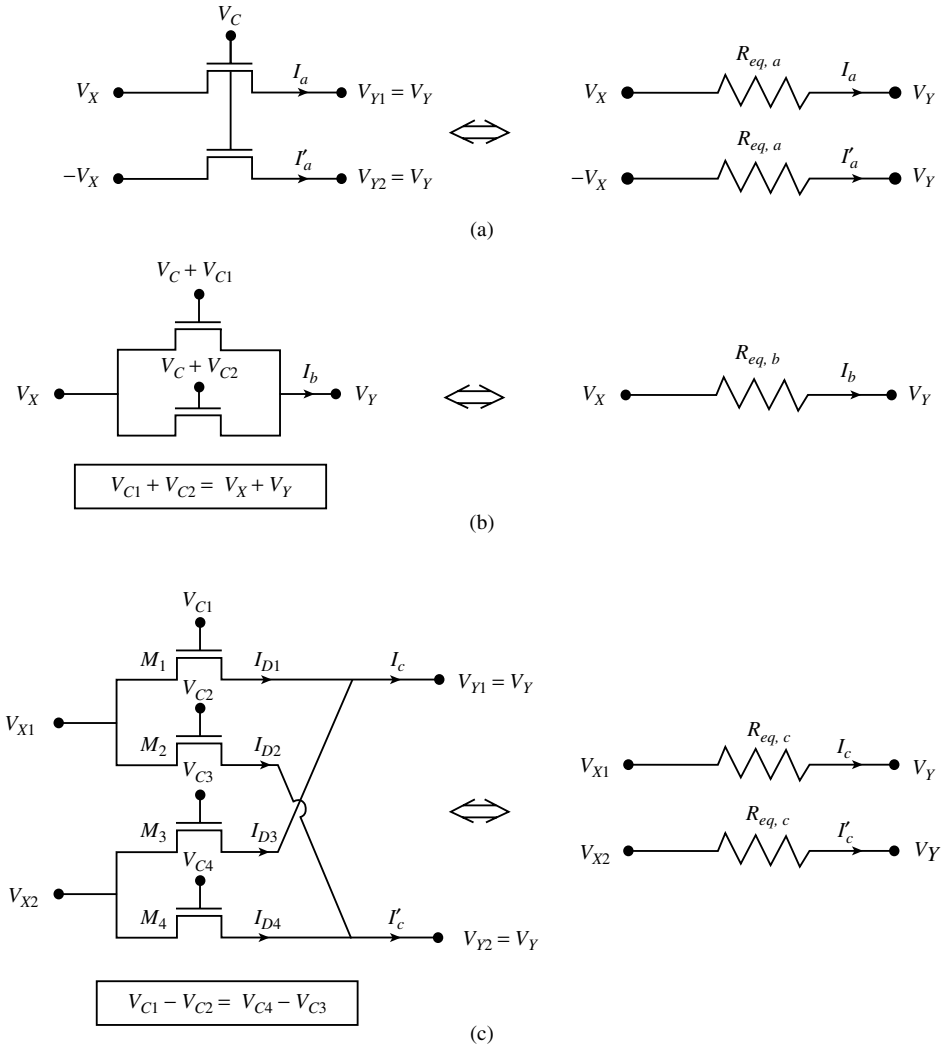

FIGURE 56.79 Matched primitive cells operating in the triode region.

Transistor pairs operating in the triode region are found mostly in simulating linear transconductors and resistors, e.g., those in MOSFET-C filters. Figure 56.79 shows three popular examples, where the nonlinear terms in the drain current equations are canceled. A simple drain current equation in the triode region is

$$I_D = K\left[\left(V_G - V_T\right)\left(V_D - V_S\right) - \frac{1}{2}\left(V_D^2 - V_S^2\right)\right] \tag{56.133}$$

$$= \frac{K}{2}\left(V_G - V_S - V_T\right)^2 - \frac{K}{2}\left(V_G - V_D - V_T\right)^2 \tag{56.134}$$

Equation (56.134) gives another form of the triode current equation. In some cases, circuit analysis can be performed more easily with this form than using (56.133). The resulting current equations of the equivalent "MOS resistors" are now obtained.

© 2003 by CRC Press LLC

For the circuit shown in Fig. 56.79(a), a two-transistor transconductor, the current different is given by [5]

$$\begin{aligned} I_a - I_a' &= K\left[\left(V_C - V_T\right)\left(V_X - V_Y\right) - \frac{1}{2}\left(V_X^2 - V_Y^2\right)\right] \\ &\quad - K\left[\left(V_C - V_T\right)\left(-V_X - V_Y\right) - \frac{1}{2}\left(V_X^2 - V_Y^2\right)\right] \\ &= 2K\left(V_C - V_T\right)V_X \end{aligned} \tag{56.135}$$

and the equivalent resistance is obtained as

$$R_{\text{eq},a} = \frac{2V_X}{I_a - I_a'} = \frac{1}{K\left(V_C - V_T\right)} \tag{56.136}$$

The circuit shown in Fig. 56.79(b) realizes a floating resistor [5], where

$$\begin{aligned} I_b &= K\left[\left(V_C + V_{C1} - V_T\right)\left(V_X - V_Y\right) - \frac{1}{2}\left(V_X^2 - V_Y^2\right)\right] \\ &\quad + K\left[\left(V_C + V_{C2} - V_T\right)\left(V_X - V_Y\right) - \frac{1}{2}\left(V_X^2 - V_Y^2\right)\right] \\ &= K\left[\left(2V_C - 2V_T + V_X + V_Y\right)\left(V_X - V_Y\right) - \left(V_X^2 - V_Y^2\right)\right] \\ &= 2K\left(V_C - V_T\right)\left(V_X - V_Y\right) \end{aligned} \tag{56.137}$$

and the equivalent resistance is

$$R_{\text{eq},\,b} = \frac{V_X - V_Y}{I_b} = \frac{1}{2K\left(V_C - V_T\right)} \tag{56.138}$$

An implementation with $V_{C1} = V_{C2} = (V_X + V_Y)/2$ has been described in [6].

The circuit shown in Fig. 56.79(c), a four-transistor transconductor [7], gives the following current equation:

$$\begin{aligned} I_c - I_c' &= K\left[\left(V_{C1} - V_T\right)\left(V_{X1} - V_Y\right) - \frac{1}{2}\left(V_{X1}^2 - V_Y^2\right)\right] \\ &\quad - K\left[\left(V_{C2} - V_T\right)\left(V_{X1} - V_Y\right) - \frac{1}{2}\left(V_{X1}^2 - V_Y^2\right)\right] \\ &\quad + K\left[\left(V_{C3} - V_T\right)\left(V_{X2} - V_Y\right) - \frac{1}{2}\left(V_{X2}^2 - V_Y^2\right)\right] \\ &\quad - K\left[\left(V_{C4} - V_T\right)\left(V_{X2} - V_Y\right) - \frac{1}{2}\left(V_{X2}^2 - V_Y^2\right)\right] \end{aligned} \tag{56.139}$$

$$\begin{aligned} &= K\left(V_{C1} - V_{C2}\right)\left(V_{X1} - V_{X2}\right) \\ &= K\left(V_{C4} - V_{C3}\right)\left(V_{X1} - V_{X2}\right) \end{aligned} \tag{56.140}$$

© 2003 by CRC Press LLC

and

$$R_{\text{eq},\,c} = \frac{V_{X1} - V_{X2}}{I_c - I_c'} = \frac{1}{K\left(V_{C1} - V_{C2}\right)} = \frac{1}{K\left(V_{C4} - V_{C3}\right)} \tag{56.141}$$

Note that I_c and I_c' are taken at the V_Y nodes. It is very interesting to know that nonlinearity cancellation is also achieved with the four transistors operating in the saturation region [2].

Figure 56.79(a) and (c) are usually used together with op amps to simulate resistors, where the virtual short property of op amps makes $V_{Y1} = V_{Y2}$.

Unmatched Device Pairs

Figure 56.80 shows primitive cells that do not require matching, unless specified. Figure 56.80(a) and (b) are parallel and series composite NMOS transistors, respectively, which are very useful in laying out very wide or long transistors, respectively. The equivalent device transconductance parameter K_{eq} is calculated as follows:

For the parallel composite transistor, the drain current is written as

$$\begin{aligned} I_{Dp} &= \frac{K_{\text{eq},p}}{2}\left(V_G - V_S - V_T\right)^2 \\ &= \frac{K_1}{2}\left(V_G - V_S - V_T\right)^2 + \frac{K_2}{2}\left(V_G - V_S - V_T\right)^2 \end{aligned} \tag{56.142}$$

That is,

$$K_{\text{eq},p} = K_1 + K_2 \tag{56.143}$$

or alternatively

$$\left(\frac{W}{L}\right)_{\text{eq},p} = \left(\frac{W}{L}\right)_1 + \left(\frac{W}{L}\right)_2 \tag{56.144}$$

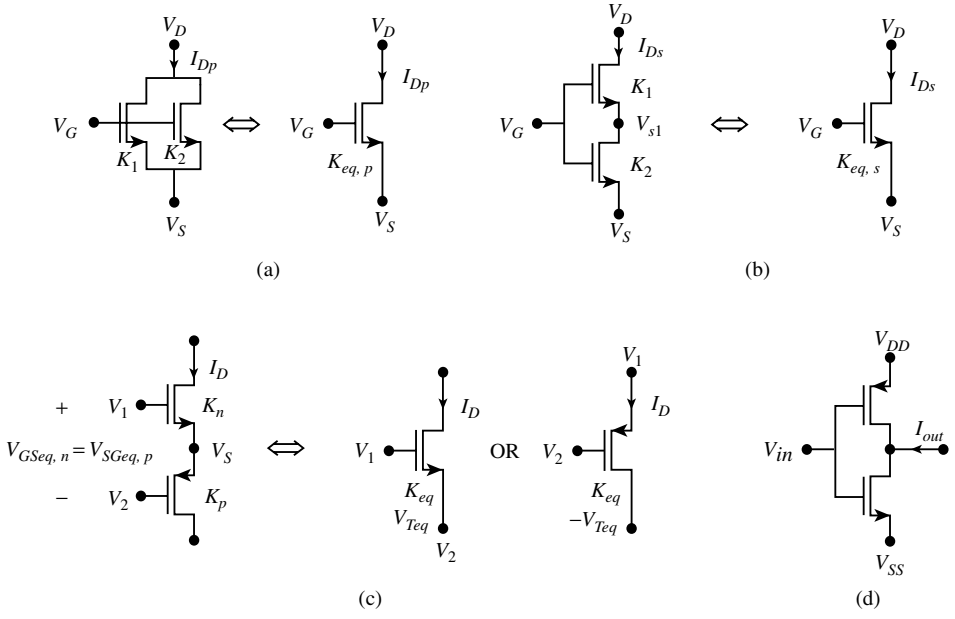

FIGURE 56.80 Unmatched primitive cells.

© 2003 by CRC Press LLC

Using the same channel length L, it can be simplified as

$$W_{\text{eq},p} = W_1 + W_2 \tag{56.145}$$

As a result, a wider transistor can be realized by parallel connection of two or more narrower transistors.

For the series composite transistor, note that the lower transistor is always operating in the triode region due to the requirement $V_G - V_{S1} > V_T$, to turn on the upper transistor. The resultant drain current is given by

$$I_{Ds} = \frac{K_{\text{eq},s}}{2}\left(V_G - V_S - V_T\right)^2 \tag{56.146}$$

$$= \frac{K_1}{2}\left(V_G - V_{S1} - V_T\right)^2 \tag{56.147}$$

$$= \frac{K_2}{2}\left[\left(V_G - V_S - V_T\right)^2 - \left(V_G - V_{S1} - V_T\right)^2\right] \tag{56.148}$$

From the preceding equations, we have

$$\left(V_G - V_S - V_T\right)^2 = \frac{2I_{Ds}}{K_{\text{eq},s}} \tag{56.149}$$

$$\left(V_G - V_{S1} - V_T\right)^2 = \frac{2I_{Ds}}{K_1} \tag{56.150}$$

Substituting the preceding equations into (56.148), we obtain

$$I_{Ds} = \frac{K_2}{2}\left(\frac{2I_{Ds}}{K_{\text{eq},s}} - \frac{2I_{Ds}}{K_1}\right) \tag{56.151}$$

That is,

$$\frac{1}{K_{\text{eq},s}} = \frac{1}{K_1} + \frac{1}{K_2} \tag{56.152}$$

or

$$\left(\frac{L}{W}\right)_{\text{eq},s} = \left(\frac{L}{W}\right)_1 + \left(\frac{L}{W}\right)_2 \tag{56.153}$$

Similarly, with fixed channel width W, the above equation is simply obtained as

$$L_{\text{eq},s} = L_1 + L_2 \tag{56.154}$$

which indicates that the equivalent transistor can be used to realize a long-channel device with shorter channel ones.

Figure 56.80(c) is a CMOS composite transistor, which can be seen as equivalent to either an NMOS or a PMOS transistor operating in the saturation region. In contrast, the composite transistors shown in Fig. 56.80(a) and (b) can operate in both saturation and triode regions. The main advantage of the

© 2003 by CRC Press LLC

equivalent composite transistor shown in Fig. 56.80(c) is that both their equivalent gate and source nodes have high input impedances, which is desired in some circuits. The equivalent K and V_T are obtained by the equations of the gate–source voltages.

$$\begin{aligned} V_1 - V_2 &= V_{GSn} + V_{SGp} \\ &= \sqrt{\frac{2I_D}{K_n}} + \sqrt{\frac{2I_D}{K_p}} + V_{Tn} - V_{Tp} \\ &= \sqrt{\frac{2I_D}{K_{\text{eq}}}} + V_{\text{Teq}} \end{aligned} \tag{56.155}$$

which give

$$\frac{1}{\sqrt{K_{\text{eq}}}} = \frac{1}{\sqrt{K_n}} + \frac{1}{\sqrt{K_p}} \tag{56.156}$$

and

$$V_{\text{Teq}} = V_{Tn} - V_{Tp} \tag{56.157}$$

Finally, Fig. 56.80(d) shows a CMOS inverter, which could be used as a transconductor [8]. Its output current is

$$\begin{aligned} I_{\text{out}} &= \frac{K_n}{2}\left(V_{\text{in}} - V_{SS} - V_{Tn}\right)^2 - \frac{K_p}{2}\left(V_{DD} - V_{\text{in}} + V_{Tp}\right)^2 \\ &= a\left(V_{\text{in}} - V_{Tn}\right)^2 + bV_{\text{in}} + c \end{aligned} \tag{56.158}$$

where

$$\begin{aligned} a &= \frac{1}{2}\left(K_n - K_p\right) \\ b &= -K_n V_{SS} + K_P\left(V_{DD} - V_{Tn} + V_{Tp}\right) \\ c &= \frac{K_n}{2}\left(2V_{SS}V_{Tn} + V_{SS}^2\right) + \frac{K_p}{2}\left[V_{Tn}^2 - \left(V_{DD} + V_{Tp}\right)^2\right] \end{aligned}$$

Composite Transistors

The body effect of a transistor is due to nonzero source to bulk voltage (V_{SB}), which widens the depletion region between the source and bulk and therefore increases the absolute value of its threshold voltage. The threshold voltage (referred to the source) is dependent on V_{SB} and is given by

$$V_{Tn} = V_{Tno} + \gamma\left(\sqrt{2|\phi_F| + V_{SB}} - \sqrt{2|\phi_F|}\right) \text{ for NMOS}$$

$$V_{Tp} = V_{Tpo} - \gamma\left(\sqrt{2|\phi_F| + V_{SB}} - \sqrt{2|\phi_F|}\right) \text{ for PMOS}$$

where $2|\phi_F|$ is the potential required for strong inversion and γ is the body effect parameter.

© 2003 by CRC Press LLC

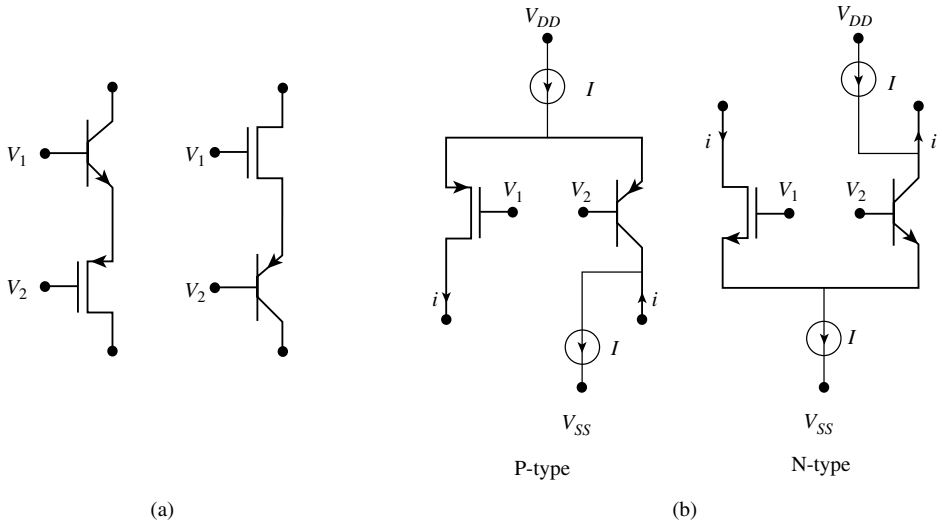

FIGURE 56.81 BiCMOS composite transistors: (a) stacked version and (b) folded version.

Usually, bulk regions of an NMOS transistor and a PMOS transistor are tied to the most negative voltage (V_{SS}) and the most positive voltage (V_{DD}) respectively to turn off the parasitic diodes associated with source-bulk and drain-bulk. In some cases, bulk regions are directly connected to transistor sources ($V_{SB} = 0$) to eliminate the body effect; e.g., in the follower of Fig. 56.78(e), the bulk must be connected to the source in each transistor to ensure equal threshold voltages. This is achieved by putting each device in a separated well, which must be the p-well for NMOS devices. However, separate wells require large layout areas. Besides, unless twin-tub processes are used, only one type of transistor (either NMOS or PMOS depending on the process) can be connected this way.

Due to the body effect, the equivalent threshold voltage of a CMOS composite transistor would be large (two threshold voltages plus extra voltage resulting from the body effect), which would render it unsuitable for low-voltage applications. The equivalent threshold voltage could be reduced by replacing one of the MOS transistors with a BJT, as shown in Fig. 56.81 [9]. For the stacked composite BiCMOS transistors, the equivalent threshold voltage is given by $V_{Teq} \approx |V_T| + 0.7$ V, where V_T is the threshold voltage of the NMOS or PMOS transistor, and 0.7 V is the BJT turn-on voltage V_{BE}, which is not subject to body effects. It can be further reduced by the folded arrangement as shown in Fig. 56.81(b), where $V_{Teq} \approx |V_T| - 0.7$ V. An all-MOS folded composite transistor can be implemented in a similar manner as shown in Fig. 56.82 [10], where $K_2 \gg K_1$. As a result,

$$K_{eq} \approx K_1$$
$$V_{Teq} = V_T - V_{GS2} \tag{56.159}$$

$$\approx -\sqrt{\frac{2I}{K_2}} \tag{56.160}$$

where $V_{GS2} \approx \sqrt{(2I)/K_2} + V_T$. SPICE simulation results for the N-type folded transistors ($W_1 = L_1 = L_2 = 3$ μm) operating in the saturation region ($V_{DG} = 0$) with various W_2 are compared with a single NMOS depletion transistor ($W = L = 3$ μm) with various V_T shown in Fig. 56.83. It can be seen that a smaller K_2 results in a smaller V_{Teq} (more negative), but with a larger K_2 the composite transistor behaves more like a single transistor having a smaller $|V_{Teq}|$, which could be useful in low-voltage applications.

Forcing $V_{SB} = 0$ to eliminate the body effect is usable only for MOS circuits conducting currents in a single direction. For the circuits shown in Fig. 56.79, since resistors operate bidirectionally, the bulk

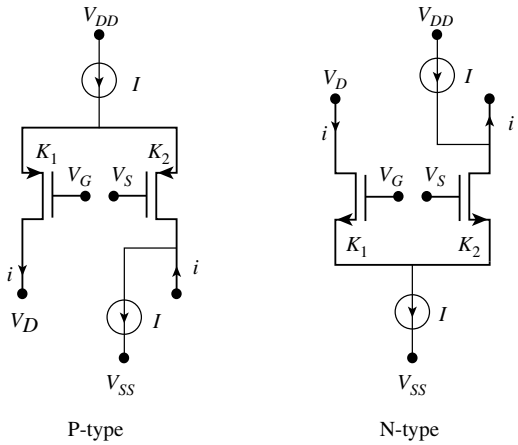

FIGURE 56.82 MOS folded composite transistors.

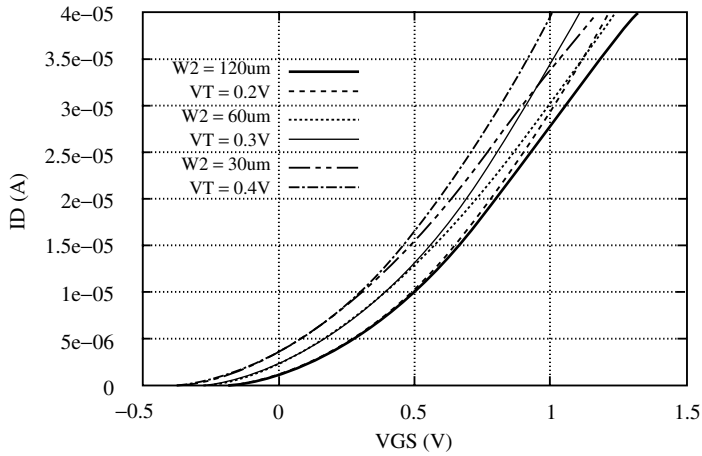

FIGURE 56.83 I_D curves for a folded N-type transistor with various W_2 and a single transistor with various V_T.

regions of each transistor must be connected to the rail to assure that parasitic diodes are turned off when currents flow in either direction. In fact, the transistors are operating in the triode region symmetrically between drain and source and biased at $V_{DS} \approx 0$. It would, however, result in nonzero V_{SB} and increase the threshold voltage, which increases the equivalent resistance, in Fig. 56.79(a) and (b), but introduces nonlinearities. To overcome this problem, one may configure two transistors into one composite transistor as shown in Fig. 56.84(a), where the bulks of the transistors are interconnected to node V_{S1}. Due to symmetry, this composite transistor can be operated in either direction. Its physical cross section is shown in Fig. 56.84(b), where the diodes represent the p–n junctions composed by bulk and source/drain nodes. This configuration is equivalent to Fig. 56.84(c), and one can find that the parasitic diode connected between V_{S1} and V_S would turn on when $V_{S1} - V_S$ is larger than the turn-on voltage of the parasitic diode. However, this is undesired, but fortunately the diode current is restricted by the drain current of M_2. This effect can be illustrated more clearly through the comparison of transistors with various bulk connections, as shown in Fig. 56.85, where Fig. 56.85(d) and (e) are composite transistors [same as Fig. 56.84 and Fig. 56.80(b), respectively], which simulate single transistors. With $V_{DG} = 0$ (diode connection), $V_S = 0$ and $V_{SS} = -5$ V, Fig. 56.86 gives simulation results of drain currents for the circuits, shown in (a) and (c)–(e), where the transistor sizes for the circuits, shown in (a)–(c), (d), and (e) are

20 µm/3 µm, 30 µm/3 µm, and 36 µm/3 µm, respectively. One can observe that the curve (c) shown in Fig. 56.86 completely departs from curve (a), due to the body effect. Curve (e) fits perfectly to curve (a). Although behaving slightly differently from curve (a), circuit (d) approximates a single transistor as well.

Figure 56.87 shows the drain current for the circuit labeled (b), whose current is much larger than those of the rest of the circuits shown in Fig. 56.85. Since the bulk of the circuit shown in Fig. 56.85(b)

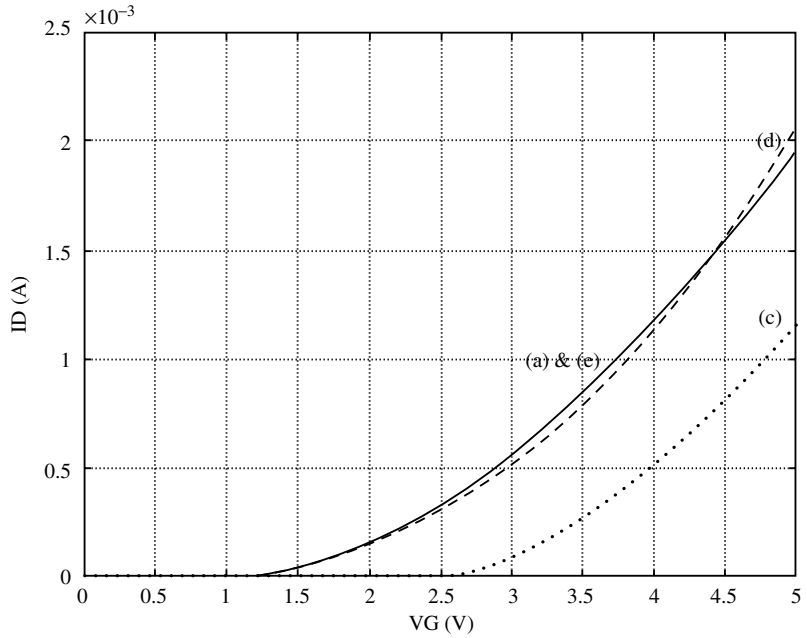

FIGURE 56.86 I_D curves for transistors with various bulk connections.

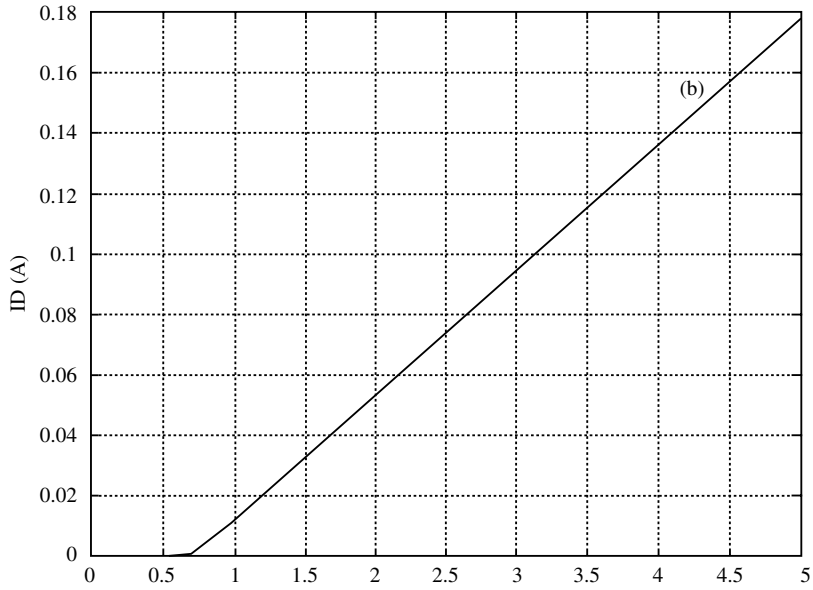

FIGURE 56.87 I_D curve for transistor with bulk connected to drain.

is connected to its drain and the parasitic diode between the drain and bulk is on, the current is dominated by the diode current due to its exponential nature. By using it as in Fig. 56.85(d), the diode current is limited to the current level of a MOS transistor. This can be seen from Fig. 56.88, showing V_{S1} of the circuit (d) saturated at a voltage ~0.7 V, which is close to the turn-on voltage of a p–n junction diode. The transistor sizes of the circuits labeled (d) and (e) are adjusted to achieve the same K value of the single transistor (a). According to (56.152), $1/K_{eq,s} = 1/K_1 + 1/K_2$. That is, to achieve $K_{eq,S} = K$, K_e ($= K_1 = K_2$) is given by

© 2003 by CRC Press LLC

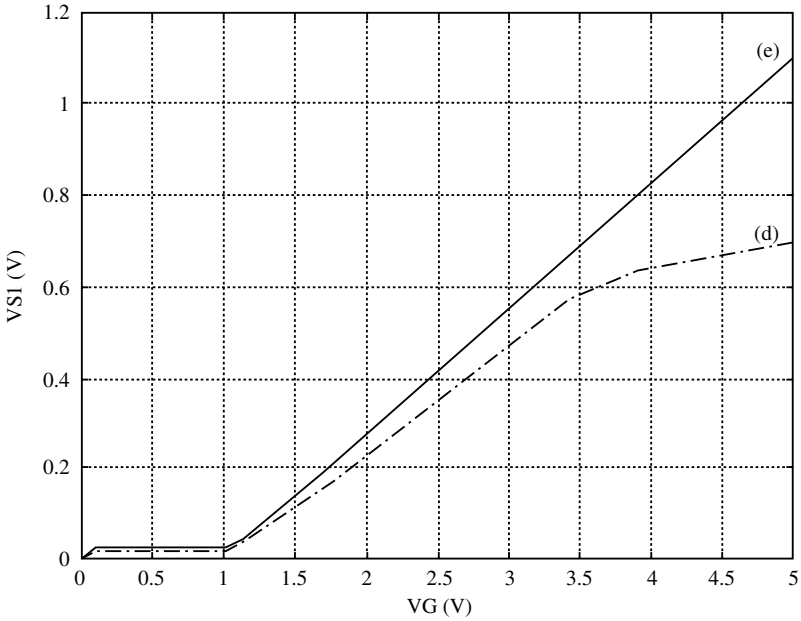

FIGURE 56.88 V_{S1} curves for composite transistors, labeled (d) and (e).

$$K_e = 2K \tag{56.161}$$

For circuit (d), K_d is obtained by rewriting (56.148), which follows that

$$\begin{aligned} I_{Ds} &= \frac{K}{2}\left(V_G - V_S - V_T\right)^2 \\ &= \frac{K_d}{2}\left(V_G - V_{S1} - V_T\right)^2 \\ &= \frac{K_d}{2}\left[\left(V_G - V_S - V_T\right)^2 - \left(V_G - V_{S1} - V_T\right)^2\right] + I_s e^{(V_{S1}-V_S)/U_T} \end{aligned}$$

where I_s is the leakage current of the diode and U_T is the thermal voltage. Therefore,

$$\begin{aligned} I_{Ds} &= \frac{K_d}{2}\left(\frac{2I_{Ds}}{K} - \frac{2I_{Ds}}{K_d}\right) + I_s e^{(V_{S1}-V_S)/U_T} \\ &= I_{Ds}\left(\frac{K_d}{K} - 1\right) + I_s e^{(V_{S1}-V_S)/U_T} \end{aligned} \tag{56.162}$$

Divided by I_{Ds}, the preceding equation becomes

$$\begin{aligned} 1 &= \frac{K_d}{K} - 1 + \frac{I_s}{I_{Ds}} e^{(V_{S1}-V_S)/U_T} \\ 2K &= K_d + K\frac{I_s}{I_{Ds}} e^{(V_{S1}-V_S)/U_T} \end{aligned} \tag{56.163}$$

and hence

© 2003 by CRC Press LLC

$$K_d < 2K \tag{56.164}$$

due to the parasitic diode. A SPICE level 2 model is used in the simulation and its higher order effects result in using a device size of 36 μm/3 μm($K_e \neq 2K$), instead of 40 μm/3 μm.

Super MOS Transistors

The channel length modulation effect models the channel shortening effect in the saturation region due to the increase in the depletion width near the drain when increasing V_{DS}. It is modeled as

$$I_D = \frac{K}{2}\left(V_{GS} - V_T\right)^2\left(1 + \lambda V_{DS}\right) \tag{56.165}$$

where λ is the channel length modulation parameter. The effect results in a finite output impedance of a transistor, since the output impedance is given by

$$r_o = \left(\frac{\partial I_D}{\partial V_{DS}}\right)^{-1} = \frac{1}{\lambda \frac{K}{2}\left(V_{GS} - V_T\right)^2} \simeq \frac{1}{\lambda I_D} \tag{56.166}$$

As mentioned previously, this effect would cause inaccuracy in the single current mirror shown in Fig. 56.78(d), and can be mitigated by using cascode, improved Wilson, or regulated current mirrors as shown in Fig. 56.89 [3]. These are based on the gain-boosting principle as shown in Fig. 56.90[11], where for the cascode stage in (a) (used in the cascode and the Wilson current mirrors) the output impedance is given by

$$r_{o,a} = \left(g_{m2}\, r_{o2} + 1\right) r_{o1} + r_{o2} \tag{56.167}$$

where g_{mi} and r_{oi} are, respectively, the small-signal transconductance and output impedance for transistor M_i. An addition gain stage A_{dd}, as in Fig. 56.90(b) (implemented in the regulated current mirror by M_{add}) increases the output impedance almost by a factor of (A_{dd} + 1) and gives

$$r_{o,b} = \left[g_{m2}\, r_{o2}\left(A_{dd} + 1\right) + 1\right] r_{o1} + r_{o2} \tag{56.168}$$

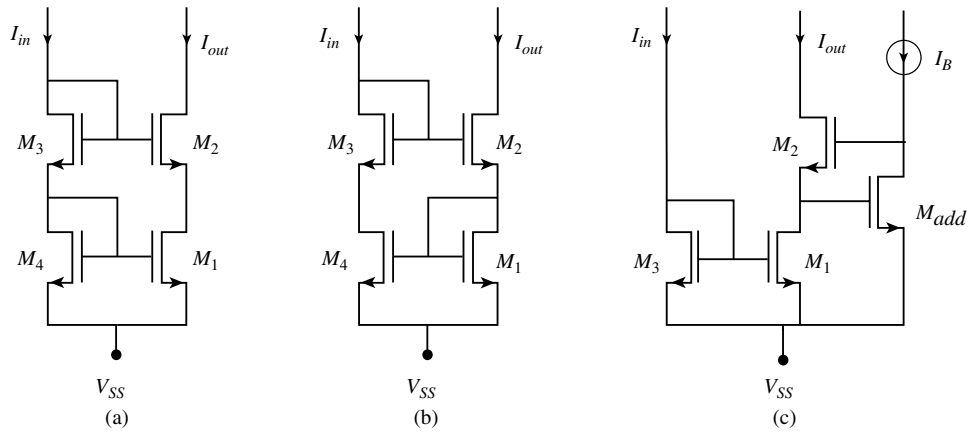

FIGURE 56.89 (a) Cascode, (b) improved Wilson, and (c) regulated current mirrors.

© 2003 by CRC Press LLC

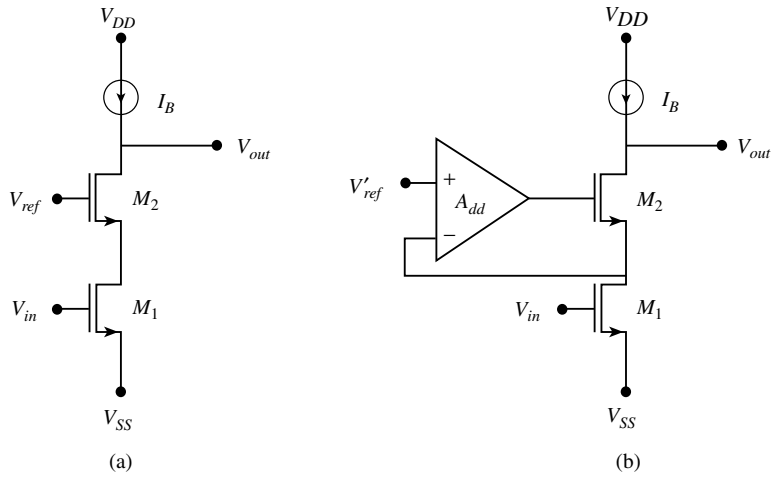

FIGURE 56.90 (a) Cascode stage and (b) cascode stage with an additional gain stage.

As a result, composite transistors with high output impedances can be obtained as shown in Fig. 56.91 [10]. Figure 56.91(a) is directly obtained from the regulated current mirror, where M_{N1} and M_{N2} are cascoded and M_{P2} and M_{N4} compose an additional gain stage. The drain-source voltage of M_{N1} biased by I_1 is given by

$$V'_{DS,a} = \sqrt{\frac{2I_1}{K_4}} + V_T \tag{56.169}$$

Figure 56.91(b), a modified version of (a), employs the biasing technique in [12], biasing V_{DS} for a triode-mode V–I converter. The resultant $V'_{DS,b}$ is given by

$$V'_{DS,b} = \sqrt{\frac{2I_1}{K_4}} - \sqrt{\frac{2I_2}{K_5}} \tag{56.170}$$

Therefore, unlike the circuit shown in Fig. 56.90(a), where $V'_{DS,a}$ is larger than V_T, M_{N1} can be biased at the edge of saturation by properly choosing currents I_1 and I_2 or K_4 and K_5 In addition, V_F provides a low impedance node for folded cascode configurations. Figure 56.91(c), also called the super-MOS transistor [11], uses a similar concept. The CMOS cascode gain stage, composed by M_{P2}, M_{P4}, M_{N4}, and M_{N6}, gives a higher gain than the previous two circuits. Since M_{N8} in the series composite transistor (constituted by M_{N7} and M_{N8}) is always operating in the triode region, V_{DS} of M_{N8} can be very small, and M_{N1} can also be biased at the edge of saturation. However, due to its circuit complexity, the input range for V_{GS} is limited. The drain currents of the circuits shown in Fig. 56.91(b) versus V_{DS} with various V_{GS} are compared to those obtained from a single transistor and are given in Fig. 56.92. It can be seen that the output impedance of the composite transistor is significantly larger than that of a single one. The use of super MOS transistors in the design of high-gain operational amplifiers is discussed in [11].

Basic Voltage Gain Cells

In this subsection, we discuss simple voltage amplifier circuits implemented in NMOS, CMOS, and BiCMOS technologies.

The NMOS Amplifier

Figure 56.93(a) shows an enhancement common-source NMOS amplifier with an enhancement load. M_1 is the driving (amplifying) transistor and the diode-connected transistor M_2 is the load device. The

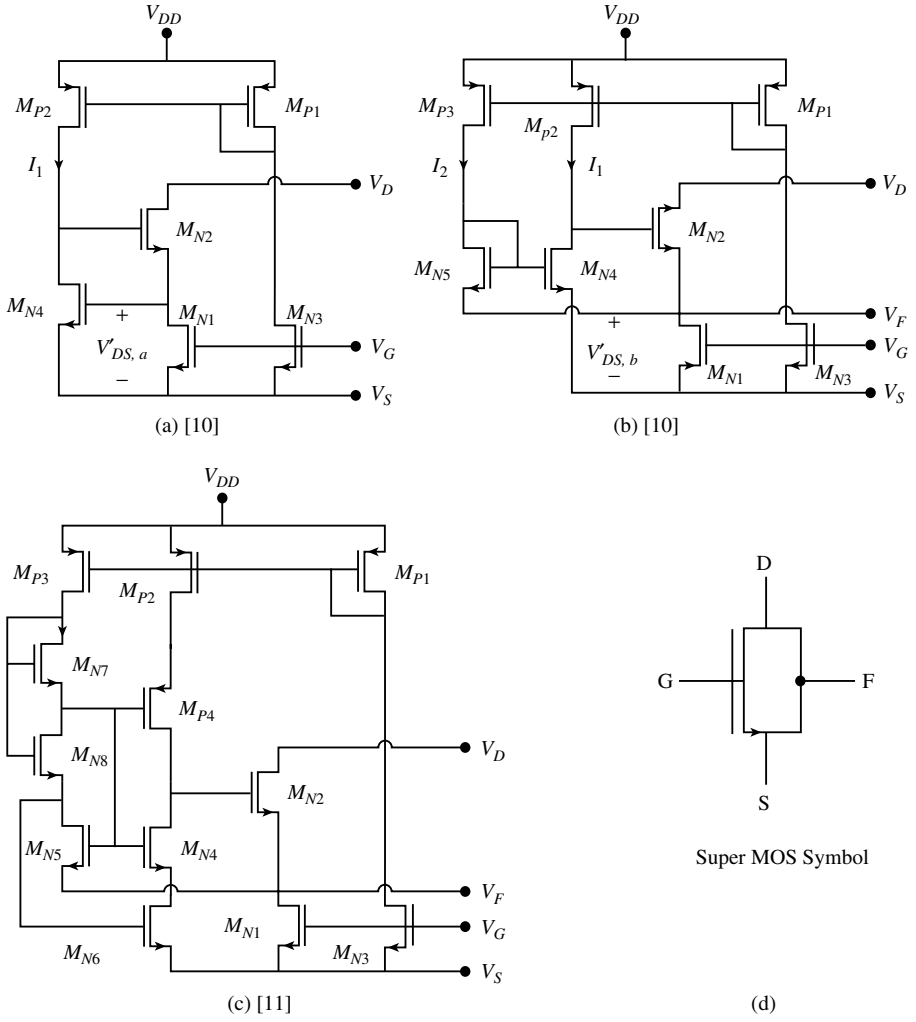

FIGURE 56.91 Composite super NMOS transistors. *Source:* (a), (b) S.-C. Huang, "Systematic design solutions for analog VLSI circuits," Ph.D. dissertation, Dep. Electr. Eng., Ohio State Univ., 1994. (c) K. Bult and G. J. Geelen, "The CMOS gain-boosting technique," *J. Analog Integrat. Circuits Signal Process.*, vol. 1, 1991.

large-signal transfer characteristics of the amplifier is shown in Fig. 56.93(b) and displays three well-defined regions. In region I, M_1 is off since $v_I < V_{T1}$. M_2, however, is always in the saturation region and is conducting a small current. The voltage across it is V_{T2} and hence the output voltage, v_O, is $V_{DD} - V_{T2}$. In region II, M_1 is conducting and is operating in saturation and the transfer curve is linear. Finally in region III, M_1 leaves the saturation region and enters the triode region. For the circuit to operate as an amplifier, the dc operating point must be located in the linear region (region II). Assuming that both M_1 and M_2 have the same threshold voltage V_T, but different values of K (K_1 and K_2) and neglecting both channel length modulation and body effects, we write

$$i_{D1} = i_{D2} = i_D = \frac{K_1}{2}\left(v_1 - V_T\right)^2 \tag{56.171}$$

and

© 2003 by CRC Press LLC

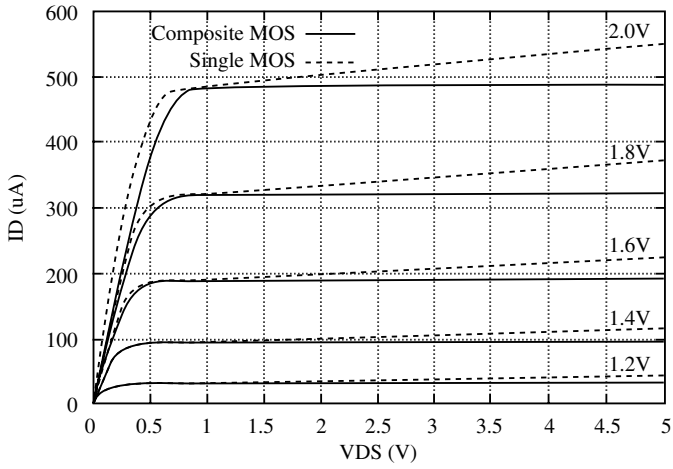

FIGURE 56.92 Simulated I_D curves for the high-output impedance composite transistor shown in Fig. 56.91(b) and for a single transistor.

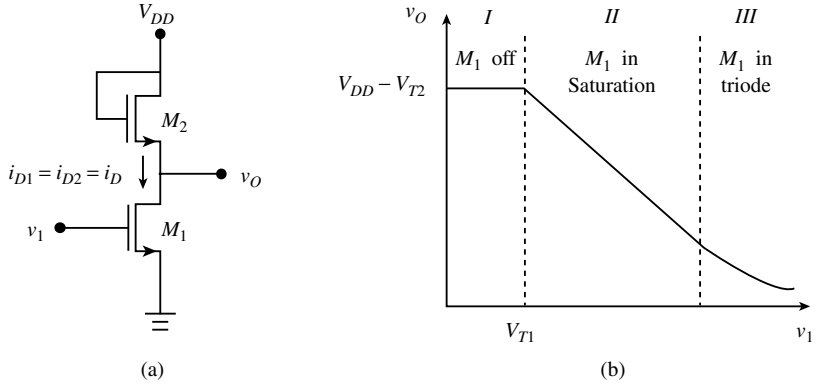

FIGURE 56.93 (a) The NMOS amplifier. (b) Transfer characteristics.

$$\begin{aligned} i_D &= \frac{K_2}{2}\left(v_{GS2} - V_T\right)^2 \\ &= \frac{K_2}{2}\left(V_{DD} - v_O - V_T\right)^2 \end{aligned} \tag{56.172}$$

Combining (56.171) and (56.172) and with some manipulations, we obtain

$$v_O = \left(V_{DD} - V_T + \sqrt{\frac{K_1}{K_2}}V_T\right) - \sqrt{\frac{K_1}{K_2}}v_I \tag{56.173}$$

which is a linear equation between v_O and v_I. This is obviously the equation of the straight-line portion (region II) of the transfer curve.

The first term in (56.173) represents the dc component of the output voltage V_O. The second term represents the small-signal component and thus the ac small-signal gain of the amplifier A_v is

$$A_v = \frac{v_o}{v_i} = -\sqrt{\frac{K_1}{K_2}} = -\sqrt{\frac{(W/L)_1}{(W/L)_2}} \tag{56.174}$$

© 2003 by CRC Press LLC

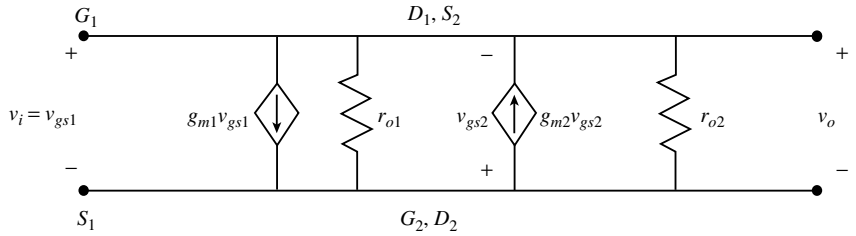

FIGURE 56.94 Small-signal equivalent circuit of the NMOS amplifier.

The small-signal equivalent circuit of the amplifier in Fig. 56.93(a) is shown in Fig. 56.94. Since D_2 and G_2 are connected in M_2, the voltage across the controlled current–source $g_{m2}v_{gs2}$ is v_{gs2}. Therefore, the controlled current–source can be represented by a resistance $1/g_{m2}$. Since $v_{gs1} = v_i$, we obtain the voltage gain as follows:

$$A_v = \frac{v_o}{v_i} = -\frac{g_{m1}}{g_{m2} + 1/r_{o1} + 1/r_{o2}} \tag{56.175}$$

Now, if r_{o1} and r_{o2} are much larger than $(1/g_{m2})$, the gain reduces to $A_v \simeq -g_{m1}/g_{m2}$, which can easily be shown to lead to the expression in (56.174). Note that the gain can also be determined by inspection from the circuit in Fig. 56.93(a) as $-g_{m1}$ multiplied by the equivalent small-signal resistance seen at the drain of M_1, which is $(1/g_{m2} \| r_{o1} \| r_{o2})$.

Practically, M_1 and M_2 share the same substrate, which is normally connected to the most negative supply voltage in the circuit (ground in this case). It follows that M_2 suffers from body effect, which is modeled in the small-signal equivalent circuit by a controlled current-source $g_{mb2}v_{bs2}$ connected between the two output terminals in Fig. 56.94, where $v_{bs2} = v_{gs2}$ and $g_{mb2} = \chi g_{m2}$ and χ is a function of the dc source–body voltage V_{SB} and lies in the range 0.1–0.3 [13]. Taking the body effect of M_2 into account, the amplifier gain becomes

$$A_v = -\frac{g_{m1}}{g_{m2} + g_{mb2}} = -\frac{g_{m1}}{g_{m2}} \frac{1}{1+\chi} \tag{56.176}$$

The CMOS Amplifier

In CMOS technology, both n-channel and p-channel devices are available, and are usually fabricated in a way that eliminates the body effect. The basic CMOS amplifier is shown in Fig. 56.95. Here, M_2 and M_3 in Fig. 56.95(c) are a pair of PMOS devices operating as a current source active load and implement the current source I_{B1} in Fig. 56.95(a). M_2 is biased in the saturation region and when M_1 is operating in the

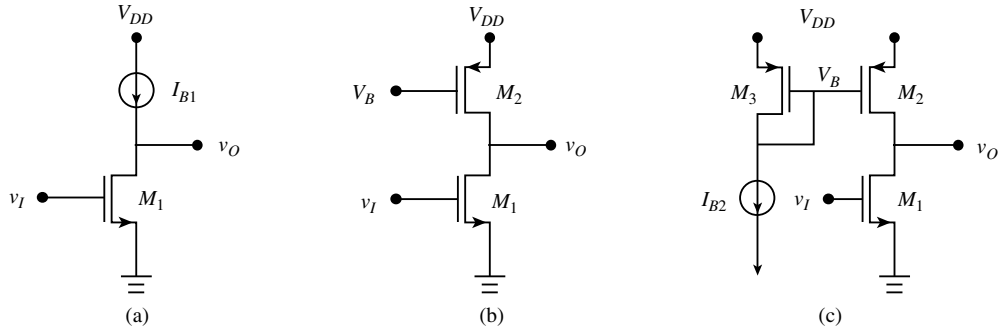

FIGURE 56.95 The CMOS amplifier: (a) basic circuit, (b) and (c) CMOS implementations.

© 2003 by CRC Press LLC

saturation region, the small-signal voltage gain will be equal to $-g_{m1}$, multiplied by the total resistance seen between the output and ground which is $(r_{o1} \| r_{o2})$.

Cascode versions of the amplifier as shown previously in Fig. 56.90 can be used to boost the gain significantly. For instance, the cascode amplifier in Fig. 56.90(a) has a gain equal to the effective transconductance $-g_{meff,}$ multiplied by $r_{o,a}$ given by (56.167), where g_{meff} is given by [14]

$$g_{meff} = g_{m1} \frac{g_{m2} r_{o1} + \dfrac{r_{o1}}{r_{o2}}}{g_{m2} r_{o1} + \dfrac{r_{o1}}{r_{o2}} + 1} \tag{56.177}$$

BiCMOS Amplifiers

A BiCMOS technology combines bipolar and CMOS transistors on a single substrate. A bipolar transistor has the advantage over a MOS of a much higher transconductance (g_m) for the same dc bias current. Also, bipolar transistors have better high–frequency performance than their MOS counterparts. On the other hand, the practically infinite input resistance at the gate of a MOSFET makes it possible to design amplifiers with extremely high input resistance and an almost zero input bias current. For these reasons, there has been an increasing interest in BiCMOS technologies for implementing high-performance integrated circuits. While most BiCMOS processes offer high-quality NMOS, PMOS, and NPN transistors, advanced BiCMOS processes offer PNP transistors as well.

Figure 56.96 shows three basic folded-cascode single-ended high-performance BiCMOS amplifiers [15]. The main features of these amplifiers are a high gain–bandwidth product and extremely high dc input impedance. The high gain is achieved by cascoding transistors in the signal path [M_1, Q_2 in Fig. 56.96(a), M_1, M_2 in Fig. 56.96(b), and M_1, Q_2, Q_3, in Fig. 56.96(c)]. The high bandwidth is achieved by exploiting the exponential nature of the current–voltage characteristics of bipolar transistors. For instance, let us consider the amplifier circuit in Fig. 56.96(a). The internal node in the signal path at the emitter of Q_2 has an extremely low impedance. This is due to the fact that while the emitter current can change significantly with the input signal, the emitter voltage remains almost constant. The same argument can be made about the internal nodes in the signal paths of the other two amplifiers [the base of Q_3 in Fig. 56.96(b) and the emitters of Q_2 and Q_3 in Fig. 56.96(c)]. The low impedance of internal nodes in the signal path places nondominant poles at very high frequencies.

The Differential Amplifier

The amplifier circuits discussed previously are of the single-ended type. A single-ended amplifier has both input and output voltage signals referred to ground. In most IC applications, a differential amplifier is utilized. In this case the amplifier has a differential input and may also have a differential output, in

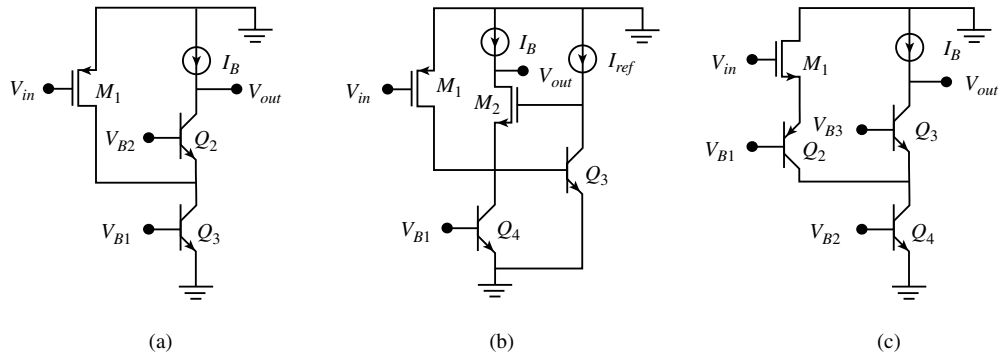

FIGURE 56.96 BiCMOS basic amplifier circuits: (a) common-source, common-base, (b) common-source, common-gate with active-feedback, and (c) common-drain, common-base, common-base.

© 2003 by CRC Press LLC

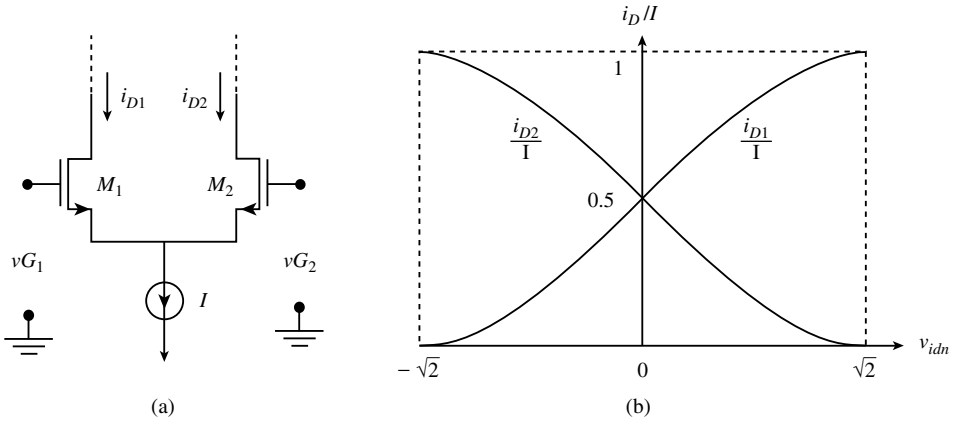

FIGURE 56.97 The MOS differential pair: (a) the circuit and (b) the transfer characteristic.

which case it is called a fully differential amplifier. It is usually easy and straightforward to convert single-ended amplifiers to differential architectures.

The most widely used differential amplifier is based on the common-source or common-gate differential pairs shown respectively in Fig. 56.78(b) and (c). The common-source pair is shown here again in Fig. 56.97. The only difference here is that the circuit is biased by a constant current source I that is usually implemented using a current-mirror circuit [see Fig. 56.78(d)].

Assuming that M_1 and M_2 are identical and neglecting both channel length modulation and body effect, we write

$$i_{D1} = \frac{K}{2}\left(v_{GS1} - V_T\right)^2 \tag{56.178}$$

$$i_{D2} = \frac{K}{2}\left(v_{GS2} - V_T\right)^2 \tag{56.179}$$

Taking the square root of both sides in each of the two equations above and defining the differential input as $v_{id} = v_{GS1} - v_{GS2}$, we get

$$\sqrt{i_{D1}} - \sqrt{i_{D2}} = \sqrt{\frac{K}{2}}\, v_{id} \tag{56.180}$$

But since the current–source bias imposes the constraint that $i_{D2} + i_{D2} = I$, one can easily show that

$$i_{D1,2} = \frac{I}{2} \pm \sqrt{KI}\left(\frac{v_{id}}{2}\right)\sqrt{1 - \frac{\left(v_{id}/2\right)^2}{\left(I/K\right)}} \tag{56.181}$$

At the bias point, the small-signal differential input voltage v_{id} is zero,

$$v_{GS1} = v_{GS2} = V_{GS} \quad \text{and} \quad i_{D1} = i_{D2} = I/2$$

This can be used to rewrite the preceding equation as follows:

$$i_{D1,2} = \frac{I}{2} \pm \left(\frac{I}{V_{GS} - V_T}\right)\left(\frac{v_{id}}{2}\right)\sqrt{1 - \left(\frac{v_{id}/2}{V_{GS} - V_T}\right)^2} \tag{56.182}$$

© 2003 by CRC Press LLC

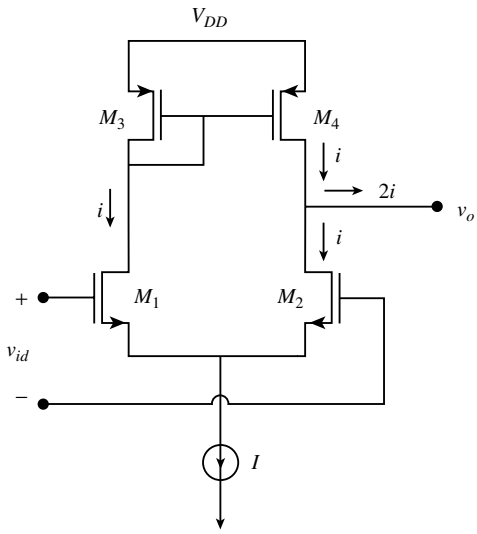

FIGURE 56.98 The simple differential-input, single-ended output CMOS amplifier.

And for $v_{id}/2 \ll V_{GS} - V_T$ (small-signal approximation),

$$i_{D1,2} \simeq \frac{I}{2} \pm \left(\frac{I}{V_{GS} - V_T} \right) \left(\frac{V_{id}}{2} \right) \tag{56.183}$$

The differential pair tranconductance g_m, defined as $g_m = (i_{D1} - i_{D2})/v_{id}$ is then given by $I/(V_{GS} - V_T)$. We recall that a single MOS transistor biased at a drain current I_D *has* a transconductance $2I_D/(V_{GS} - V_T)$. Thus, we see that each transistor in the pair has a transconductance $2(I/2)/(V_{GS} - V_T)$, which is equal to the differential pair transconductance, g_m. Equations (56.182) and (56.183) indicate that for small-signal inputs, the current in M_1 increases by i_d and that in M_2 decreases by i_d. From (56.182), we can find v_{id} at which current streering between M_1 and M_2 occurs. that is $i_{D1} = I$ and $i_{D2} = 0$ or vice versa for negative v_{id}. Equating the second term in (56.182) to $I/2$, we get.

$$|v_{id}|\max = \sqrt{2}\left(V_{GS} - V_T\right) \tag{56.184}$$

Figure 56.97(b) shows plots of the normalized currents i_{D1}/I and i_{D2}/I versus the normalized differential input voltage $v_{idn} = v_{id}/(V_{GS} - V_T)$.

A simple CMOS differential amplifier is shown in Fig. 56.98, where the PMOS pair is used as an active load. The small-signal current i is given by $g_m(v_{id}/2)$, where $g_m = I/(V_{GS} - V_T)$. The small-signal output voltage is given by $v_o = 2i(r_{o2} \parallel r_{o4})$ and the voltage gain is $A_v = v_o/v_{id} = g_m((r_{o2} \parallel r_{o4})$.

When $v_{id} = 0$, the bias current I does not actually split equally between M_1 and M_2. This is due to mismatches in K, ΔK, and V_T, ΔV_T, which contribute to a dc offset voltage that is usually larger than that in differential amplifiers implemented with bipolar transistors. For instance, modern silicon-gate MOS technologies have ΔV_T as high as 2mV [13]. Note that ΔV_T has no counterpart in bipolar junction transistors.

The Folded-Cascode Operational Amplifier

The folded-cascode operational amplifier (op amp) is a basic building block in modern analog integrated circuits. Figure. 56.99 shows two folded-cascode op amp circuits in CMOS and BiCMOS technologies [15]. Actually, several combinations of bipolar and CMOS devices could be used in the design of this amplifier. Here, we assume that PNP bipolar transistors are not available, which implies a BiCMOS

© 2003 by CRC Press LLC

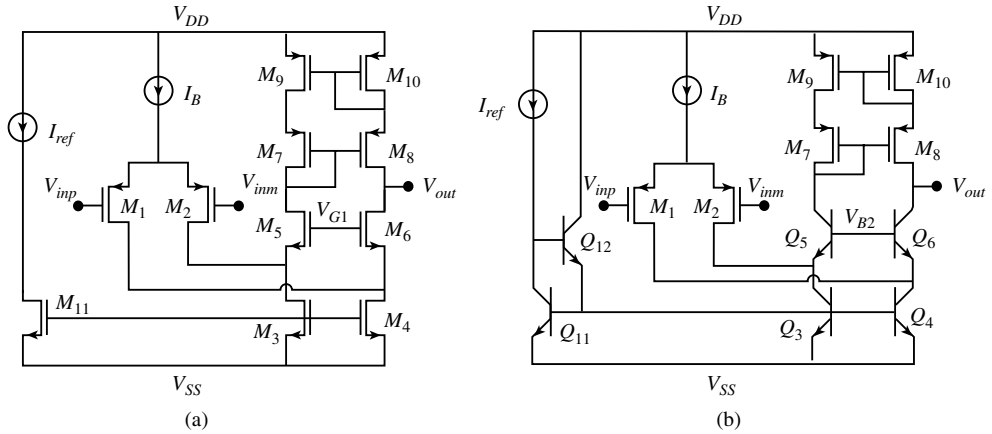

FIGURE 56.99 Folder-cascode amplifier: (a) common-source, common-gate and (b) common-source, common-base.

process having less complexity. The input common-source MOS pair is of the PMOS type. The cascode common-gate or common-base pair [M_5 and M_6 in Fig. 56.99(a) and Q_5 and Q_6 in Fig. 56.99(b)] is "folded" and, therefore, is implemented with devices of the opposite type to that used in the input pair. This is unlike the basic "unfolded" cascode amplifier in Fig. 56.90, where both input and cascode devices are of the same type.

The greater values of transconductance associated with the common-base bipolar devices in the BiCMOS op amp place the nondominant parasitic poles at much higher frequencies. Note that the BiCMOS op amp circuit is based on the single-ended amplifier shown in Fig. 56.96(a). The BiCMOS op amp combines the increased bandwidth the advantages of an MOS input stage; namely a nearly infinite input impedance, a zero input bias current, and a higher slew rate [13].

Conclusion

Analog design is more complicated and less systematic than digital design and involves many trade-offs to meet certain design specifications. It strongly relies on human heuristics. The transfer of these human experiences into a computer-aided design environment is essential to the success of analog design in the context of very large scale integration (VLSI) of both analog and mixed analog/digital integrated circuits. This transfer, however. requires the development of systematic approaches to the analysis and design of analog integrated circuits. To this end, understanding the basic operations of the analog cells discussed here is critical. The use of these cells in the systematic design of analog VLSI systems, such as filters and data converters, is discussed in [10].

57.1 Broadband Bipolar Networks

Chris Toumazou, Alison Payne, and John Lidgey

Introduction

Numerous textbooks have presented excellent treatments of the design and analysis of broadband bipolar amplifiers. This chapter is concerned with techniques for integrated circuit amplifiers, and is written mainly as a tutorial aimed at the practicing engineer.

For broadband polar design it is first important to identify the key difference between lumped and distributed design techniques. Basically when the signal wavelengths are close to the dimensions of the integrated circuit, then characteristic impedances become significant, lines become lossy, and we essentially need to consider the circuit in terms of transmission lines. At lower frequencies where the signal wavelength is much larger than the dimensions of the circuit, the design can be considered in terms of lumped components, allowing some of the more classical low-frequency analog circuit techniques to be applied. At intermediate frequencies we enter the realms of hybrid lumped/distributed design. Many RF designs fall into this category, although every day we see new technologies and circuit techniques developed that increase the frequency range for which lumped approaches are possible. In broadband applications, ICs are generally designed without the use of special microwave components, so broadband techniques are very similar to those employed at lower frequencies. However, several factors still have to be considered in RF design: all circuit parasitics must be identified and included to ensure accurate simulation; feedback can generally only be applied locally as phase shifts per stage are significant; the cascading of several local feedback stages is difficult since ac coupling is often impractical; the NPN bipolar transistor is the main device used in silicon, since it has potentially a higher f_t than PNP bipolar or MOSFET devices; active PNP loads are generally avoided due to their poor frequency and noise performance and so resistive loads are used instead.

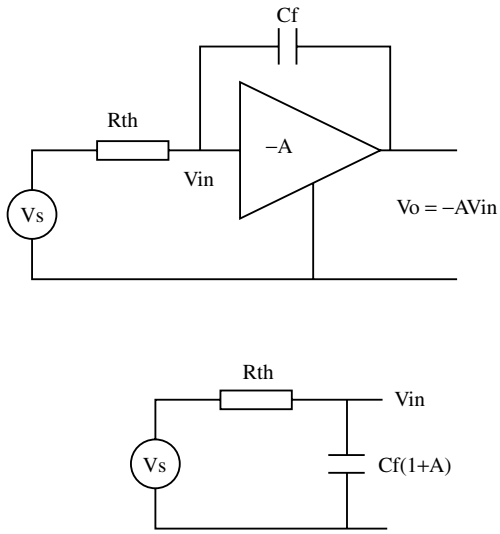

FIGURE 57.1 Example of the Miller effect.

The frequency performance of an RF or broadband circuit will depend on the frequency capability of the devices used, and no amount of good design can compensate for transistors with an inadequate range. As a rule, designs are kept as simple as possible, since at high frequencies all components have associated parasitics.

Miller's Theorem

It is important to describe at the outset a very useful approximation that will assist in simplifying the high-frequency analysis of some of the amplifiers to be described. The technique is known as Miller's theorem and will be briefly discussed here. A capacitor linking input to output in an inverting amplifier results in an input referred shunt capacitance that is multiplied by the voltage gain of the stage, as shown in Fig. 57.1. This increased input capacitance is known as the Miller capacitance.

It is straightforward to show that the input admittance looking into the inverting input of the amplifier is approximately $Y_{in} = j\omega C_f (1 + A)$. The derivation assumes the inherent poles within the amplifier are at a sufficiently high frequency so that the frequency response of the circuit is dominated by the input of the amplifier. If this is not the case then Miller's approximation should be used with caution as will be discussed later. From the preceding model, it is apparent that the Thévenin input signal sources sees an enlarged capacitance to ground. Miller's approximation is often a useful way of simplifying circuit analysis by assuming that the input dominant frequency is given by the simple low-pass *RC* filter in Fig. 57.1. However, the effect is probably one of the most detrimental in broadband amplifier design, affecting both frequency performance and/or stability.

Bipolar Transistor Modeling at High Frequencies

In this section, we consider the high-frequency small-signal performance of the bipolar transistor. The section assumes the reader has some knowledge of typical device parameters, and has some familiarity with the technology. For small-signal analysis, the simplified hybrid-π model shown in Fig. 57.2 is used, where

r_b = base series resistance
r_c = collector series resistance
r_π = dynamic base–emitter resistance
r_o = dynamic collector–emitter resistance

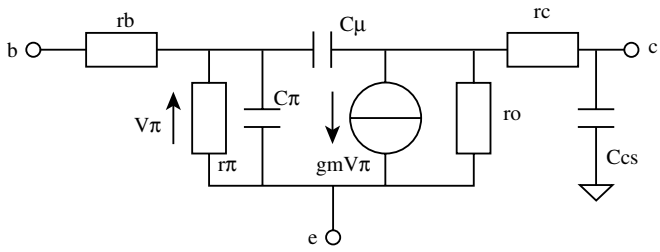

FIGURE 57.2 Hybrid π model of BJT.

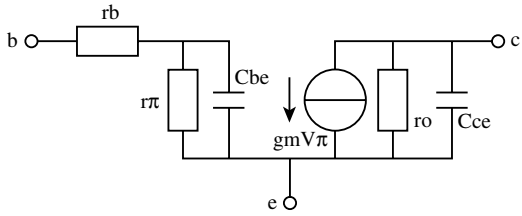

FIGURE 57.3 Simplified Miller-approximated hybrid π model of BJT.

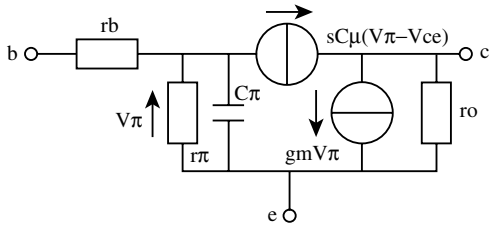

FIGURE 57.4 Simplified high-frequency model.

C_π = base–emitter junction capacitance
C_μ = collector–base junction capacitance
C_{cs} = collector–substrate capacitance
g_m = small-signal transconductance

At low frequencies, the Miller approximation allows the hybrid-π model to be simplified to the circuit shown in Fig. 57.3, where the net input capacitance now becomes $C_{be} = C_\pi + C_\mu\,(1 - A_v)$, the net output capacitance becomes $C_{ce} = C_\mu(1 - 1/A_v)$, where A_v is the voltage gain given by $A_v = (V_{ce}/V_{be}) \approx -\,g_m R_1$ where R_1 is the collector load resistance. r_C and C_{cs} have been neglected. Thus, $C_{be} \approx C_\pi + g_m R_1 C_\mu$ and $C_{ce} \approx C_\mu$. The output capacitance C_{ce} is often neglected from the small-signal model. The approximation $A_v = -\,g_m R_1$ assumes that $r_\pi \gg r_b$, and that the load is purely resistive. At high frequencies, however, we cannot neglect the gain roll-off due to C_π and C_μ, and even at frequencies as low as 5 percent of f_t the Miller approximation can introduce significant errors.

A simplified hybrid-π model that takes the high-frequency gain roll-off into account is shown in Fig. 57.4. C_μ is now replace by an equivalent current source $sC_\mu\,(V_\pi - V_{ce})$.

A further modification is to split the current source between the input and output circuits as shown in Fig. 57.5.

Finally, the input and output component terms can be rearranged leading to the modified equivalent circuit shown in Fig. 57.6, which is now suitable for broadband design. From Fig. 57.6, the transconductance $(g_m - sC_\mu)$ shows the direct transmission of the input signal through C_μ. The input circuit current

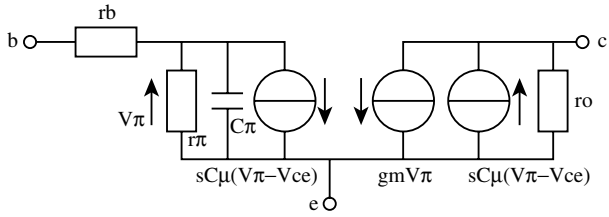

FIGURE 57.5 Split current sources.

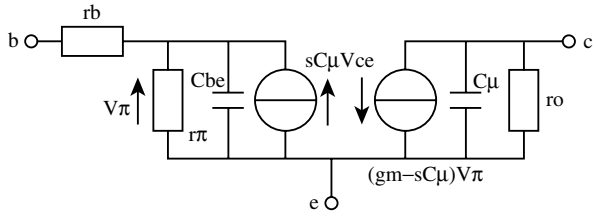

FIGURE 57.6 Modified equivalent circuit.

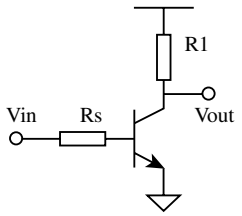

FIGURE 57.7 Common-emitter amplifier.

source ($sC_\mu V_{ce}$) shows the feedback from the output to the input via C_μ. Depending on the phase shift between V_{ce} and V_{be}, this feedback can cause high-frequency oscillation. At lower frequencies, $sC_\mu \ll g_m$ and $V_{ce}/V_\pi \approx -g_m R_1$, which is identical to the Miller approximation. The model of Fig. 57.6 is the most accurate for broadband amplifier design, particularly at high frequencies.

Single-Gain Stages

Consider now the high-frequency analysis of single-gain stages.

Common-Emitter (CE) Stage

Figure 57.7 shows a common-emitter amplifier with load R_1 and source R_s. External biasing components are excluded from the circuit.

First analysis using the Miller approximation yields the small-signal high-frequency model shown in Fig. 57.8, where

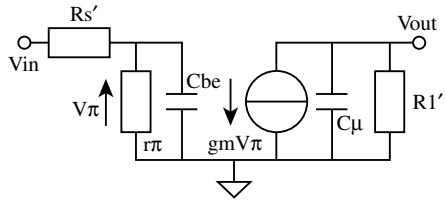

FIGURE 57.8 High-frequency model of the common emitter.

© 2003 by CRC Press LLC

$$R_{1'} = \left(R_1 \| r_0\right), \quad R_{s'} = R_s + r_b \quad \text{and} \quad C_{be} = C_\pi + g_m R_{1'} C_\mu$$

$$\frac{V_\pi}{V_{\text{in}}} = \left(\frac{r_\pi}{r_\pi + R_{s'}}\right)\left(\frac{1}{1 + s\left(r_\pi \| R_{s'}\right)C_{be}}\right) \tag{57.1}$$

$$\frac{V_{\text{out}}}{V_\pi} = \frac{-g_m R_{1'}}{1 + sC_\mu R_{1'}},$$

and thus

$$\frac{V_{\text{out}}}{V_{\text{in}}} = -\left(\frac{g_m R_{1'} r_\pi}{r_\pi + R_{s'}}\right)\left(\frac{1}{\left(1 + sC_\mu R_{1'}\right)\left(1 + s\left(r_\pi \| R_{s'}\right)C_{be}\right)}\right) \tag{57.2}$$

This approximate analysis shows:

- "Ideal" voltage gain = $-g_m R_1$
- Input attenuation caused by R_s' in series with r_π
- Input circuit pole p_1 at $s = 1/C_{be}(r_\pi \| R_s') \approx 1/C_{be}R_s'$
- Output attenuation caused by r_0 in parallel with R_1
- Output circuit pole p_2 at $s = 1/C\mu R_1'$

The input circuit pole is generally dominant, and thus the output pole p_2 can often be neglected. With a large load capacitance C_1, $p_2 \approx 1/C_1 R_1'$, and the gain and phase margin will be reduced. However, under these conditions the Miller approximation will no longer be valid, since the gain roll-off due to the load capacitance is neglected.

If we now consider analysis using the broadband hybrid-π model of Fig. 57.6, then the equivalent model of the common emitter now becomes that shown in Fig. 57.9, where

$$C_{be} = C_\pi + C_\mu, \quad R_{s'} = R_s + r_b \quad \text{and} \quad R_{1'} = R_1 \| r_0$$

From the model it can be shown that

$$\frac{V_{\text{out}}}{V_\pi} = \frac{-\left(g_m - sC_\mu\right)R_{1'}}{1 + sC_\mu R_{1'}} \tag{57.3}$$

$$\left(V_{\text{in}} - V_\pi\right)/R_{s'} + sC_\mu V_{\text{out}} = V_\pi / r_\pi + sC_{be}V_\pi \tag{57.4}$$

and

$$V_{\text{in}} r_\pi + V_{\text{out}} sC_\mu r_\pi R_{s'} = V_\pi\left(r_\pi + R_{s'}\right)\left(1 + sC_{be}\left(r_\pi \| R_{s'}\right)\right) \tag{57.5}$$

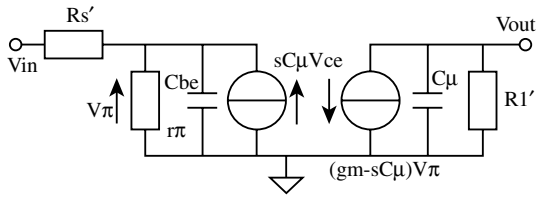

FIGURE 57.9 Equivalent circuit model of the common emitter.

© 2003 by CRC Press LLC

Rearranging these equations yields

$$\frac{V_{\text{out}}}{V_{\text{in}}} = -\left(\frac{g_m R_{1'} r_\pi}{r_\pi + R_{s'}}\right) \times \left(\frac{1 - sC_\mu / g_m}{\left(1 + sC_{be} R_{s'}\right)\left(1 + sC_\mu R_{1'}\right) + sC_\mu g_m R_{1'} R_{s'} - s^2 C_\mu^2 R_{s'} R_{1'}}\right) \tag{57.6}$$

This analysis shows that there is a right-hand-plane (RHP) zero at $s = 1/(C_\mu r_e)$, which is not predicted by the Miller approximation. Assuming $R_\pi \gg R_{S'}$ and $C_\pi \gg C_\mu$, the denominator can be written as

$$1 + s\left(R_{s'}\left(C_\pi + C_\mu g_m R_{1'}\right) + C_\mu R_{1'}\right) + s^2 C_\mu C_\pi R_{1'} R_{s'} \tag{57.7}$$

which can be described by the second-order characteristic equation

$$1 + s\left(1/p_1 + 1/p_2\right) + s^2/p_1 p_2 \tag{57.8}$$

By comparing coefficients in (57.7) and (57.8) the sum of the poles is the same as that obtained in (57.2) using the Miller approximation, but the pole product $p_1 p_2$ is greater. This means that the poles are farther apart than predicted by the Miller approximation. In general, the Miller approximation should be reserved for analysis at frequencies of operation well below f_t, and for situations where the capacitive loading is not significant. The equivalent circuit of Fig. 57.9 therefore gives a more accurate result for high-frequency analysis. For a full understanding of RF behavior, computer simulation of the circuit including all parasitics is essential.

Since the CE stage provides high current and voltage gain, oscillation may well occur. Therefore, care must be taken during layout to minimized parasitic coupling between the input and output. The emitter should be at ground potential for ac signals, and any lead inductance from the emitter to ground will generate phase-shifted negative feedback to the base, which can result in instability.

Common-Collector (CC) Stage

The common collector or emitter follower shown in Fig. 57.10 is a useful circuit configuration since it generally serves to isolate a high gain stage from a load. The high-frequency performance of this stage must be good enough so as not to degrade the frequency performance or stability of the complete amplifier. An equivalent high-frequency small-signal model of the common collector is shown in Fig. 57.11.

The following set of equations can be derived from Fig. 57.11:

$$\left(V_{\text{in}} - V_b\right)/R_{s'} = V_\pi / r_\pi + sC_{be} V_\pi + sC_\mu V_{\text{out}}, \qquad V_b = V_{\text{out}} + V_\pi \tag{57.9}$$

and

$$V_\pi / r_\pi + sC_{be} V_\pi + sC_\mu V_{\text{out}} + \left(g_m - sC_\mu\right)V_\pi - sC_\mu V_{\text{out}} - V_{\text{out}}/R_{1'} = 0 \tag{57.10}$$

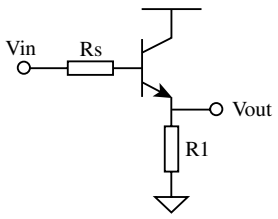

FIGURE 57.10 Common-collector amplifier.

© 2003 by CRC Press LLC

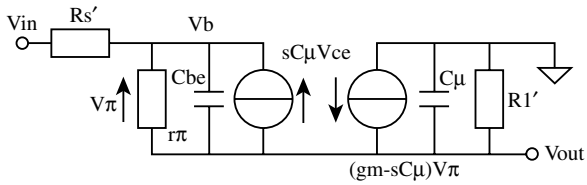

FIGURE 57.11 Equivalent circuit of the common collector.

Rearranging these equations yields

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{R_{1'}\left(1 + g_m r_\pi + sC_\pi r_\pi\right)}{\left(R_{s'} + r_\pi\right)\left(1 + s\left(R_{s'} \| r_\pi\right)C_{be}\right) + R_{1'}\left(1 + sC_\mu R_{s'}\right)\left(1 + g_m r_\pi + sC_\pi r_\pi\right)} \tag{57.11}$$

The preceding expression can be simplified by assuming $R_\pi \gg R_{S'}$, $g_m r_\pi \gg 1$, $C_\pi \gg C_\mu$ to,

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \left(\frac{r_\pi}{r_\pi + R_{s'}}\right)\left(\frac{1 + sC_\pi / g_m}{\left(1 + sC_\mu R_{s'}\right)\left(1 + sC_\pi / g_m\right) + \left(1 + sC_\pi R_{s'}\right)/g_m R_{1'}}\right) \tag{57.12}$$

This final transfer function indicates the presence of a left-half-plane (LHP) zero at $s = (g_m/C_\pi) = \omega_t$. The denominator can be rewritten as approximately

$$\left(1 + 1/g_m R_{1'}\right) + s\left(C_\mu R_{s'} + C_\pi / g_m + C_{be} R_{s'} / g_m R_{1'}\right) + s^2 C_\mu C_\pi R_{s'} / g_m \tag{57.13}$$

which simplifies to

$$1 + s\left(C_\pi r_e + C_\mu R_{s'} + \left(C_\mu + C_\pi\right) r_e R_{s'} / R_{1'}\right) + s^2 C_\mu C_\pi R_{s'} R_{1'} \tag{57.14}$$

Assuming a second-order characteristic form of $1 + s(1/p_1 + 1/p_2) + s^2/p_1 p_2$, if $p_1 \ll p_2$, the above reduces to $1 + s/p_1 + s^2/p_1 p_2$. If $(R_{S'}/R_{1'}) \ll 1$, then $p_1 \approx 1/(C_\pi r_e)$, and this dominant pole will be approximately canceled by the zero. The frequency response will then be limited by the nondominant pole $p_2 \approx 1/C_\mu R_{s'}$.

The frequency response of a circuit containing several stages is thus rarely limited by the CC stage, due to this dominant pole-zero cancellation. For this analysis to be valid, $R_{S'} \ll R_{1'}$. As $R_{s'}$ increases the poles will move closer together, and the pole-zero cancellation will degrade. In practice, the CC stage is often used as a buffer, and is thus driven from a high source resistance into a low value load resistance.

A very important parameter of the common-collector stage is output impedance. It is generally assumed that the output impedance of a common collector is low, also that there is good isolation between a load and the amplifying stage, and that any amount of current can be supplied to the load. Furthermore, it is assumed that capacitive loads will not degrade the frequency performance since the load will be driven by an almost short circuit. While this may be the case at low frequencies, it is a different story at high frequencies. Consider the following high-frequency analysis. We first assume that the small-signal model shown in Fig. 57.12 is valid.

From the Fig. 57.12, the output impedance can be approximated as

$$\frac{V_{\text{out}}}{I_{\text{out}}} = \frac{Z_\pi + R_{s'}}{1 + g_m Z_\pi} \tag{57.15}$$

© 2003 by CRC Press LLC

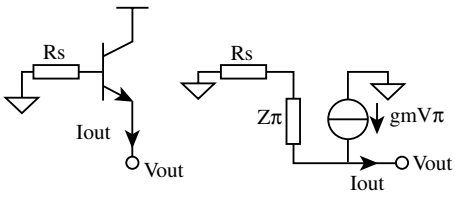

FIGURE 57.12 Equivalent circuit of the CC output stage.

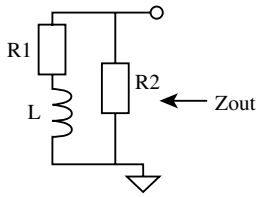

FIGURE 57.13 Equivalent high-frequency model of CC output stage.

where $Z_\pi = (r_\pi \| C_{be})$ and $R_{s'} = R_s + r_b$. At very low frequencies ($\omega \to 0$):

$$R_{\text{out}} = \frac{r_\pi + R_{s'}}{1 + g_m r_\pi} \approx 1/g_m + R_{s'}/g_m r_\pi \approx r_e + R_{s'}/\beta \tag{57.16}$$

At very high frequencies ($\omega \to \infty$):

$$R_{\text{out}} = \frac{1/sC_{be} + R_{s'}}{1 + g_m/sC_{be}} \approx R_{s'} \tag{57.17}$$

If $r_e > R_{s'}$, then the output impedance decreases with frequency, that is, Z_{out} is capacitive. If $R_{s'} > r_e$, then Z_{out} increases with frequency, and so Z_{out} appears inductive. It is usual for an emitter follower to be driven from a high source resistance, thus the output impedance appears to be inductive and can be modeled as shown in Fig. 57.13, where

$$R_1 = r_e + R_{s'}/\beta, \quad R_2 = R_{s'}, \quad L = R_{s'}/\omega_t$$

The inductive behavior of the CC stage output impedance must be considered in broadband design since any capacitive loading on this stage could result in peaking or instability. The transform from base resistance to emitter inductance arises because of the 90° phase shift between base and emitter currents at high frequencies, due principally to C_π. This transform property can be used to advantage to simulate an on-chip inductor by driving a CC stage from a high source resistance. Similarly, by loading the emitter with an inductor we can increase the effective base series resistance $R_{s'}$ without degrading the noise performance of the circuit. A capacitive load will also be transformed by 90° between the base and emitter; for example, a capacitive loading on the base can look like a negative resistance at the emitter.

Common-Base (CB) Stage

The common-base amplifier shown in Fig. 57.14 offers the highest frequency performance of all the single-stage amplifiers. When connected as a unity gain current buffer, the CB stage operates up to the f_t of the transistor.

Using the simplified hybrid π model of Fig. 57.3, it follows that

$$\frac{I_{\text{out}}}{I_{\text{in}}} \approx \frac{\beta}{\beta + 1} \quad \text{where} \quad \beta = \frac{\beta_o}{1 + s/\omega_o} \tag{57.18}$$

© 2003 by CRC Press LLC

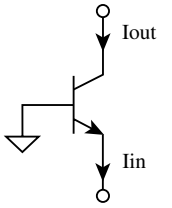

FIGURE 57.14 Common-base configuration.

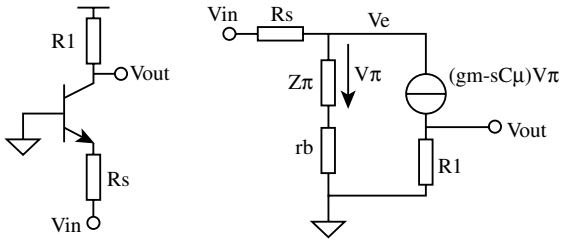

FIGURE 57.15 CB stage as a voltage amplifier.

$$\frac{I_{\text{out}}}{I_{\text{in}}} \approx \frac{a_o}{1+s/\omega_t} \quad \text{where } a_o = \beta_o/(\beta_o+1) \text{ and } \omega_t = \beta_o\omega_o \tag{57.19}$$

The CB stage thus provides wideband unity current gain. Note that the input impedance of the CB stage is the same as the output impedance of the CC stage, and thus can appear inductive if the base series resistance is large.

In many situations, the CB stage is connected as a voltage amplifier, an example of this being the current-feedback amplifier, which will be discussed in a later section. Consider the following high-frequency analysis of the CB stage being employed as a voltage gain amplifier. Figure 57.15 shows the circuit together with a simplified small-signal model. From the equivalent model the gain of the circuit can be approximated as

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{kR_1}{R_s}\left(\frac{1-sC_\mu/g_m}{1+s(C_\pi/g_m)(kR_{s'}/R_s)}\right) \tag{57.20}$$

where

$$R_{s'} = R_s + r_b, \text{ and } k \approx \frac{R_s}{R_s+1/g_m}$$

If $R_S \gg 1/g_m$, then $k \approx 1$ and so

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{R_1}{R_s}\left(\frac{1-sC_\mu/g_m}{1+s(C_\pi/g_m)(1+r_b/R_s)}\right) \tag{57.21}$$

Thus, it can be seen that the circuit has a right-hand-plane zero at $s = 1/(r_e C_\mu)$, since $r_e = 1/g_m$ and a pole at $1/C_\pi r_e(1 + r_b/R_s) = \omega_t/(1 + r_b/R_s)$. Note that in the case of a current source drive ($R_S \gg r_b$), the pole is at the ω_t of the transistor. However, this does assume that the output is driven into a short circuit. Note also the excellent isolation between the input and output circuits, since there is no direct path through C_μ and so no Miller effect.

© 2003 by CRC Press LLC

Neutralization of C_μ

Many circuit techniques have been developed to compensate for the Miler effect in amplifiers and hence extend the frequency range of operation. The common-emitter stage provides the highest potential power gain, but the bandwidth of this configuration is limited since the amplified output voltage effectively appears across the collector–base junction capacitance resulting in the Miller capacitance multiplication effect. This bandwidth limiting due to C_μ can be overcome by using a two-transistor amplifying stage such as the CE–CB cascode stage or the CC–CE cascade. Consider now a brief qualitative description of each in turn. The circuit diagram of the CE–CB cascode is shown in Fig. 57.16.

The CE transistor Q_1 provides high current gain of approximately β and a voltage gain of $A_{v1} \approx -g_{m1} R_1 = -g_{m1} r_{e2}$, which in magnitude will be close to unity. Therefore, the Miller multiplication of C_μ is minimized, and the bandwidth of Q_1 is maximized. The CB transistor Q_2 provides a voltage gain $A_{v2} \approx R_1/r_{e2}$. The total voltage gain of the circuit can be approximated as $A_v \approx -g_{m1} R_1$, which is equal to that of a single CE stage. The total frequency response is given by the cascaded response of both stages. Since both transistors exhibit wideband operation, then the dominant poles of each stage may be close in frequency. As a result, the total phase shift through the cascode configuration is likely to be greater than that obtained with a single device, and care should be taken when applying negative feedback around the pair.

Consider now the CC–CE stage of Fig. 57.17. In this case voltage gain is provided by the CE stage transistor Q_2 and is $A_{v2} \approx -g_{m2} R_1$. This transistor is being driven from the low output impedance of Q_1 and so the input pole frequency of this device ($\approx 1/C_{be2}R_{s2}$) is maximized. The CC stage transistor Q_1 is effectively a buffer that isolates C_μ of Q_2 from the source resistance R_s. The low-frequency voltage gain of this circuit is reduced when compared with a single-stage configuration because the input signal effectively appears across two base-emitter junctions.

The two-transistor configurations help to maintain a wideband frequency response by isolating the input and output circuits. In integrated circuit design, another method of neutralizing the effect of C_μ is possible when differential gain stages are used.

For example, Fig. 57.18 shows a section of a differential input amplifier. If the inputs are driven differentially, then the collector voltages V_{c1} and V_{c2} will be 180° out of phase. The neutralization capacitors

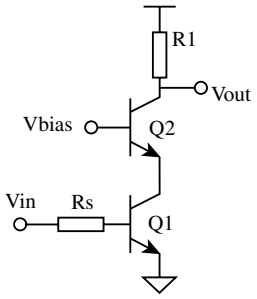

FIGURE 57.16 CE–CB cascode.

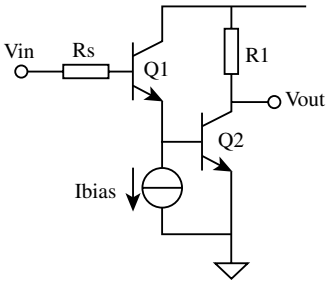

FIGURE 57.17 CC–CE stage.

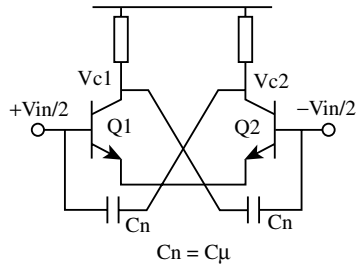

FIGURE 57.18 Differential gain stage.

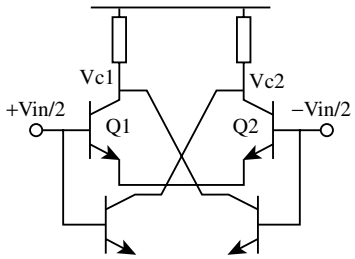

FIGURE 57.19 Implementation of neutralization capacitors.

C_n thus inject a current into the base of each transistor that is equal and opposite to that caused by the intrinsic capacitance C_μ. Consequently, the neutralization capacitors should be equal to C_μ in order to provide good signal cancellation, and so they may be implemented form the junction capacitance of two dummy transistors with identical geometries to Q_1 and Q_2 as shown in Fig. 57.19.

Negative Feedback

Negative feedback is often employed around high gain stages to improve the frequency response. In effect, the gain is reduced in exchange for a wider, flatter bandwidth. The transfer function of a closed-loop system can be written

$$H(s) = \frac{A(s)}{1 + A(s)B(s)} \tag{57.22}$$

where $A(s)$ is the open-loop gain and $B(s)$ is the feedback fraction. If the open-loop gain $A(s)$ is large, then $H(s) \approx 1/B(s)$. In RF design, compound or cascaded stages can produce excessive phase shifts that result in instability when negative feedback is applied. To overcome this problem, it is generally accepted to apply local negative feedback around a single stage only. However, the open-loop gain of a single stage is usually too low for the approximation $H(s) = 1/B(s)$ to hold.

RF Bipolar Transistor Layout

When laying out RF transistors, the aim is to

- Minimize C_μ and C_π.
- Minimize base width to reduce the forward transit time t_f and thus maximize f_t.
- Minimize series resistance r_b and r_c.

To minimize junction capacitance, the junction area must be reduced; however, this will tend to increase the series resistance. Transistors are generally operated at fairly high currents to maximize f_t. However, if the emitter gets too crowded, then the effective value of β will be reduced. The requirements given above are generally best met by using a stripe geometry of the type shown in Fig. 57.20.

© 2003 by CRC Press LLC

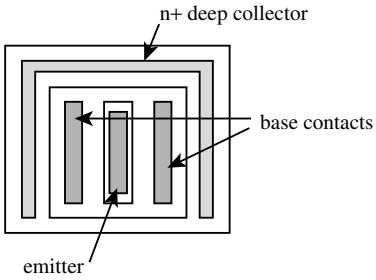

FIGURE 57.20 Stripe geometry.

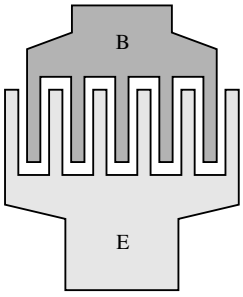

FIGURE 57.21 Transistor layout with interleaving fingers.

The stripe geometry maximizes the emitter area-to-periphery ratio, which reduces emitter crowding while minimizing the junction capacitance. The length of the emitter is determined by current-handling requirements. The base series resistance is reduced by having two base contacts and junction depths are minimized to reduce capacitance. The buried layer, or deep collector, reduces the collector series resistance. High-power transistors are produced by paralleling a number of transistors with interleaving "fingers," as shown in Fig. 57.21. This preserves the frequency response of the stripe geometry while increasing the total current-handling capability.

Bipolar Current-Mode Broadband Circuits

Recently there has been strong interest in applying so-called current-mode techniques to electronic circuit design. Considering the signal operating parameter as a current and driving into low impedance nodes has allowed the development of a wealth of circuits with broadband properties. Many of the following circuit and system concepts date back several years; it is progress in integrated circuit technology that has given a renewed impetus to "practical" current-mode techniques.

The NPN bipolar transistor, for example, is used predominantly in analog IC design because electron mobility is greater than hole mobility in silicon. This means that monolithic structures are typically built on P-type substrates, because vertical NPN transistors are then relatively easy to construct and to isolate from each other by reverse biasing the substrate.

Fabricating a complementary PNP device on a P-type substrate is less readily accomplished. An N-type substrate must be created locally and the PNP device placed in this region. Early bipolar processes created PNP devices as lateral transistors and engineers dealt with their inherently poor, low-frequency characteristics by keeping the PNP transistors out of the signal path whenever possible.

However, high-speed analog signal processing demands symmetrical silicon processes with fully complementary BJTs. Newer, advanced processes have dielectrically isolated transistors rather than reversed-biased PN junction isolation. These processes are able to create separate transistors, each situated in a local semiconductor region. Then, both PNP and NPN devices are vertical and their performance characteristics are much more closely matched.

Dielectric isolation processes have revolutionized high-speed analog circuit design and have been key in making high-performance current-conveyor and current-feedback op-amp architectures practical. In

© 2003 by CRC Press LLC

the following sections, we will briefly review the development of the current-conveyor and current-feedback op-amp.

The Current Conveyor

The current conveyor is a versatile broadband analog amplifier that is intended to be used with other circuit components to implement many analog signal-processing functions. It is an analog circuit building block in much the same way as a voltage op-amp, but it presents an alternative method of implementing analog systems that traditionally have been based on voltage op-amps. This alternative approach leads to new methods of implementing analog transfer functions, and in many cases the conveyor-based implementation offers improved performance when compared to the voltage op-amp-based implementation in terms of accuracy, bandwidth, and convenience. Circuits based on voltage op-amp are generally easy to design since the behavior of a voltage op-amp can be approximated by a few simple design rules. This is also true for current conveyors, and once the appropriate design rules are understood, the application engineer is able to design conveyor-based circuits just as easily.

The first-generation current conveyor or CCI was proposed by Smith and Sedra in 1968 [1] and the more versatile second-generation current conveyor, or CCII, was introduced by the same two authors in 1970 [2], as an extension of the CCI. The CCII, is without doubt the more valuable and adaptable building block of the two, and we will concentrate mostly on this device. Figure 57.22(a) shows the voltage–current describing matrix for the CCII, while Fig. 57.22(b) shows the schematic normally used for the CCII with the power supply connections omitted.

The voltage at the low-impedance input node *X* follows that at the high-impedance input node *Y*, while the input current at node *X* is mirrored or "conveyed" to the high-impedance output node *Z*. The ± sign indicates the polarity of the output current with respect to the input current; by convention, a positive sign indicates that both the input and output currents simultaneously flow into or out of the device, thus Fig. 57.22(b) illustrates a CCII +. For the first-generation conveyor, or CCI, the input current at node *X* was reflected to input *Y*, that s, the two inputs had equal currents. In the case of the second-generation conveyor input, *Y* draws no current, and this second generation, or CCII formulation, has proved to be much more adaptable and versatile than its first-generation predecessor. Because of the combined voltage and current following properties, CCII's may be used to synthesize a number of analog circuit functions that are not so easily or accurately realizable using voltage op-amps.

Some of these application areas are shown in Fig. 57.23. As current-conveyors become more readily available and circuits designers become more familiar with the versatility of this device it is certain that further ingenious uses will be devised.

The Ideal Transistor and the Current-Conveyor. So far a transistor-level realization of the CCII has not been discussed. The current-vlotage transfer relationship for the CCII+ is given by

$$V_X = V_Y, \quad I_Y = 0 \quad \text{and} \quad I_Z = I_X \tag{57.23}$$

These equations show that a simple voltage-following action exists between input node *Y* and output node *X*, and that there is a simple current-following action between input node *X* and output node *Z*. Also, these characteristic equations tell us that the impedance relationship for the ideal current conveyor are

$$Z_{INY} = \infty, \quad Z_X = 0 \quad \text{and} \quad Z_{OUTZ} = \infty \tag{57.24}$$

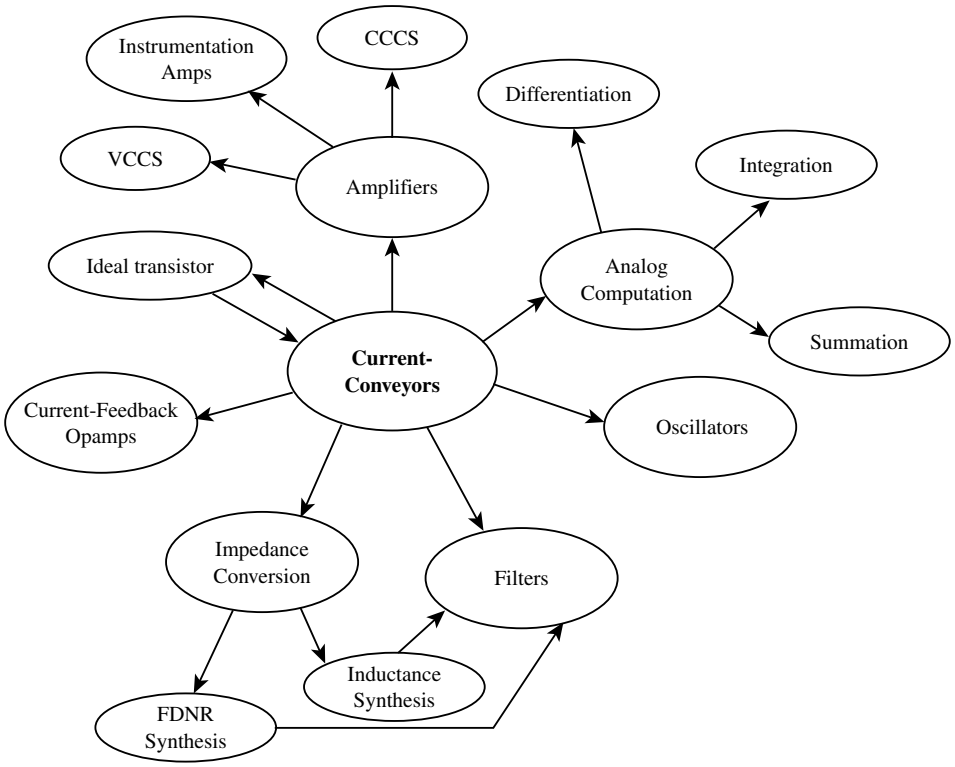

FIGURE 57.23 Current-conveyor applications.

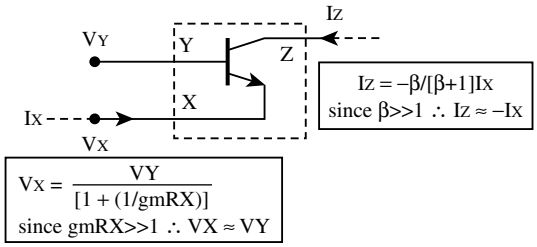

FIGURE 57.24 Single BJT CCII–.

Figure 57.24 shows a schematic representation of a CCII — built with a single BJT and on reflection it is clear that the current conveyor is effectively an ideal transistor, with infinite β and infinite g_m.

Driving into the base of a BJT gives almost unity voltage gain from input base to output emitter, with high input impedance and low output impedance, and driving into the emitter of a BJT gives almost unity current gain from emitter input to collector output, with low input impedance and high output impedance. Drawing the comparison further, the high-input-impedance *Y* node corresponds to the base (or gate) of a transistor, the low-input-impedance *X* node corresponds to the emitter (or source) of a transistor, and the high-output-impedance *Z* node corresponds to the collector (or drain) of a transistor. Clearly, one transistor cannot function alone as a complete current conveyor since an unbiased single transistor at best can only handle unipolar signals and the high-accuracy unity voltage and unity current gain required for a high-performance current conveyor cannot be obtained. However, the generic relationship between the current conveyor and an ideal transistor is valid, and it provides valuable insight into the development and operation of monolithic current conveyors described in the next section.

Supply-Current Sensing. Many of the current-conveyor theories and applications have been tested out in practice using "breadboard" conveyor circuits, due to the lack of availability of a commercial device. Some researchers have built current conveyors from matched transistor arrays, but the most common way of implementing a fairly high-performance current conveyor has been based on the use of supply-current sensing on a voltage op-amp [3], [4], as shown in Fig. 57.25. The high-resistance op-amp input provides the current-conveyor *Y* node, while the action of negative feedback provides the low-resistance *X* node. Current-mirrors in the op-amp supply leads copy the current at node *X* to node *Z*.

Using this type of architecture, several interesting features soon became apparent. Consider the two examples shown in Fig. 57.26. In Fig. 57.26(b), R_s represents the output resistance of the current source. The open-loop gain of an op-amp can generally be written

$$\frac{V_{\text{out}}}{V_{\text{in}}} = \frac{A_o}{1 + j\left(f/f_o\right)} \tag{57.25}$$

where A_o is the open-loop dc gain magnitude and f_o is the open-loop –3 dB bandwidth. Since $A_o \gg 1$, the transfer function of the voltage follower of Fig. 57.26(a) can be written as

$$\frac{V_{\text{out}}}{V_{\text{in}}} \approx \frac{1}{1 + j\left(f/GB\right)} \tag{57.26}$$

where $GB = A_o f_o$. From (57.26), the –3 dB bandwidth of the closed-loop voltage follower is equal to the open-loop gain-bandwidth product or *GB* of the op-amp. If the op-amp is configured instead to give a closed-loop voltage gain *K*, it is well known that the closed-loop bandwidth correspondingly reduces by the factor *K*.

The transfer function for the current-follower circuit of Fig. 57.26(b), as shown in [4], is given by

$$\frac{I_{\text{out}}}{I_{\text{in}}} \approx \lambda \frac{1 + j\left(f/GB\right)}{1 + j\left(f/kGB\right)} \tag{57.27}$$

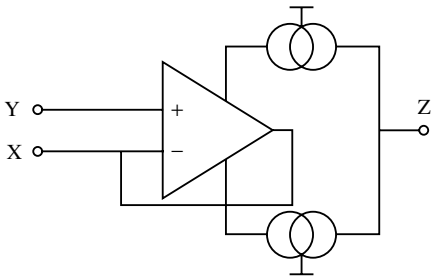

FIGURE 57.25 Supply-current sensing on a voltage op-amp.

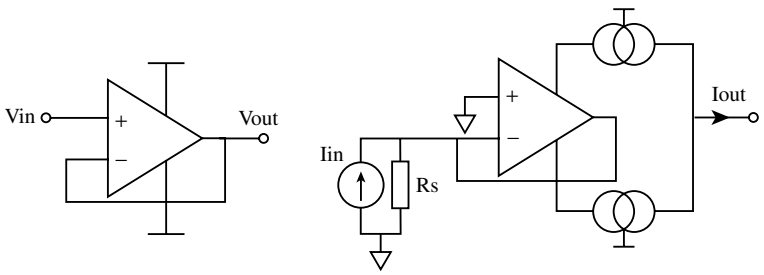

FIGURE 57.26 (a) Voltage follower. (b) Current follower.

© 2003 by CRC Press LLC

where λ is the current transfer ratio of the current mirrors and $k = (R_s + r_o/A_o)/(R_s + r_o)$, and r_o represents the output resistance of the op-amp. Since $A_o \gg R_s \gg r_o$, then $K \approx 1$, and the pole and zero in (57.27) almost cancel. The current-follower circuit thus operates well above the gain–bandwidth product *GB* of the op-amp, and the –3-dB frequency of this circuit will be determined by higher frequency parasitic poles within the current mirrors.

This "extra" bandwidth is achieved because the op-amp is being used with input and output nodes held at virtual ground. The above example is generic in the development of many of the circuits that follow. It demonstrates that reconfiguring a circuit topology to operate with current signals can often result in a superior frequency performance.

First-Generation Current Conveyors. Smith and Sedra's original paper presenting the first-generation CCI current conveyor showed a transistor-level implementation based on discrete devices, shown in Fig. 57.27. Assuming that transistors Q_3–Q_5 and resistors R_1–R_3 are matched, then to first order the currents through these matched components will be equal. Transistors Q_1 and Q_2 are thus forced to have equal currents, and equal V_{be}s. Input nodes *X* and *Y* therefore track each other in both voltage and current. In practice there will be slight differences in the collector currents in the different transistors, due to the finite β of the devices. These differences can be reduced, for example, by using more elaborate current mirrors. The polarity of the output current at node *Z* can be inverted easily by using an additional mirror stage, and the entire circuit can also be inverted by replacing NPN transistors with PNPs, and vice versa. Connecting two complementary current conveyors, as shown in Fig. 57.28 results in a class *AB* circuit

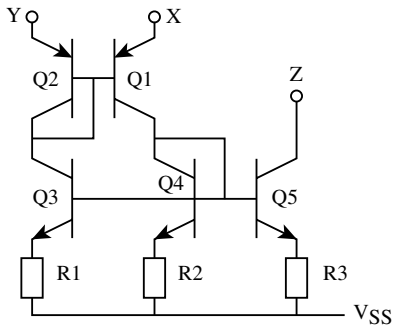

FIGURE 57.27 First-generation current conveyor (CCI).

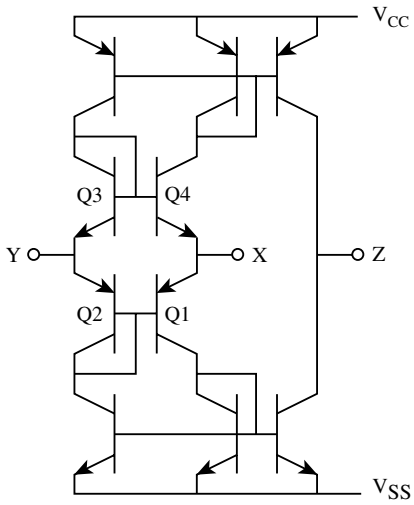

FIGURE 57.28 Class *AB* current conveyor.

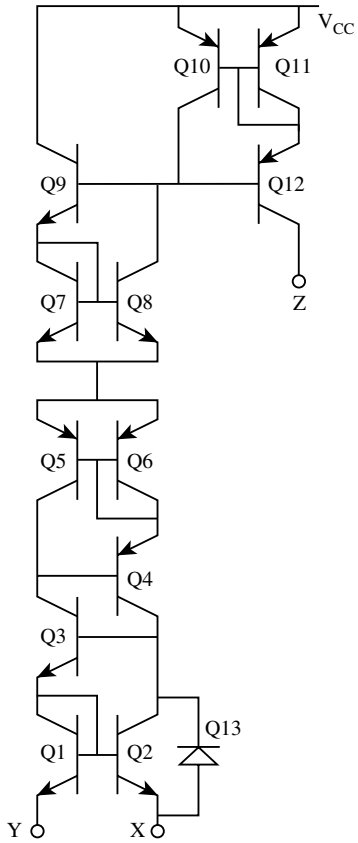

FIGURE 57.29 Simplified PA630 current conveyor (CCI).

capable of bipolar operation. Note that in practice this circuit may require additional components to guarantee start-up.

An integrated current conveyor based on the architecture shown in Fig. 57.27 is commercially available as the PA630 [5], and the basic topology of this device is shown in Fig. 57.29. An NPN Wilson mirror (Q_1–Q_3) and a PNP Wilson mirror (Q_4–Q_6) are used to provide the current and voltage following properties between inputs *X* and *Y*, similar to the circuit of Fig. 57.27. Taking a second output from the PNP current mirror to provide the *Z* output would destroy the base-current compensation scheme of the Wilson mirror. Therefore, a second NPN Wilson mirror (Q_7–Q_9) is used to perform a current-splitting action and so the combined emitter current of Q_7 and Q_8 is divided in two, with one half being shunted via Q_9 to the supply rail, and the other half driving an output PNP Wilson mirror (Q_{10}–Q_{12}). This results in an output current at node *Z* that to first order is virtually equal to that at the *X* and *Y* inputs. Q_{13} is included to ensure that the device always starts up when turned on. The complete architecture of the PA630 CCI also includes frequency compensation to ensure stability, and modified output current mirrors that use the "wasted" collector current of Q_9 to effectively double the output resistance at node *Z*. A full description of the architecture and operation of this device can be found in [6].

The current-conveyor architecture shown in Fig. 57.29 includes both NPN and PNP transistors in the signal path, and thus the bandwidth and current-handling capability of this device will be poor if only lateral PNPs are available. The development of complementary bipolar processes, with vertical PNP as well as NPN transistors, has made possible the implementation of high-performance integrated circuit current conveyors.

Second-Generation Current Conveyors. A second-generation current conveyor (CCII) can also be simply implemented on a complementary bipolar process, by replacing the diode at the CCI *Y* input with a

© 2003 by CRC Press LLC

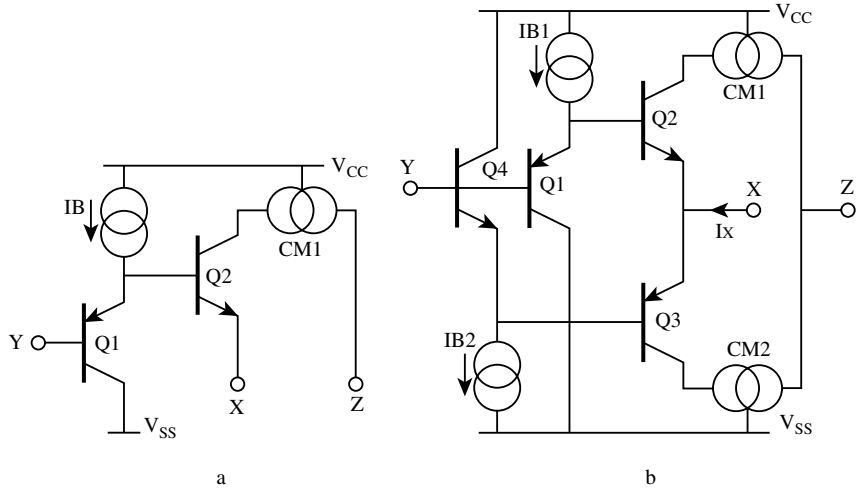

FIGURE 57.30 (a) Class *A* CCII. (b) Class *AB* CCII.

transistor, and taking the input from the high resistance base terminal, as shown in Fig. 57.30(a). This can be extended to a class *AB* version, as shown in Fig. 57.30(b). Referring to Fig. 57.30(b), transistors Q_1–Q_4 act as a voltage buffer that transfers the voltage at node *Y* to node *X*. The current source and sink ($I_{B1} = I_{B2} = I_B$) provide the quiescent bias current for these input transistors. Any input current (I_x) at node *X* is split between Q_2 and Q_3, and is copied by current mirrors CM_1 and CM_2 to the output node *Z*. This CCII architecture forms the basis of the commercially available CCII01 current conveyor [7]. As we shall see later, it is also used as the basic input stage of the current-feedback op-amp, which has emerged as a high-speed alternative to the more conventional voltage op-amp [8].

The simple CCII architecture of Fig. 57.30(b) will clearly exhibit a quiescent voltage offset between nodes *X* and *Y* due to the mismatch between the V_{be}s of the NPN and PNP transistors Q_1/Q_2 and Q_3/Q_4, since

$$\begin{aligned} V_Y - V_X &= V_{BE}(p) - V_{BE}(n) \\ &= V_T \ln\left(I_{sp}/I_{sn}\right) \end{aligned} \tag{57.28}$$

where I_{sp} and I_{sn} are the reverse saturation currents of the PNP and NPN transistors, respectively, and V_T is the thermal voltage. This process-dependent voltage offset can be reduced by including additional matching diodes in the input stage, as shown in Fig. 57.31. Referring to this diagram,

$$\begin{aligned} V_Y - V_X &= V_{BE}(Q_1) + V_{D_2} - V_{BE}(Q_2) - V_{D_1} \\ V_Y - V_X &= \left[V_{BE}(Q_1) - V_{D_1}\right] - \left[V_{BE}(Q_2) - V_{D_2}\right] \end{aligned} \tag{57.29}$$

Inclusion of these diodes clearly reduces the quiescent input voltage offset, provided that D_1 is matched to Q_1, D_2 is matched to Q_2, etc. However, the addition of diodes D_1 and D_2 has several disadvantages. First, the input voltage dynamic range of the circuit will be reduced by the forward voltage across the additional diode. Second, the small-signal input resistance seen looking into node *X* will be double that for the basic architecture given in Fig. 57.30(b). This nonzero input resistance at node *X* (R_x) will compromise the performance of the current conveyor, especially in applications where a nonzero input voltage is applied at node *Y*. The effect of the small-signal input resistance R_x is to produce a signal-dependent voltage offset V_d between nodes *X* and *Y*, where

$$V_d = R_x I_x \tag{57.30}$$

© 2003 by CRC Press LLC

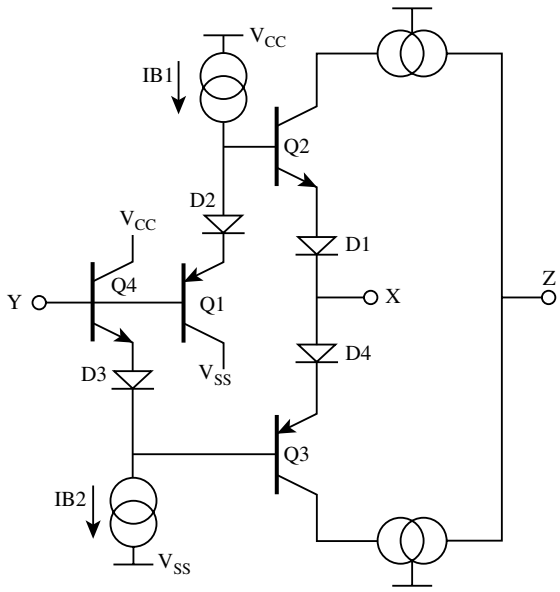

FIGURE 57.31 CCII with input matching diodes.

Since the value of R_x is determined by the small-signal resistance $(r_{e2} + r_{d2})$ in parallel with $(r_{e3} + r_{d3})$, its value could be reduced by increasing the value of the quiescent bias current I_B. However, an increase in bias current will lead to an increase in the total power consumption, as well as a possible increase in offsets, and so is certainly not an ideal solution. Further techniques for CCII implementation are discussed in [14].

The previous conveyor is typical of commercial conveyor architectures [7], which are generally built on a high-speed dielectric isolation (fully complementary) bipolar process. Such devices feature an equivalent slew rate of some 2000 V/μs and a bandwidth of around 100 MHz.

Until high-performance current conveyors are widely available, these devices will continue to be used in research laboratories rather than in the applications arena. Process technologies and design techniques have now advanced to the stage where the implementation of an integrated current conveyor is both desirable and viable, and a whole host of applications are waiting for its arrival.

Current-Feedback Operations Amplifier

In this section, the design and development of a high-gain wide-bandwidth transimpedance or current-feedback operational amplifier is considered. The design of conventional operational amplifiers has remained relatively unchanged since the introduction of the commercial operational amplifier in 1965. Recently, a new amplifier architecture, called a current-feedback operational amplifier, has been introduced. This amplifier architecture is basically a transimpedance amplifier, or a current-controlled voltage source, while the classical voltage-feedback operational amplifier is a voltage-controlled voltage source.

The current-feedback operational amplifier has two major advantages, compared to its voltage-feedback counterpart. First, the closed-loop bandwidth of the current-feedback amplifier is larger than that of classical voltage-feedback design for comparable open-loop voltage gain. Second, the current-feedback operational amplifier is able to provide a constant closed-loop bandwidth for closed-loop voltage gains up to about 10. A further advantage of the current-feedback architecture is an almost unlimited slew rate due to the class-*AB* input drive, which does not limit the amount of current available to charge up the compensation capacitor as is the case in the conventional voltage-feedback op-amp. This high-speed performance of the current-feedback operational amplifier is extremely useful for analog signal processing applications within video and telecommunication systems.

The generic relationship between the CCII+ and the current-feedback op-amp is extremely close and several of the features offered by the CCII are also present in the current-feedback op-amp. The basic

© 2003 by CRC Press LLC

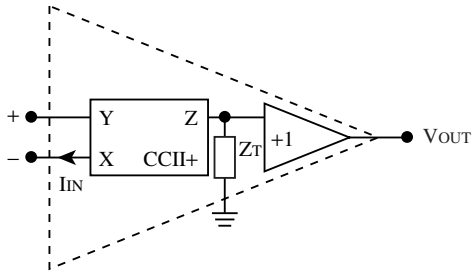

FIGURE 57.32 Current-feedback op-amp structure.

structure of the current-feedback op-amp is essentially that of a CCII+ with the Z node connected directly to an output voltage follower, as shown in Fig. 57.32. Any current flowing into the low impedance inverting input is conveyed to the gain node (Z_T), and the resulting voltage is buffered to the output. Z_T is thus the open-loop transimpedance gain of the current-feedback op-amp, which in practice is equal to the parallel combination of the CCII+ output impedance, the voltage buffer input impedance and any additional compensation capacitance at the gain node. Generally, in current-feedback op-amps, the gain node is not connected to an external pin, and so the Z node of the CCII+ cannot be accessed.

Current-Feedback Op-Amp Architecture. In the following sections we review the basic theory and design of the current-feedback op-amp and will identify the important features and mechanisms that result in broadband performance. We will begin by reviewing the voltage-feedback op-amp and comparing it with the current-feedback op-amp in order to see the differences clearly.

A schematic of the classical voltage-feedback op-amp comprising a long-tail pair input stage is shown in Fig. 57.33(a), which contrasts a typical current-feedback architecture, which is shown in Fig. 57.33(b). In both circuits, current mirrors are represented by two interlocking circles with an arrow denoting the input side of the mirror.

The current-feedback op-amp of Fig. 57.33(b) shows that the noninverting input is a high-impedance input that is buffered to a low-impedance inverting terminal via a class *AB* complementary common-collector stage (Q_1, Q_2, D_1, D_2). Note that this classical input buffer architecture is used here for simplicity. In practice a higher performance topology such as that described in Fig. 57.31 would more likely be employed. The noninverting input is a voltage input; this voltage is then buffered to the inverting low-impedance current input to which feedback is applied. In contrast, both the noninverting and inverting input of the voltage-feedback op-amp are high-impedance voltage inputs at the bases of transistors Q_1 and Q_2.

In both architectures, the collector currents of Q_1 and Q_2 are transferred by the current mirror to a high-impedance node represented by resistance R_Z and capacitance C_Z. This voltage is then transferred to the output by voltage buffers that have a voltage gain A_{vb}, providing the necessary low output impedance for current driving. In the case of the current-feedback op-amp, the output buffer is usually the same topology as the input buffer stage shown in the Fig. 57.33(b), but with slightly higher output current bias levels and larger output devices to provide an adequate output drive capability. Ideally, the bias current I_{CQ1} and I_{CQ2} will be canceled at the gain node giving zero offset current.

Differential-Mode Operation of the Current-Feedback Op-Amp. A schematic diagram of the current-feedback op-amp with a differential input voltage applied at the noninverting and inverting input is shown in Fig. 57.34.

The positive input voltage is applied to the base of transistor Q_1 (NPN) via D_1, and the negative input voltage is applied to the emitter of Q_1, causing the V_{BE} of Q_1 to increase and the V_{BE} of Q_2 to reduce. I_{C1} will therefore increase by an amount ΔI and so I_{C2} will decrease by the same amount $-\Delta I$. A net current of $2\Delta I$ is therefore sourced out of the high-impedance node (Z) giving rise to a positive voltage ($2\Delta IZ$). This voltage is then buffered to the output.

© 2003 by CRC Press LLC

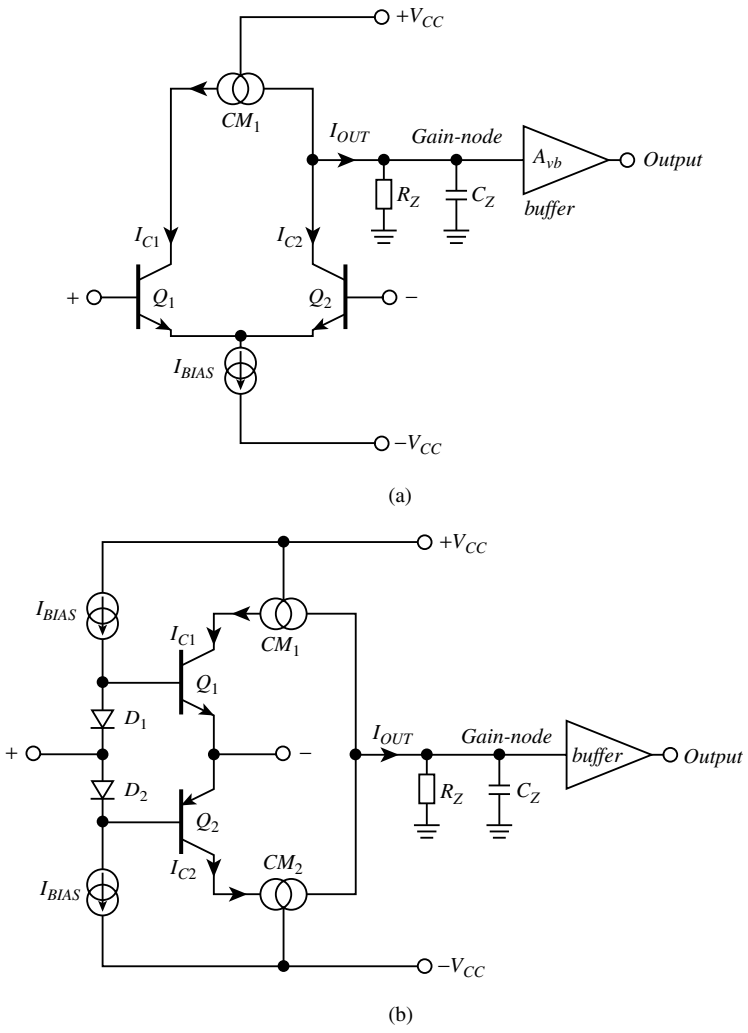

FIGURE 57.33 (a) Simplified classic voltage-feedback op-amp architecture. (b) Typical current-feedback op-amp architecture.

With negative feedback applied around the current-feedback op-amp, the low-impedance inverting input will sense the current "feedback" from the output via the feedback network. This feedback current flowing into the inverting input is given by

$$i_{\text{in}-} = I_{C2} - I_{C1} \tag{57.31}$$

The difference between the collector current I_{C1} and I_{C2}, $i_{\text{in}-}$, will thus be driven into gain node Z, giving rise to the output voltage

$$V_{\text{out}} = Zi_{\text{in}-} \tag{57.32}$$

It is clear that the output voltage is dependent on the current that flows into the inverting input, hence the amplifier has a high open-loop transimpedance gain Z.

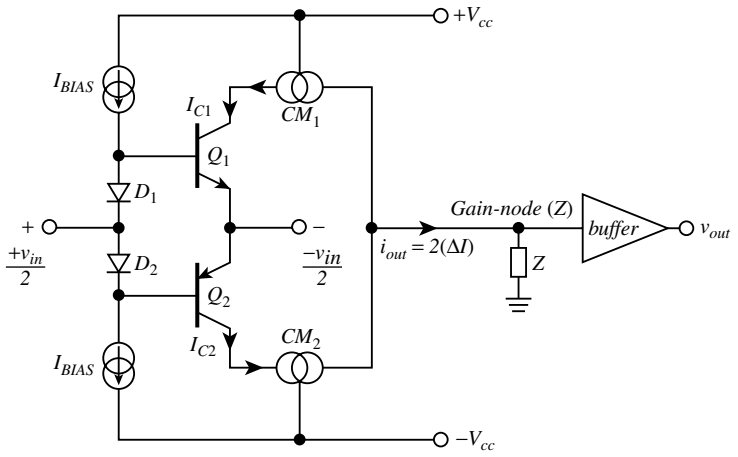

FIGURE 57.34 Current-feedback op-amp with differential input voltage applied.

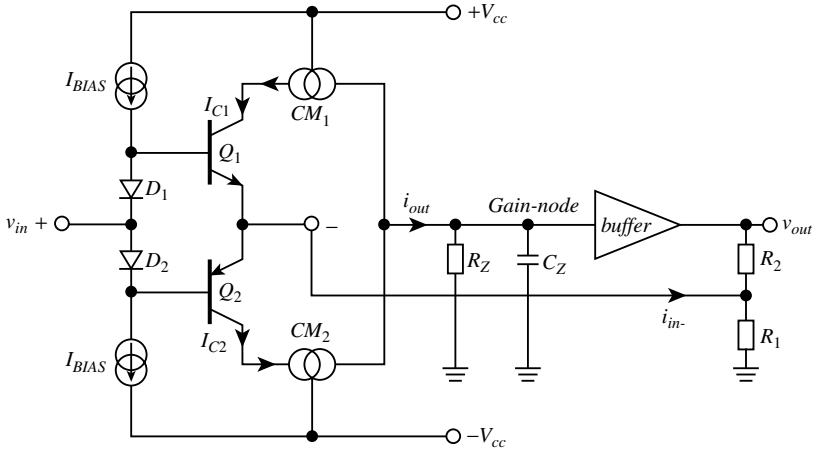

FIGURE 57.35 Noninverting current-feedback op-amp.

Closed-Loop Noninverting Operation of the Current-Feedback Op-Amp. A schematic diagram of the current-feedback op-amp connected with negative feedback as a noninverting amplifier is shown in Fig. 57.35. For a positive input voltage v_{in}, the output voltage v_{out} will swing in the positive direction and the inverting input current i_{in-} will flow out:

$$i_{in-} = \frac{v_{in-}}{R_1} - \frac{\left(v_{out} - v_{in-}\right)}{R_2} \tag{57.33}$$

The input stage is simply a voltage follower and so ideally, $v_{in+} = v_{in-} = v_{in}$. Because $v_{out} = Zi_{in-}$, then substituting for v_{in-} and i_{in-} in (57.33) yields

$$\frac{v_{out}}{Z} = \frac{v_{in}}{R_1} - \frac{\left(v_{out} - v_{in}\right)}{R_2} \tag{57.34}$$

© 2003 by CRC Press LLC

rearranging for v_{out}/v_{in}

$$v_{out}\left(\frac{1}{R_2}+\frac{1}{Z}\right)=v_{in}\left(\frac{1}{R_1}+\frac{1}{R_2}\right) \tag{57.35}$$

$$\frac{v_{out}}{v_{in}}=\left(1+\frac{R_2}{R_1}\right)\left(\frac{1}{1+\frac{R_2}{Z}}\right) \tag{57.36}$$

This result shows that the closed-loop noninverting gain of the current-feedback op-amp is similar to that of a classical voltage-feedback op-amp. From (57.36), the open-loop transimpedance gain Z must be as large as possible to give good closed-loop gain accuracy. Since v_{out}/Z represents the error current i_{in-} then maximizing the Z term will minimize the inverting error current. Note that at this stage it is only the R_2 term in the denominator of the second term in (57.36) that sets the bandwidth of the amplifier; the gain-setting resistor R_1 has no effect on the closed-loop bandwidth.

Closed-Loop Inverting Operation of Current-Feedback Op-Amp. A current-feedback op-amp connected as an inverting amplifier is shown in Fig. 57.36. The low-impedance inverting input samples the input current and drives the output until the voltage at its terminal is at a virtual ground because of negative feedback. Ideally the closed-loop gain is given by

$$A_{CL}=-\frac{R_2}{R_1} \tag{57.37}$$

From Fig. 57.36, application of Kirchhoff's current law to the current i_1, i_{in-}, and i_2 gives

$$i_{in-}+i_2 = i_1$$

$$i_{in-}-\frac{v_{out}}{R_2} = \frac{v_{in}}{R_1}$$

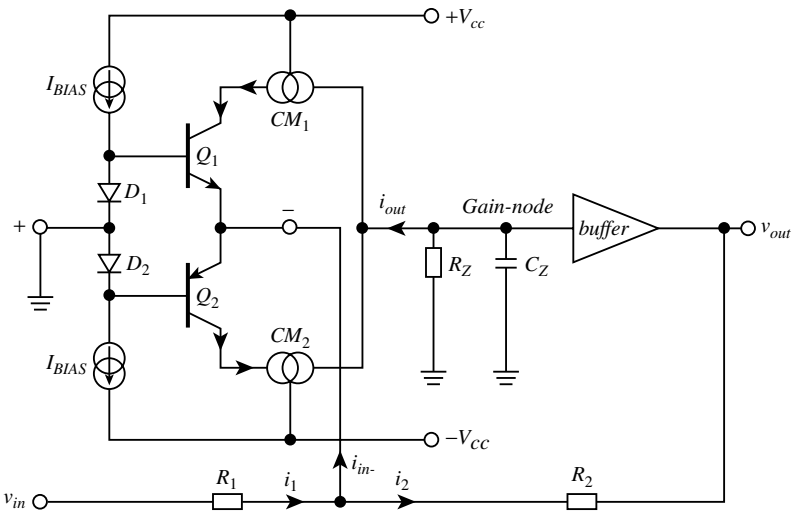

FIGURE 57.36 Inverting current-feedback op-amp amplifier.

© 2003 by CRC Press LLC

because $v_{out}/Z = -i_{in-}$, then

$$-\frac{v_{out}}{Z} - \frac{v_{out}}{R_2} = \frac{v_{in}}{R_1}$$

which can be rearranged as

$$\frac{v_{out}}{v_{in}} = -\frac{R_2}{R_1}\left(\frac{1}{1+\dfrac{R_2}{Z}}\right) \tag{57.38}$$

Again, the high-Z term is required to provide good closed-loop gain accuracy.

More Detailed Analysis of the Current-Feedback Op-Amp. A simplified macromodel of the current-feedback architecture configured as a noninverting amplifier is shown in Fig. 57.37. The input stage is represented by a semi-ideal voltage buffer to the inverting input. The output resistance of the input stage buffer R_{inv} is included since it has a significant effect on the bandwidth of the amplifier, as will be shown later. The current that flows out from the inverting terminal i_3 is transferred to the gain node, which is represented by R_Z and C_Z, via a current mirror that has a current gain K. The voltage at the gain node is transferred to the output in the usual way by a voltage buffer, with voltage gain A_{vb}. The net transfer function is given by

$$\frac{v_{out}}{v_{in}} = \frac{1+\dfrac{R_2}{R_1}}{1+j\omega C_Z\left[\dfrac{R_{inv}\left(1+\dfrac{R_2}{R_1}\right)+R_2}{A_{vb}K}\right]} \tag{57.39}$$

Hence, the pole frequency is also given by

$$f_{-3dB} = \frac{A_{vb}K}{2\pi C_Z\left[R_{inv}\left(1+\dfrac{R_2}{R_1}\right)+R_2\right]} \tag{57.40}$$

(A full derivation of this transfer function is given in Appendix A.)

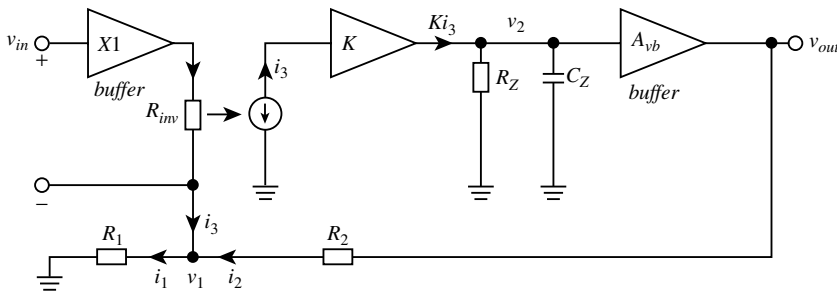

FIGURE 57.37 Inverting amplifier with current-feedback op-amp macromodel.

© 2003 by CRC Press LLC

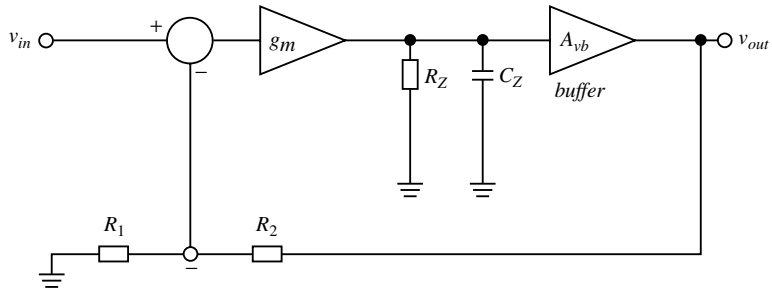

FIGURE 57.38 Noninverting amplifier with voltage-feedback op-amp macromodel.

To compare this result to the classical voltage-mode op-amp architecture, a simplified schematic diagram of the voltage-feedback op-amp configured as a noninverting amplifier is shown in Fig. 57.38.

Again from a full analysis, given in Appendix B, the transfer function obtained is

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1+\dfrac{R_2}{R_1}}{1+j\omega\left[\dfrac{R_z C_Z}{1+\dfrac{g_m A_{vb} R_Z}{\left(1+\dfrac{R_2}{R_1}\right)}}\right]} \tag{57.41}$$

The pole frequency is given by

$$f_{-3\text{dB}} = \frac{1+\dfrac{g_m A_{vb} R_Z}{\left(1+\dfrac{R_2}{R_1}\right)}}{2\pi R_Z C_Z} \tag{57.42}$$

Pole Frequency Comparison. If one compares the closed-loop pole frequency Eqs. (57.40) and (57.42) for the current-feedback and voltage-feedback op-amp, respectively, it is clear that the bandwidth of the voltage-feedback op-amp is dependent on the closed-loop gain $(1 + R_2/R_1)$ resulting in the well-known constant gain-bandwidth product $f_{\text{MAX}} = (A_v)_{CL} f_T$. This means that an increase in the closed-loop gain results in a decrease in the bandwidth by the same factor as illustrated in Fig. 57.39. In contrast, the pole frequency of the current-feedback op-amp is directly dependent on R_2 and can be set almost independently of the closed-loop gain. Thus, the closed-loop bandwidth is almost independent of closed-loop gain as shown in Fig. 57.40, assuming that R_{inv} is close to zero. Intuitively, this is the case since the feedback error current that is set by the feedback resistor R_2 is the current available to charge up the compensation capacitor. However, if one considers (57.40) in some detail it can be seen that for high closed-loop gains and a nonzero R_{inv}, then the R_{inv} term starts to dictate and so the bandwidth will become more dependent on the closed-loop gain.

Slow Rate of the Current-Feedback Op-Amp. As mentioned earlier, one other advantage of the current-feedback op-amp over the classical voltage-feedback op-amp is the high slew rate performance. For the classical long-tail, or emitter-coupled pair input stage shown in Fig. 57.41, the maximum current available to charge up the compensation capacitor C_Z at the gain node is I_{BIAS}, and this occurs when Q_1 or Q_2 is driven fully on. The resulting transconductance plot shown in Fig. 57.42 limits the slew rate of the amplifier.

© 2003 by CRC Press LLC

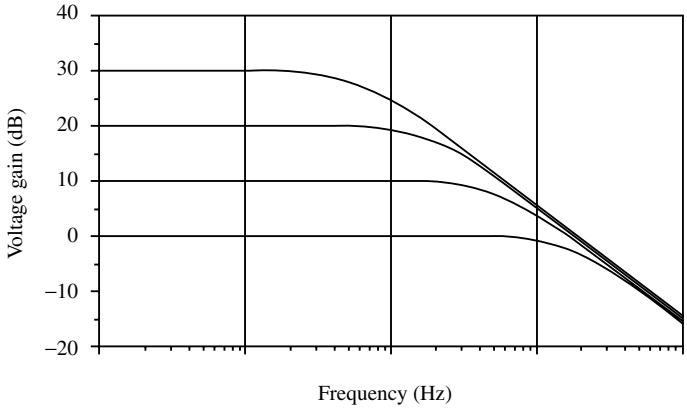

FIGURE 57.39 Frequency response of voltage-feedback op-amp amplifier for various closed-loop gains.

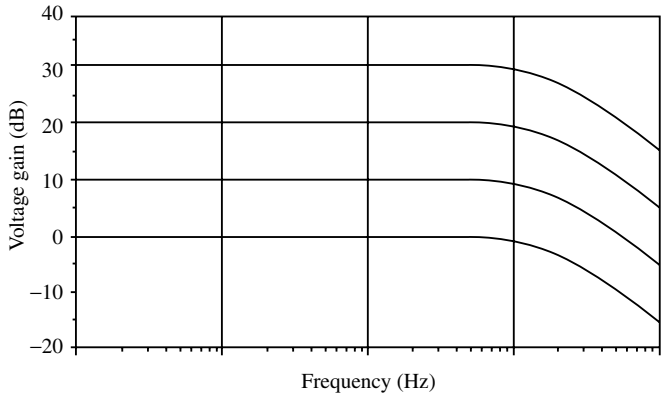

FIGURE 57.40 Frequency response of current-feedback op-amp amplifier for various closed-loop gains.

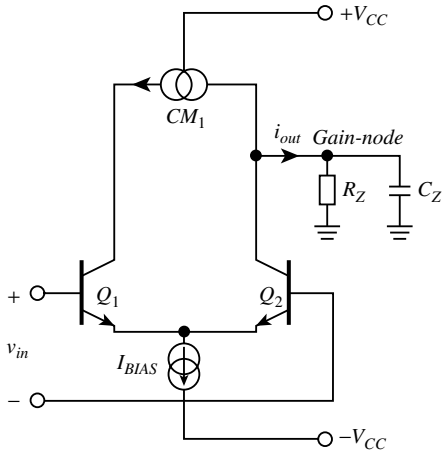

FIGURE 57.41 Long-tail pair input stage.

In contrast, the slew rate of the current-feedback op-amp is virtually infinite, as can be seen from the input stage schematic shown in Fig. 57.43. Referring to Fig. 57.43, a change in the input voltage ΔV_{in} at $V(+)$ will be copied by the input buffer to $V(-)$. When connected as noninverting amplifier, the current

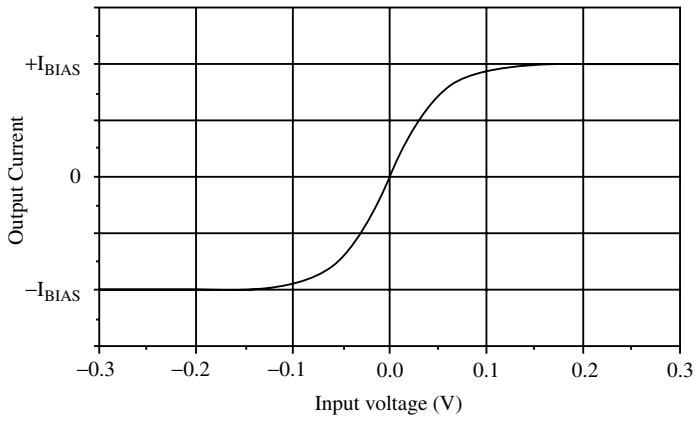

FIGURE 57.42 Long-tail pair input transconductance.

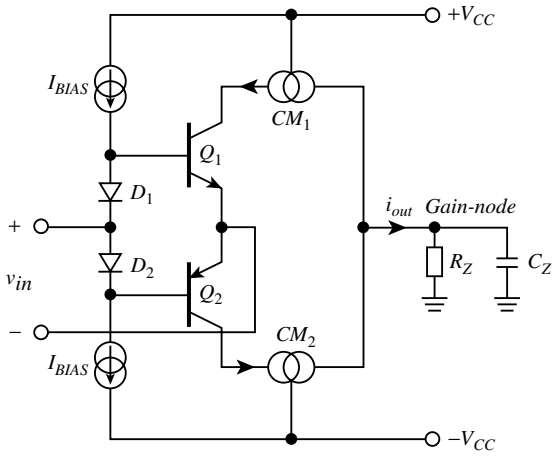

FIGURE 57.43 Current-feedback op-amp input stage.

through R_1 will change by $\Delta V_{in}/R_1$, while the current through R_2 will change by $\Delta V_{in}/R_2$, since the output voltage at this point remains stationary. The total change in current through R_1 and R_2 must be supplied by the internal input buffer, and will be $\Delta I(-) = \Delta V_{in}((R_2 + R_1)/(R_2 \cdot R_1))$. This large input error current causes a rapid change in the output voltage, until V_{out} is again at the value required to balance the circuit once more, and reduce $I(-)$ to zero. The larger the input voltage slew rate, the larger the change in input error current, and thus the faster the output voltage slew rate. Current-feedback op-amps theoretically have no slew-rate limit. A typical current-feedback op-amp will exhibit a slew rate of between 500 and 2000 V/μS.

An analysis of this input stage (see Appendix C) shows that the transconductance follows a $\sinh(x)$ type function, as shown in Fig. 57.44. In theory, this characteristic provides nearly unlimited slew-rate capability [9]. However, in practice a maximum slew rate will be limited by the maximum current drive into the gain node, which depends on the power dissipation of the circuit, the ability of power supply to deliver sufficient current, and the current-handling capability of the current mirrors.

Wideband and High-Gain Current-Feedback Op-Amp. Previously, we have shown that the bandwidth of the current-feedback op-amp is almost independent of the closed-loop gain setting. Therefore, the closed-loop gain-bandwidth *GB* increases linearly with the closed-loop gain. However, the bandwidth of the practical current-feedback op-amp starts decreasing with high gain as a result of the finite inverting-input

© 2003 by CRC Press LLC

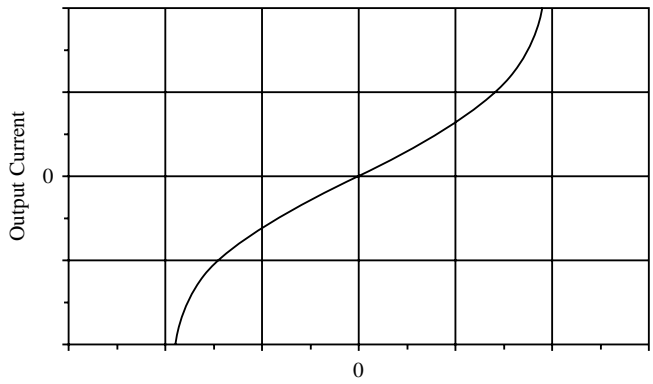

FIGURE 57.44 Input-stage transconductance of the current-feedback op-amp.

impedance [10], as shown by (57.40). This is because for high gain, $R_{inv}(1 + R_2/R_1) > R_2$, and so the $R_{inv}(1 + R_2/R_1)$ term dominates the expression for closed-loop bandwidth, resulting in a direct conflict between gain and bandwidth.

At low gains when $R_2 > R_{inv}(1 + R_2/R_1)$, the closed-loop pole frequency is determined only by the compensation capacitor and the feedback resistor R_2. Thus, the absolute value of the feedback resistor R_2 is important, unlike the case of the voltage-feedback op-amp. Usually, the manufacturer species a minimum value of R_2 that will maximize bandwidth but still ensure stability. Note that because of the inherent architecture a very high bandwidth can be achieved with the current-feedback design for a given value of R_2.

In practice, for gains higher than about 10, the $R_{inv}(1 + R_2/R_1)$ term in (57.40) becomes dominant and the amplifier moves toward constant gain–bandwidth product behavior. The *GB* can be increased by reducing R_2 [11] but this will compromise stability and/or bandwidth, or alternatively, C_Z can be reduced. The latter option is limited since the minimum value of C_Z is determined by the device parameters and layout parasitics. Two possible ways of improving the high-gain constant bandwidth capability of the current-feedback op-amp can be seen by inspection of (57.40). Either the *K* factor, which represents current gain in the current mirrors at the *Z*-node can be increased from unity to increase the bandwidth as it rolls off with high gain, or the inverting input impedance of the amplifier should be reduced toward zero. In the following section we consider the design of a suitable broadband variable-gain current-mirror circuit with a possible application being to improving the maximum bandwidth capability of current-feedback op-amps.

Basic Current Mirror. A typical current-feedback op-amp circuit is shown in Fig. 57.45. It includes a complementary common-collector input stage (Q_1–Q_4) and a similar output buffer (Q_5–Q_8), with linking cascode current mirrors setting the *Z*-node impedance (Q_{12}–Q_{14}, Q_9–Q_{11}). The cascoded mirror provides unity current gain. Any attempt to increase the current gain via emitter degeneration usually results in much poorer current-mirror bandwidth. Consider now the development of a suitable broadband, variable gain current mirror.

A schematic diagram of a simple Widlar current mirror and its small-signal equivalent circuit are shown in Figs. 57.46 and 57.47, respectively. For simplicity, we will assume that the impedance of the diode-connected transistor Q_1 is resistive and equal to R_D. The dc transfer function of the mirror is derived in Appendix D and is given by

$$\frac{I_{out}}{I_{in}} = \frac{\beta}{\beta + 2} \tag{57.43}$$

and the –3-dB bandwidth is given by

© 2003 by CRC Press LLC

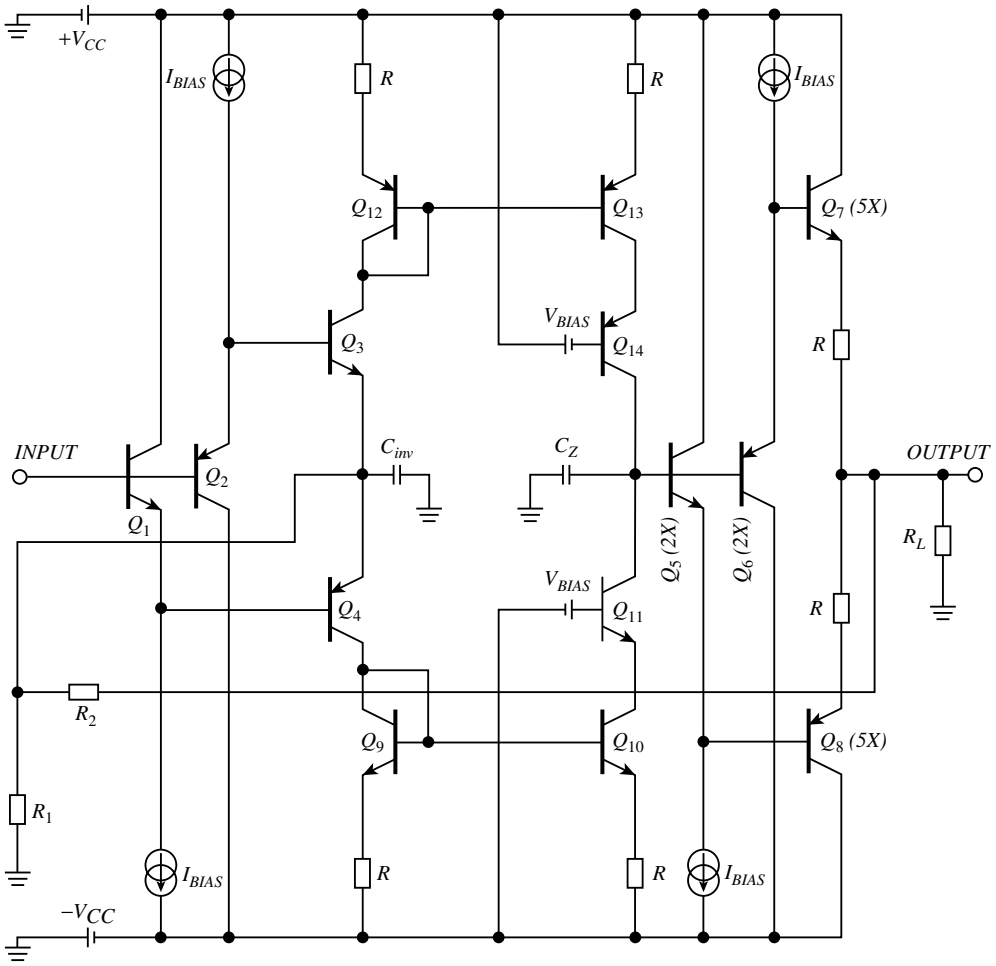

FIGURE 57.45 Transistor-level schematic of a typical current-feedback op-amp. x = unit transistor area.

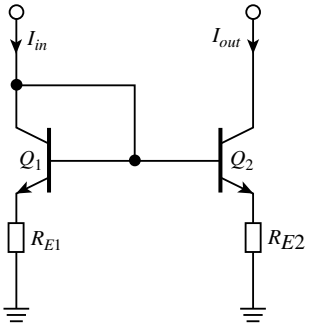

FIGURE 57.46 Simple Widlar current mirror with emitter degeneration.

$$f_{-3\text{dB}} = \frac{1}{2\pi C_{\pi}\left\{\dfrac{r_{\pi 2}\left(r_{bb2}+R_D\right)}{r\pi + r_{bb2}+R_D}\right\}} \tag{57.44}$$

In order to increase the current gain it is usual to insert an emitter-degeneration resistor R_{E1} in the emitter of Q_1. The dc transfer function, derived in the Appendix E, is then

© 2003 by CRC Press LLC

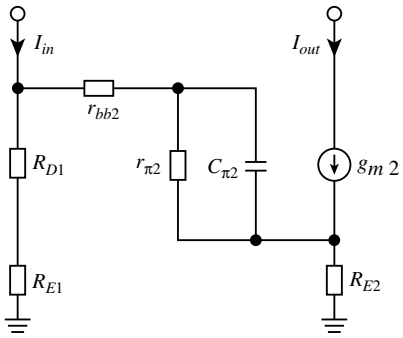

FIGURE 57.47 Small-signal equivalent circuit of Fig. 57.46 current mirror.

$$I_{\text{in}}R_{E1} = V_T \ln\frac{I_{\text{out}}}{I_{\text{in}}} \tag{57.45}$$

and the ac small-signal current gain is given by

$$\frac{i_{\text{out}}}{i_{\text{in}}} = \left(R_{E1} + R_{D1}\right)g_{m2} \tag{57.46}$$

where

$$R_{D1} = \frac{I_{\text{in}}}{\dfrac{KT}{q}} \tag{57.47}$$

The –3-dB bandwidth now becomes

$$f_{-3\text{dB}} = \frac{1}{2\pi C_{\pi 2}\left\{\dfrac{r_{\pi 2}\left(r_{bb2} + R_{D1} + R_{E1}\right)}{r_{\pi 2} + r_{bb2} + R_{D1} + R_{E1}}\right\}} \tag{57.48}$$

It can be seen that increasing R_{E1} to increase the gain results in a reduction in the mirror bandwidth. The method of increasing the area of Q_2 to increase the current gain is not advantageous because the capacitance $C_{\pi 2}$ increases simultaneously, and so again, the bandwidth performance is compromised. We can conclude that this approach, though apparently well founded, is flawed in practice.

Improved Broadband Current Mirror. A current mirror with current gain is shown in Fig. 57.48 and the small-signal equivalent circuit is shown in Fig. 57.49. In this current mirror Q_1 and Q_2 are connected as diodes in series with R_{E1}. Q_3 is connected as a voltage buffer with the bias current source I_{EQ3}. Q_4 is the output transistor with degeneration resistor R_{E4} for current gain setting. The basic idea is to introduce the common collector Q_3 to buffer the output from the input and hence isolate gain setting resistor R_{E4} from the bandwidth determining capacitance of the input. The dc transfer function is given by

$$I_{\text{in}}R_{E1} - I_{\text{out}}R_{E4} + V_T \ln\frac{I_{\text{in}}^2}{I_{CQ3}I_{\text{out}}} = 0 \tag{57.49}$$

and the ac small-signal current gain is given by

$$\frac{i_{\text{out}}}{i_{\text{in}}} = \frac{\left(R_{E1} + R_{D1} + R_{D2}\right)g_{m4}}{1 + g_{m4}R_{E4}} \tag{57.50}$$

© 2003 by CRC Press LLC

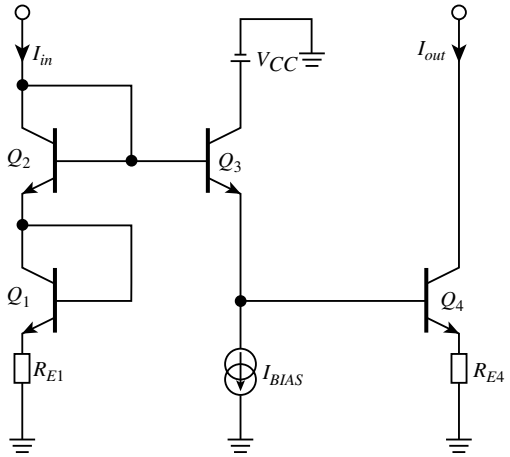

FIGURE 57.48 Improved current mirror with current gain.

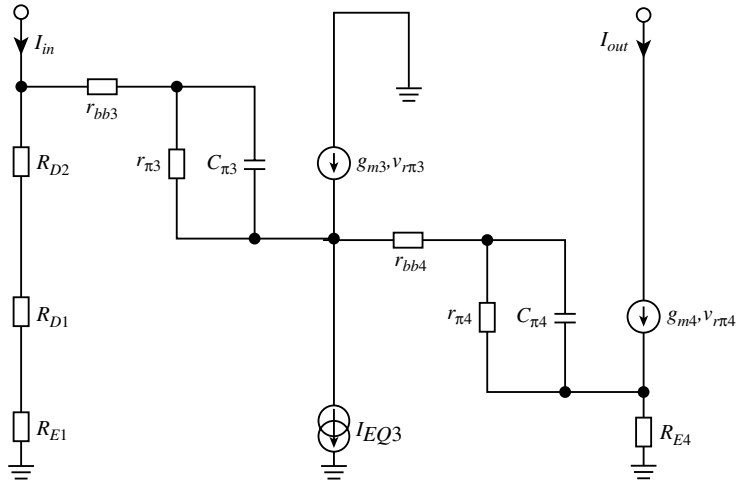

FIGURE 57.49 Equivalent circuit of improved current mirror with current gain.

and the –3-dB bandwidth now becomes

$$f_{-3\text{dB}} = \frac{1}{2\pi C_{\pi 4}\left(\dfrac{r_{\pi 4}R_x}{r_{\pi 4}+R_x}\right)} \tag{57.51}$$

where

$$R_x = r_{bb4} + \frac{r_{\pi 3} + r_{bb3} + R_{D1} + R_{D2} + R_{E1}}{\beta_3} \tag{57.52}$$

It can be seen clearly that the dominant pole (57.51) of the current mirror with current gain is now only slightly decreased when we increase the current gain by increasing R_{E1}. However, the nondominant pole at the input node is increased, and this will marginally effect the resultant overall stability performance if employed in a current-feedback op-amp. This current mirror with current gain has been employed successfully in current-feedback op-amp design for increased gain-bandwidth capability [12].

Phase Linearity. The internal signal path in a current-feedback op-amp is very linear due largely to the symmetrical architecture. Consequently, these devices have a very linear phase response. Furthermore, all the frequency components of a signal are delayed by the same amount when passing through the amplifier, and so the waveform is reproduced accurately at the output. Current-feedback op-amps typically exhibit differential phase error of around ±1° at frequencies of approximately half the bandwidth.

Choosing the Value of R_2. From (57.40), we can see that for a fixed value of C_z, a smaller feedback resistor R_2 will give a higher closed-loop bandwidth. It might be expected that the maximum bandwidth would be obtained with the minimum feedback resistance; that is, with $R_2 = 0$. In practice, current-feedback op-amps are generally unstable when their feedback resistance is reduced below a particular value. The reason for this is that the dominant closed-loop pole at frequency of $f \approx 1/2\pi C_z R_2$ must be significantly lower than any nondominant parasitic pole frequency within the op-amp, so that a reasonable gain and phase margin is maintained. If the value of R_2 is reduced, then this dominant pole will move upward in frequency toward the parasitic poles, reducing the gain and phase margin, and eventually leading to instability. Obviously, the "correct" value for R_2 will depend on the internal value of C_z and the location of any parasitic poles within the device. These are the sort of parameters that are known to the manufacturer, but are generally not listed in a data sheet. Therefore, the manufacturer of a particular device will generally recommend a value of R_2 that guarantees stability, while maintaining a reasonably wide bandwidth. Reducing R_2 below this recommended or optimum value will tend to lead to peaking and instability, while increasing R_2 above the optimum value will reduce the closed-loop bandwidth. If band limiting is required, then a larger value of R_2 than the optimum can be chosen to limit the bandwidth as required.

Since a current-feedback op-amp requires a minimum value of R_2 to guarantee stability, these devices cannot be used with purely capacitive feedback because the reactance of a capacitor reduces at high frequencies. This means that the conventional voltage op-amp integrator cannot be implemented using a current-feedback op-amp.

Practical Considerations for Broadband Designs.

1. *Ground Planes.* The purpose of a ground plane is to provide a low impedance path for currents flowing to ground, since any series impedance in the ground connections will mean that not all ground nodes are at the same potential. In addition, the inductance of a printed circuit track is approximately inversely proportional to the track width, and so the use of thin tracks can result in inductive ground loops, leading to ringing or even oscillations. The use of an unbroken ground plane on one side of the circuit board can minimize the likelihood of inductive loops within the circuit. However, any particularly sensitive ground-connected nodes in the circuit should be grounded as physically close together as is possible.
2. *Bypass Capacitors.* Power supply lines often have significant parasitic inductance and resistance. Large transient load currents can therefore result in voltage spikes on the power supply lines, which can couple onto the signal path within the device. Bypass capacitors are therefore used to lower the impedance of the power supply lines at the point of load, and thus short out the effect of the supply line parasitics. The type of bypass capacitor to use is determined by the application and frequency range of interest. High-speed op-amps work best when their power supply pins are decoupled with radio-frequency-quality capacitors.

   Manufacturers often recommend using a composite large-small parallel bypass capacitor with something like a 4.7-uF tantalum capacitor on all supply pins, with a parallel 100-nF ceramic to ensure good capacitive integrity at higher frequencies, where the tantalum becomes inductive. However, a note of caution here: This large-small double capacitor technique relies on the large capacitor having sufficiently high ESR so that at resonance the two capacitors do not create a high-Q parallel filter. In surface-mount designs a single bypass capacitor may well be better than two due to the inherent high-Q of surface-mount capacitors.

© 2003 by CRC Press LLC

All bypass capacitor connections should be minimized, since track lengths will simply-add more series inductance and resistance to the bypass path. The capacitor should be positioned right next to the power supply pin, with the other lead connected directly to the ground plane.

3. *Sensitive Nodes.* Certain nodes within a high-frequency circuit are often sensitive to parasitic components. A current-feedback op-amp, for example, is particularly sensitive to parasitic capacitance at the inverting input, since any capacitance at this point combines with the effective resistance at that node to form a second nondominant pole in the feedback loop. The net result of this additional pole is a reduced phase margin, leading to peaking and even instability. Clearly, great care must be taken during layout to reduce track lengths, etc., at this node. In addition, the stray capacitance to ground at $V(-)$ can be reduced by putting a void area in the ground plane at this point. If the op-amp is used as an inverting amplifier, then the potential of the inverting input is held at virtual ground, and any parasitic capacitance will have less effect. Consequently, the current-feedback op-amp is more stable when used in the inverting rather than the noninverting configuration.
4. *Unwanted Oscillations.* Following the preceding guidelines should ensure that your circuit is well behaved. If oscillations still occur, a likely source is unintentional positive feedback due to poor layout. Output signal paths and other tracks should be kept well away from the amplifier inputs to minimize signal coupling back into the amplifier. Input track lengths should also be kept as short as possible for this same reason.

Broadband Amplifier Stability

Operational amplifiers are generally designed with additional on-chip frequency compensation capacitance in place. This is doe to present the applications engineer with an op-amp that is simple to use in negative feedback, with minimal chance of unstable operation. In theory, all will be well, but for three main reasons, op-amps become unstable in the real world of analog electronic circuit design. This section outlines the three main causes for unstable operation of broadband amplifiers and shows practical ways of avoiding these pitfalls.

Op-Amp Internal Compensation Strategy

Before dealing with specific stability problems in broadband amplifiers and how to solve them, we will look briefly at the internal frequency compensation strategy used in op-amp design. Generally, op-amps can be classified into two groups, those with two high-voltage gain stages and those with only one stage. The two-stage design provides high open-loop gain but relatively low bandwidth, while the higher speed signal-stage amplifier provides lower open-loop gain but much higher usable bandwidth. Insight into the internal op-amp architecture and the type of compensation used will give the designer valuable information on how to tame the unstable op-amp.

Review of the Classical Feedback System

Analyzing the classical feedback system in Fig. 57.50 gives the well-known expression for the closed-loop gain, A_c:

$$A_c = A/\left[1 + B \cdot A\right] \tag{57.53}$$

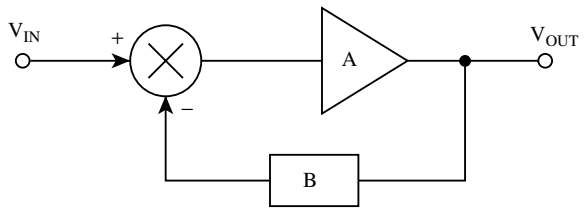

FIGURE 57.50 Classical feedback system.

© 2003 by CRC Press LLC

where A is the open-loop gain of the amplifier and B the feedback fraction. $T = B \cdot A$ is referred to as the loop-gain, and the behavior of T over frequency is a key parameter in feedback system design. Clearly, if $T \gg 1$ or $A \gg A_c$, then the closed-loop gain is virtually independent of the open-loop gain A, thus

$$A_c \approx B^{-1} \tag{57.54}$$

This is the most important and desirable feature of negative feedback systems. However, the system will not necessarily be stable since, at higher frequencies, phase lag in the open-loop gain A may cause the feedback to become positive.

Stability Criteria

Though negative feedback is desirable, it results in potential instability when the feedback becomes positive. The loop-gain T is the best parameter to test whether an amplifier is potentially unstable. The phase margin Φ_M is a common feature of merit used to indicate how far the amplifier is from becoming an oscillator:

$$\Phi_M = 180° + \Phi\left(|BA| = 1\right) \tag{57.55}$$

When $\Phi_M = 0°$, the phase of the loop gain, $T = B \cdot A$ is exactly –180° for $|B \cdot A| = 1$. The closed-loop gain A_c will become infinite and we have got an oscillator! Clearly, what is required is that $\Phi_M > 0$ and generally the target is to make $\Phi_M \geq 45°$ for reasonably stable performance. However, excessive Φ_M is undesirable if settling time is an important parameter in a particular application.

An op-amp is a general purpose part and so the IC designer strives to produce a maximally versatile amplifier by ensuring that even with 100 percent feedback, the amplifier circuit will not become unstable. This is done by maintaining a $\Phi_M > 0$ for 100 percent feedback, that is, when $B = 1$. If the feedback network B is taken to be purely resistive, then any additional phase lag in the loop gain must come from the open-loop amplifier A. Tailoring the phase response of A so that the phase lag is less than 180° up to the point at which $|A| < 1$ or 0 dB, ensures that the amplifier is "unconditionally stable"; that is, with any amount of resistive feedback, stable operation is "guaranteed."

Most open-loop op-amps, whether single-stage or two-stage, will exhibit a two-pole response. The separation of these two poles whether at low frequency or high frequency will have a major effect on the stability of the system and it is the op-amp designer's objective to locate these open-loop poles to best advantage to achieve maximum bandwidth, consistent with versatile and stable performance.

Two-Stage Op-Amp Architecture

A schematic of the standard two-stage op-amp topology is shown in Fig. 57.51. The input differential pair T_1/T_2 provides high gain, as does the second gain stage of T_3/T_4 Darlington pair common emitter.

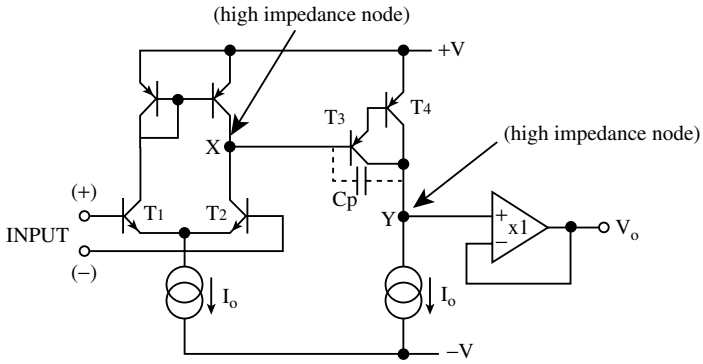

FIGURE 57.51 Architecture of the standard two-stage op-amp.

© 2003 by CRC Press LLC

A high-voltage gain is achieved with this structure, so that output stage is usually a unity voltage gain common-collector output buffer to provide a useful load current drive capability.

The amplifier structure in Fig. 57.51 has two internal high-impedance nodes, node *X* and node *Y*. These high impedance nodes are responsible for introducing two dominant poles into the frequency response and their relative location is critical in determining the stability of the amplifier. Each pole contributes a low-pass filter function to the open-loop gain expression of the form

$$\left[1 + jf / f_P\right]^{-1} \tag{57.56}$$

Each pole introduces 45° of phase lag at the pole frequency f_P and an additional 45° at $f \approx 10 \cdot f_P$. With a two-pole amplifier the open-loop gain A is given by

$$A = A_0 / \left[1 + jf / f_{P1}\right]\left[1 + jf / f_{P2}\right] \tag{57.57}$$

where A_0 is the dc open-loop gain and f_{P1} and f_{P2} are the two-pole frequencies. A typical plot of A versus f is shown in Fig. 57.52(a). At low frequencies, where $f \ll f_{P1}$ the gain is flat, and at f_{P1} the gain begins to fall at a rate increasing to –20 dB/decade. The roll-off steepens again at f_{P2} to a final gradient of –40 dB/decade.

It is generally the case that $f_{P1} \ll f_{P2}$ as shown in Fig. 57.52(a). Turning our attention to the phase plot in Fig. 57.52(a), at $f = f_{P1}$ the output lags the input by 45°, and as the frequency rises toward f_{P2} the phase

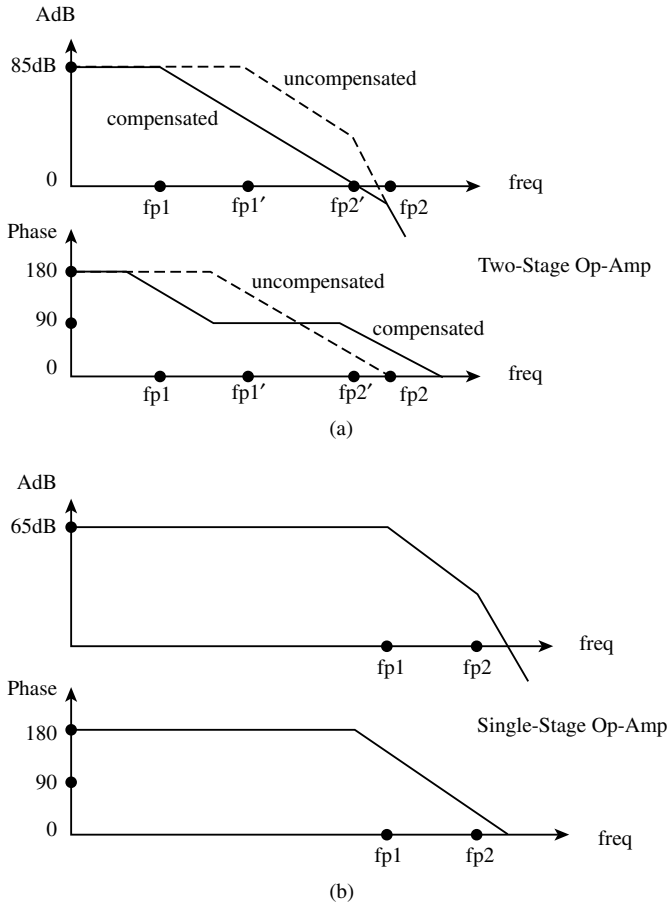

FIGURE 57.52 Pole frequency and phase response for (a) two-stage op-amp and (b) single-stage op-amp.

© 2003 by CRC Press LLC

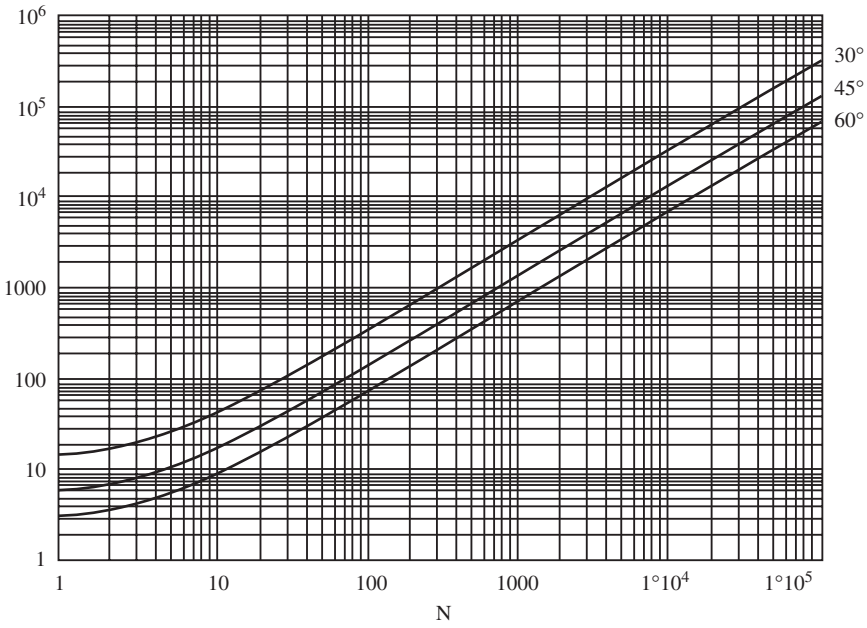

FIGURE 57.53 Low-frequency gain A_0 vs. N ($= f_{P2}/f_{P1}$) for a two-pole amplifier.

lag increases through 135° at f_{P2} to 180° at $f \approx 10 \cdot f_{p2}$. To ensure unconditionally stable performance, the second pole must be sufficiently far from the first so that the phase margin is large enough.

Figure 57.53 shows curves of the dc value of open-loop gain A_0 versus the ratio N of the pole frequencies ($N = f_{P2}/f_{P1}$) for different values of phase margin. For a given value of $A_0 = 1000$ or +60 dB, the ratio of the pole frequencies must be $N \approx 700$ to obtain a phase margin of 45°.

Miller Compensation and Pole Separation

Without any added compensation capacitance the two open-loop poles of the op-amp are invariably too close to make the amplifier unconditionally stable. The most common compensation method is to add a capacitor between the base and collector of the Darlington pair, shown as C_p in Fig. 57.51. This is known as Miller compensation because this strategy makes use of the Miller capacitance multiplication effect discussed earlier. The net result is that the two poles now become significantly far apart, with f_{P1} reducing and f_{P2} increasing, and so the phase margin can be increased to make the op-amp unconditionally stable. However, the penalty of this method is poorer bandwidth and also lower slew rate because of the large capacitance needed, which in practice may be 20 pF or more.

Single-Stage Op-Amp Compensation

Figure 57.54 shows a typical simplified circuit schematic of a single-stage op-amp. The input is a differential emitter-coupled pair followed by a folded cascode transistor and an output complementary common-collector buffer. The key difference between this architecture and the two-stage design shown earlier is that X is a low-impedance node, and so the only high-impedance node in the circuit is node Y. Interestingly, the higher frequency nondominant pole of the two-stage amplifier has now become the dominant frequency pole of the single-stage design, as indicated by the second set of curves in Fig. 57.52(b), which leads to several advantages:

1. The frequency performance off the amplifier is extended. This frequency extension does not lead to a deterioration in phase margin, but simply means that the phase margin problem is shifted up in the frequency domain.
2. Capacitance at the high-impedance Y node reduces bandwidth, but now improves phase margin.

© 2003 by CRC Press LLC

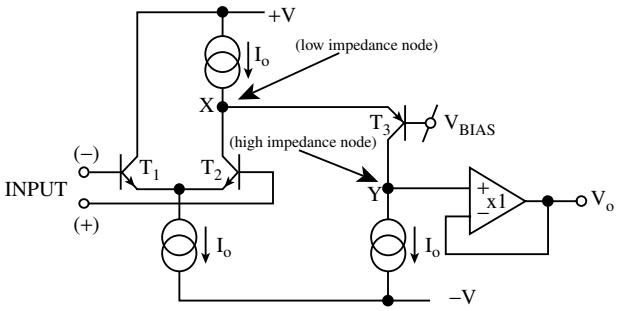

FIGURE 57.54 Architecture of single-stage op-amp.

3. A single value of a few pF's of grounded capacitor at *Y* will now act as a satisfactory compensation capacitor, unlike the large Miller capacitor required in the two-stage design.
4. The slewing capability of this single-stage structure is very good as a result of the much smaller compensation capacitor.
5. Clearly, it is much more straightforward to develop a stable amplifier for high-frequency applications if it has essentially only one voltage gain stage and so high-frequency op-amp designers generally opt for a single gain stage architecture.

Grounded Capacitor Compensation

Typical A_{OL} vs. f responses of two single-stage op-amps are shown in Fig. 57.55, indicating one high-frequency pole and its proximity to the nondominant pole.

The curves are taken from data for (a) a 2-GHz gain–bandwidth product voltage-feedback op-amp and (b) a 150-MHz current-feedback op-amp. In both cases the phase characteristics demonstrate the expected 45° lag at the pole frequency, and the slow roll-off in phase at high frequency due to the presence of the very-high-frequency poles.

Both single-stage and two-stage op-amps can be approximated by the two-pole macromodel shown in Fig. 57.56. Transconductance G_M and output resistance R_0 represent the gain per stage of $G_M \cdot R_0$. The difference between the two-stage and single-stage op-amp models is that R_{01} of the single-stage is of the order of $[G_M]^{-1}$ and the dominant compensation capacitor is C_2. C_P in the case of the single stage will simply be a feedback parasitic capacitor, while in the case of a two-stage it will be the dominant Miller compensating capacitor. This simple model is an excellent first-cut tool for determining pole locations, and the value of compensation capacitor for a desired bandwidth and stability.

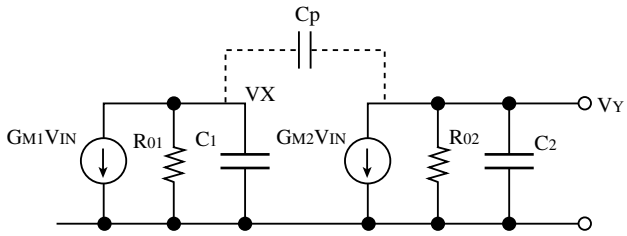

FIGURE 57.56 Partial equivalent circuit of two-pole op-amp.

High-Frequency Performance

Although the bandwidth in a single-stage design is significantly extended, circuit parasitics become more important. We are confronted with the problem of potential instability, since at higher frequencies the "working environment" of the op-amp becomes very parasitic sensitive; in other words, now op-amp-embedded parasitics cannot be neglected.

An op-amp in closed-loop can be considered at three levels, as shown schematically in Fig. 57.57. The inner triangle is the ideal op-amp, internally compensated by the op-amp designer for stable operation using the circuit techniques outlined earlier. High-frequency amplifiers are sensitive to parasitics of the surrounding circuit. The key parasitics within the outer triangle include power supply lead inductance, stray capacitance between power supply pins, and input to ground capacitance. The effect of these parasitics is to destabilize the amplifier, and so the designer is confronted with the task of reestablishing stable operation. The approach needed to achieve this parallels the work of the op-amp designer. The parasitics almost always introduce additional extrinsic nondominant poles, which need to be compensated. The task of compensation cannot be attempted without considering the outer or third level, which

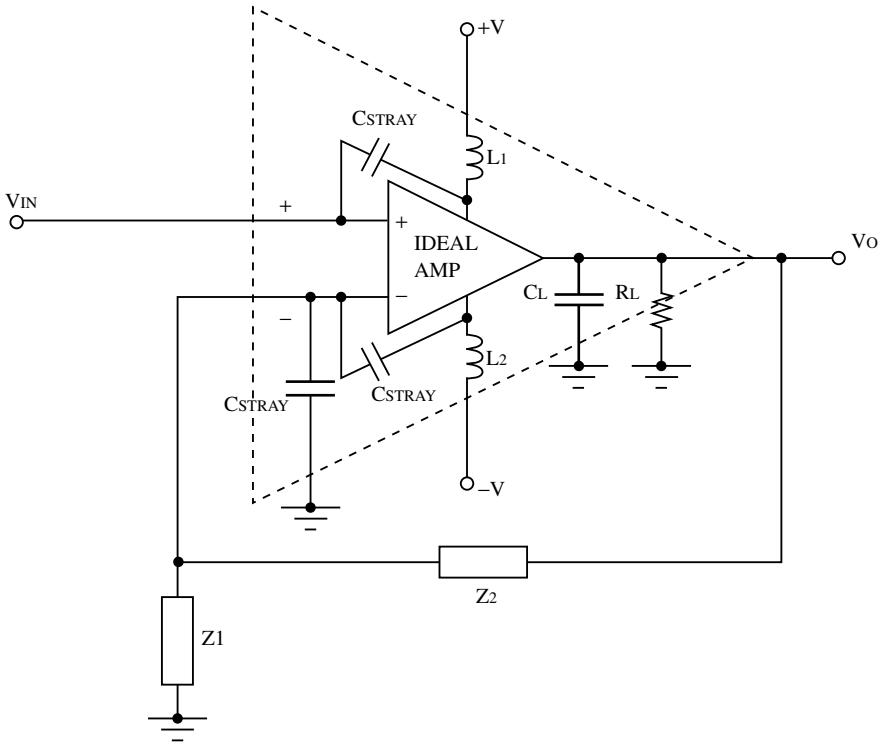

FIGURE 57.57 Real feedback amplifier.

© 2003 by CRC Press LLC

includes the closed-loop gain defining components together with the load impedance. Again, stray reactance associated with these components will modify the loop gain, and so to guarantee stable operation of the closed-loop amplifier it is necessary to compensate the complete circuit.

Power Supply Impedance

In this section, we consider the ways in which the impedance of the power supply can affect the frequency response of the amplifier. First, some important rules:

1. There is no such thing as an ideal zero-impedance power supply.
2. Real power supplies have series *R-L* impedance and at high frequencies the inductance matters most.
3. Power supply inductance causes "bounce" on the power supply voltage, generating unwanted feedback via parasitic capacitive links to the inputs. Power supply "bounce" increases with increasing load current.
4. Supply decoupling capacitors act as "short term local batteries" to maintain power supply integrity, and it is important that they are placed as close as possible to the power supply pins of the op-amp.

Large electrolytic capacitors are fine at low frequencies but are inductive at high frequencies. Figure 57.58 shows commonly used decoupling circuitry. Small-sized tantalum electrolytics are preferred, while a parallel ceramic capacitor with low series inductance takes over the decoupling role at high frequencies. The added series *R* prevents the inductance of the electrolytic resonating with the ceramic capacitor. The waveforms in Fig. 57.59 illustrate the benefits of good decoupling.

Effects of Resistive and Capacitive Loads

The load presented to an amplifier is likely to have both resistive and capacitive components, as illustrated previously in Fig. 57.57. Increasing the load current causes power supply ripple, so good power supply decoupling is vital.

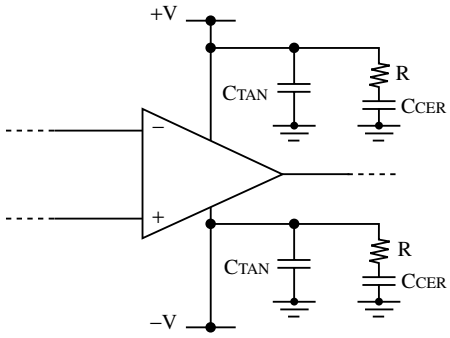

FIGURE 57.58 Supply decoupling circuitry. *Note:* C_{CER} = ceramic capacitor and C_{TAN} = tantalum.

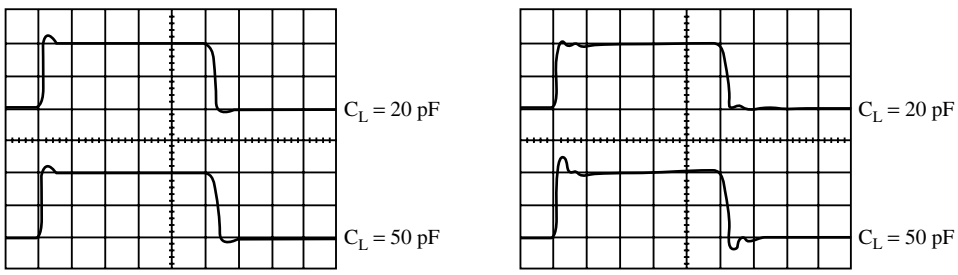

(a) (b)

FIGURE 57.59 High-speed voltage buffer: (a) with and (b) without supply decoupling.

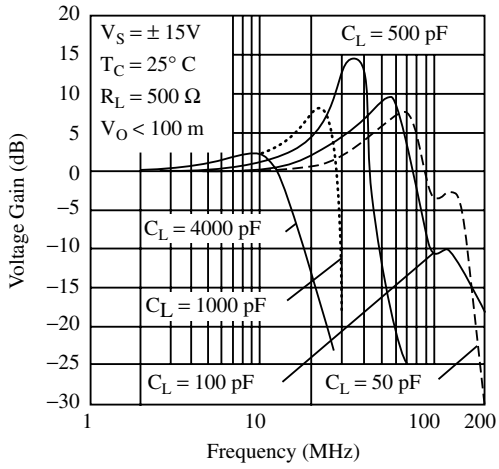

FIGURE 57.60 Load capacitance causes gain peaking.

A closed-loop amplifier with voltage-sampled negative feedback results in a very-low output impedance, so it is natural to think that the effects of any load would be shunted out by this low impedance. In reality, the load has an important effect on the amplifier and must not be overlooked. Resistive loads, for example, cause two main effects. First, as a voltage divider with the open-loop output resistance of the op-amp r_0, the open-loop gain is reduced. This effect is small unless the load resistance approaches r_0. Second, the load current is routed to the output pin via the supply pins, and as the load current increases, the supply pin voltage is modulated. This effect is more important, since the integrity of the power supply will be degraded. Again, good supply decoupling is essential to minimize this effect.

Capacitive load current is proportional to the derivative of output voltage, and the maximum capacitive output current demand occurs when dV_{OUT}/dt is a maximum. Though not directly a stability issue, the designer must remember that a capacitive load demands high output current at high frequencies and at high amplitude, that is

$$I_{MAX} = C_L \cdot 2\pi f_{MAX} \cdot V_{OUTPEAK} \tag{57.58}$$

Figure 57.60 illustrates the effect of load capacitance on the loop gain.

C_1 together with the equivalent output resistance of the op-amp, adds an additional pole into the loop gain of the form

$$V_F/V_{OUT} = B = 1/\left[1 + jf/f_L\right] \quad \text{where} \quad f_L = 1/2\pi r_0 \cdot C_L \tag{57.59}$$

The load resistance has a minor influence on the loop gain compared to the effects of load capacitance by slightly reducing the value of dc open-loop gain by factor K, where $K = R_L/[r_0 + R_L]$, as described above. Since the effective output resistance reduces to $r_{0'} = r_0/R_L$, then f_L changes to $f_{L'} = 1/2\pi r_{0'} C_L$.

Neutralizing the Phase Lag

To compensate for high-frequency phase lag, the simplest technique is to add a series resistance R between the output of the op-amp and the load connection point, as shown in Fig. 57.61.

The series resistor adds a zero into the V_F/V_{OUT} equation, which changes to

$$V_F/V_{OUT} = K \cdot \left[1 + jf/f_Z\right]/\left[1 + jf/f_P\right] \tag{57.60}$$

where $K = [R + R_L]/[r_0 + R + R_L]$, $f_P = 1/[2\pi(r_0 + R)/R_L \cdot C_L]$ and $f_Z = 1/[2\pi R_L/R \cdot C_L] = f_P \cdot [1 + r_0/R]$, so clearly; $f_P < f_Z$.

© 2003 by CRC Press LLC

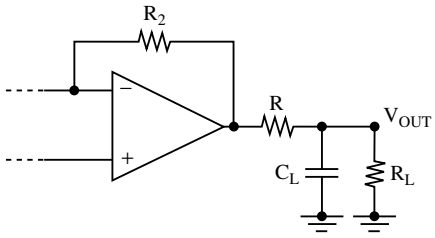

FIGURE 57.61 Load capacitance neutralization.

The phase lag introduced by the pole is compensated by the phase lead of the zero at higher frequencies. The maximum phase lag is limited if the zero is close to the pole, almost eliminating the effects of the load capacitor. Maximum phase lag in V_F/V_{OUT} occurs at $f = f_M$, where f_M is given by

$$f_M = \left[f_P \cdot f_Z\right]^{1/2} = f_P \cdot (1 + r_0/R)^{1/2} \tag{57.61}$$

and at f_M the phase lag $\Phi = \Phi'$ is given by

$$\begin{aligned} \Phi' &= 90° - 2 \cdot \tan^{-1}\left[f_M/f_P\right] = 90° - 2 \cdot \tan^{-1}\left[(1 + r_0/R)^{1/2}\right] \\ \Phi' &\approx -19.5° \quad \text{for} \quad R = r_0 \\ \Phi' &\approx -8.2° \quad \text{for} \quad R = 2 \cdot r_0 \\ \Phi' &\approx -6.4° \quad \text{for} \quad R = 3 \cdot r_0 \end{aligned} \tag{57.62}$$

These values show that the added lag Φ' is not excessive as long as $R > r_0$. The disadvantage with this method is that the series resistor is in direct line with the output current, increasing the output resistance of the amplifier and limiting the output current drive capability. The output impedance also goes inductive at high frequencies.

An alternative way of solving the problem of capacitive load is to view the closed-loop output resistance of the op-amp as being inductive, since the closed-loop output impedance of the op-amp is essentially the open-loop output resistance divided by the loop gain. As the loop gain falls with frequency, the output impedance rises, and thus appears inductive. Adding a load capacitor generates a resonant circuit. The solution is to "spoil" the Q of the resonator, therefore minimizing the added phase lag of C_L.

Adding a so-called series R–C "snubber," as in Fig. 57.62, effects a cure. The resistor R is ac coupled by the capacitor at high frequencies and spoils the Q. Effectively, C_L resonates with the inductive output impedance, and at this frequency leaves the R–C snubber as a "new" load. The equivalent circuit is therefore close to the previous compensation method shown in Fig. 57.61, but with the added advantage that now the load current is not carried by the series resistance. To select the snubber component values, make $R = 1/2\pi f_0 C$, where f_0 is the resonant frequency, which can simply be determined experimentally from the amplifier without the snubber in place. The value of the series capacitance is a compromise: too big and it will increase the effective load capacitance. Choosing $C = C_L$ works reasonably well in practice.

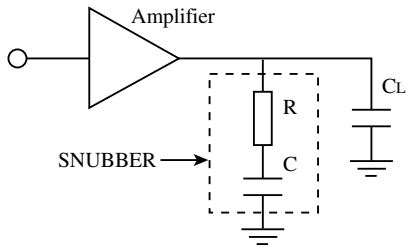

FIGURE 57.62 Snubber cures capacitive load peaking.

© 2003 by CRC Press LLC

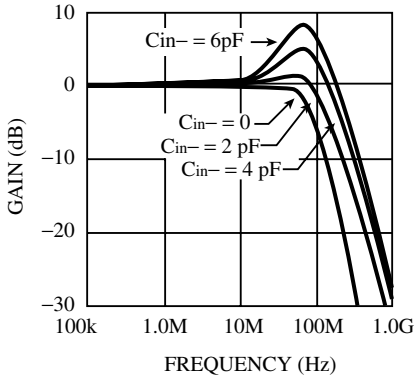

FIGURE 57.63 Stray input capacitance causes gain peaking.

Inverting Input Capacitance to Ground

With most broadband bipolar op-amps, parasitic capacitance to ground adds an additional pole (and hence phase lag) into the feedback path, which threatens stability. Stray capacitance C_1 at the inverting input pin (shown previously in Fig. 57.57) modifies B and adds phase lag in the loop-gain T, compromising stability.

Solving for B with C_1 taken into account will clarify the problem. It is simple to show that

$$B = V_F / V_{OUT} = Z_1 / \left[Z_1 + Z_2 \right] \tag{57.63}$$

where $Z_1 = R_1/[1 + j\omega R_1 C_1]$ and $Z_2 = R_2$. Substituting, we get

$$B = K / \left[1 + jf / f_C \right] \tag{57.64}$$

where $K = R_1\ [R_1 + R_2]$ and $f_{C=} 1/[2\pi C_1 R_1/R_2]$.

The additional pole at $f = f_C$ will now give the circuit a very undesirable three-pole loop gain, which could cause significant gain peaking, as shown in Fig. 57.63. f_C could be made high by choosing relatively low values of $R_1//R_2$ but the additional pole can be eliminated by adding a feedback capacitor C_2 across resistor R_2 to give pole-zero cancellation.

$$Z_1 = R_1 / \left[1 + j\omega R_1 C_1 \right] \quad \text{and} \quad Z_2 = R_2 / \left[1 + j\omega R_2 C_2 \right] \tag{57.65}$$

If $R_1\ C_1 = R_2 C_2$, then $B = Z_1/[Z_1+Z_2] = R_1/[R_1 + R_2]$, making B frequency independent. The design equation for C_2 is then

$$C_2 = C_1 \cdot R_1 / R_2 \tag{57.66}$$

If the open-loop phase margin Φ_M needs to be increased for the desired value of closed-loop gain, and the inverting capacitance C_1 has its inevitable high-frequency influence, then the optimum solution for C_2 would be to locate the zero on the second pole of the loop-gain response following the procedure given above.

Conclusions

This chapter hopefully serves to illustrate some of the modern techniques the practicing engineer will encounter when designing broadband bipolar amplifiers. It focuses mainly upon key generic building blocks and methodologies for broadband design. Many circuits and design techniques have not been covered, but analysis techniques described should serve as a foundation for the analysis of other broadband designs. Furthermore, comprehensive analytical treatment of many alternative broadband bipolar circuits can be found in the texts [6] and [13]–[15].

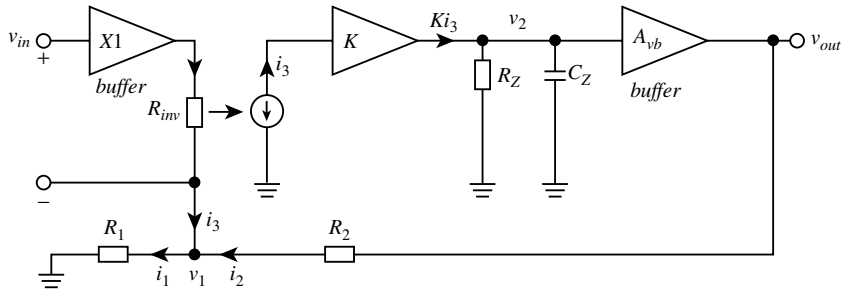
Appendices

A: Transfer Function and Bandwidth Characteristic of Current-Feedback Operational Amplifier



$$-i_1 + i_2 + i_3 = 0 \tag{57.67}$$

$$i_1 = \frac{v_1}{R_1} \tag{57.68}$$

$$i_2 = \frac{v_{\text{out}} - v_1}{R_2} \tag{57.69}$$

$$i_3 = \frac{v_{\text{in}} - v_1}{R_{\text{inv}}} \tag{57.70}$$

$$v_2 = \frac{Ki_3R_Z}{1 + j\omega R_Z C_Z} \tag{57.71}$$

$$v_{\text{out}} = A_{vb}v_2 \tag{57.72}$$

Substituting (57.68)–(57.70) into (57.67) yields

$$-\frac{v_1}{R_1} + \frac{v_{\text{out}} - v_1}{R_2} + \frac{v_{\text{in}} - v_1}{R_{\text{inv}}} = 0$$

Rearranging for v_1 gives

$$v_1 = \frac{\dfrac{v_{\text{in}}R_2}{R_{\text{inv}}} + v_{\text{out}}}{1 + \dfrac{R_2}{R_1} + \dfrac{R_2}{R_{\text{inv}}}}$$

From (57.71) and (57.72), it is clearly seen that

$$v_{\text{out}} = \frac{A_{vb}Ki_3R_Z}{1 + j\omega R_Z C_Z} \tag{57.73}$$

Substituting for i_1 and i_2 from (57.68) and (57.69) into (57.67) gives

$$i_3 = v_1\left(\frac{1}{R_1} + \frac{1}{R_2}\right) - \frac{v_{\text{out}}}{R_2}$$

© 2003 by CRC Press LLC

Substitute for v_1:

$$i_3 = \left[\frac{\dfrac{v_{in}R_2}{R_{inv}} + v_{out}}{1 + \dfrac{R_2}{R_1} + \dfrac{R_2}{R_{inv}}}\right]\left(\frac{1}{R_1} + \frac{1}{R_2}\right) - \frac{v_{out}}{R_2}$$

Substitute for i_3 from (57.73):

$$\frac{v_{out}\left(1 + j\omega R_Z C_Z\right)}{A_{vb}KR_Z} = \left\{\left[\frac{\dfrac{v_{in}R_2}{R_{inv}} + v_{out}}{1 + \dfrac{R_2}{R_1} + \dfrac{R_2}{R_{inv}}}\right]\left(\frac{1}{R_1} + \frac{1}{R_2}\right) - \frac{v_{out}}{R_2}\right\}$$

rearranging

$$v_{out}\left[\frac{\left(1 + j\omega R_Z C_Z\right)}{A_{vb}KR_Z} - \frac{\left(\dfrac{1}{R_1} + \dfrac{1}{R_2}\right)}{\left(1 + \dfrac{R_2}{R_1} + \dfrac{R_2}{R_{inv}}\right)} + \frac{1}{R_2}\right] = \frac{\dfrac{v_{in}R_2}{R_{inv}}\left(\dfrac{1}{R_1} + \dfrac{1}{R_2}\right)}{\left(1 + \dfrac{R_2}{R_1} + \dfrac{R_2}{R_{inv}}\right)}$$

$$\frac{v_{out}}{v_{in}} = \frac{1 + \dfrac{R_2}{R_1}}{\dfrac{R_{inv}\left(1 + \dfrac{R_2}{R_1} + \dfrac{R_2}{R_{inv}}\right)\left(1 + j\omega R_Z C_Z\right)}{A_{vb}KR_Z} - R_{inv}\left(\dfrac{1}{R_1} + \dfrac{1}{R_2}\right) + \dfrac{R_{inv}\left(1 + \dfrac{R_2}{R_1} + \dfrac{R_2}{R_{inv}}\right)}{R_2}}$$

$$\frac{v_{out}}{v_{in}} = \frac{1 + \dfrac{R_2}{R_1}}{\dfrac{R_{inv}\left(1 + \dfrac{R_2}{R_1}\right) + R_2}{A_{vb}KR_Z} + \dfrac{\left(R_{inv}\left(1 + \dfrac{R_2}{R_1}\right) + R_2\right)j\omega R_Z C_Z}{A_{vb}KR_Z} + 1}$$

Factorize the denominator

$$\frac{v_{out}}{v_{in}} = \frac{1 + \dfrac{R_2}{R_1}}{\left[1 + \dfrac{R_{inv}\left(1 + \dfrac{R_2}{R_1}\right) + R_2}{A_{vb}KR_Z}\right]\left[1 + \dfrac{\left(R_{inv}\left(1 + \dfrac{R_2}{R_1}\right) + R_2\right)j\omega R_Z C_Z}{A_{vb}KR_Z}\right]}$$

© 2003 by CRC Press LLC

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1+\dfrac{R_2}{R_1}}{\left[1+\dfrac{R_{\text{inv}}\left(1+\dfrac{R_2}{R_1}\right)+R_2}{A_{vb}KR_Z}\right]\left[1+j\omega C_Z\left\{\dfrac{R_{\text{inv}}\left(1+\dfrac{R_2}{R_1}\right)+R_2}{A_{vb}K+\dfrac{R_{\text{inv}}\left(1+\dfrac{R_2}{R_1}\right)+R_2}{R_Z}}\right\}\right]}$$

If we assume that R_Z is very large, then

$$\frac{R_{\text{inv}}\left(1+\dfrac{R_2}{R_1}\right)+R_2}{R_Z} \approx 0$$

and the transfer function becomes

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1+\dfrac{R_2}{R_1}}{1+j\omega C_Z\left[\dfrac{R_{\text{inv}}\left(1+\dfrac{R_2}{R_1}\right)+R_2}{A_{vb}K}\right]}$$

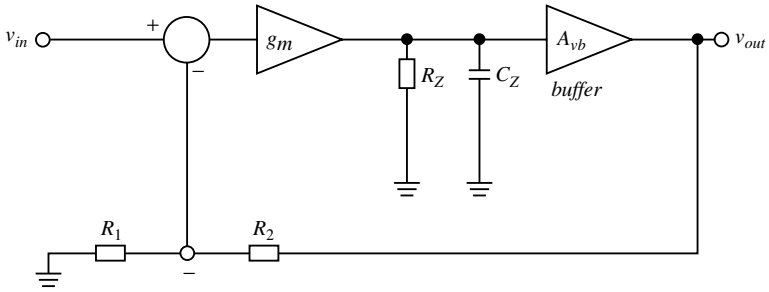
The pole frequency is given by

$$f_{-3\text{ dB}} = \frac{A_{vb}K}{2\pi C_Z\left[R_{\text{inv}}\left(1+\dfrac{R_2}{R_1}\right)+R_2\right]}$$

The gain–bandwidth product is given by

$$GBW = \frac{A_{vb}K\left[1+\dfrac{R_2}{R_1}\right]}{2\pi C_Z\left[R_{\text{inv}}\left(1+\dfrac{R_2}{R_1}\right)+R_2\right]}$$

B: Transfer Function and Bandwidth Characteristic of Voltage-Feedback Operational Amplifier



© 2003 by CRC Press LLC

$$v_{\text{out}} = \left(v_{in} - \frac{R_1}{R + R_2 v_{\text{out}}} \right) \frac{g_m R_Z A_{vb}}{1 + j\omega R_Z C_Z}$$

$$v_{\text{out}} \left[1 + \frac{R_1 g_m A_{vb} R_Z}{(R_1 + R_2)(1 + j\omega R_Z C_Z)} \right] = v_{\text{in}} \frac{g_m A_{vb} R_Z}{1 + j\omega R_Z C_Z} \tag{57.74}$$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{\dfrac{g_m A_{vb} R_Z}{1 + j\omega R_Z C_Z}}{1 + \dfrac{R_1 g_m A_{vb} R_Z}{(R_1 + R_2)(1 + j\omega R_Z C_Z)}}$$

Multiply the numerator and denominator by $(1 + j\omega R_Z C_Z)/g_m A_{vb} R_Z$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1}{\dfrac{1 + j\omega R_Z C_Z}{g_m A_{vb} R_Z} + \dfrac{R_1}{(R_1 + R_2)}}$$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + \dfrac{R_2}{R_1}}{\left[\dfrac{1 + j\omega R_Z C_Z}{g_m A_{vb} R_Z} \right] \left[1 + \dfrac{R_2}{R_1} \right] + 1}$$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + \dfrac{R_2}{R_1}}{\dfrac{1 + \dfrac{R_2}{R_1}}{g_m A_{vb} R_Z} + \dfrac{j\omega R_Z C_Z \left(1 + \dfrac{R_2}{R_1} \right)}{g_m A_{vb} R_Z} + 1}$$

get $1 + [1 + (R_2/R_1)/g_m A_{vb} R_Z]$ out of the denominator

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + \dfrac{R_2}{R_1}}{\left[1 + \dfrac{1 + \dfrac{R_2}{R_1}}{g_m A_{vb} R_Z} \right] \left[1 + \dfrac{\dfrac{j\omega R_Z C_Z \left(1 + \dfrac{R_2}{R_1} \right)}{g_m A_{vb} R_Z}}{1 + \dfrac{1 + \dfrac{R_2}{R_1}}{g_m A_{vb} R_Z}} \right]}$$

multiply the denominator bracket by $g_m A_{vb} R_z/[1 + (R_2/R_1)]$

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1 + \dfrac{R_2}{R_1}}{\left[1 + \dfrac{1 + \dfrac{R_2}{R_1}}{g_m A_{vb} R_Z} \right] \left[1 + \dfrac{j\omega R_Z C_Z \left(1 + \dfrac{R_2}{R_1} \right)}{g_m A_{vb} R_Z + \left(1 + \dfrac{R_2}{R_1} \right)} \right]}$$

© 2003 by CRC Press LLC

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1+\dfrac{R_2}{R1}}{\left[1+\dfrac{1+\dfrac{R_2}{R_1}}{g_m A_{vb} R_Z}\right]\left[1+\dfrac{j\omega R_Z C_Z}{1+\dfrac{g_m A_{vb} R_Z}{\left(1+\dfrac{R_2}{R_1}\right)}}\right]}$$

assuming that $g_m A_{vb} R_Z$ is much larger than $1 + R_2/R_1$, then

$$\frac{v_{\text{out}}}{v_{\text{in}}} = \frac{1+\dfrac{R_2}{R_1}}{1+j\omega\left[\dfrac{R_Z C_Z}{1+\dfrac{g_m A_{vb} R_Z}{\left(1+\dfrac{R_2}{R_1}\right)}}\right]}$$

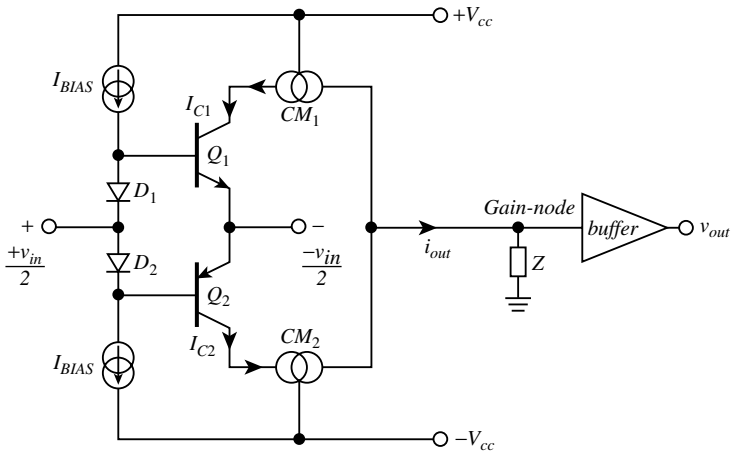
The pole frequency is given by

$$f_{-3\text{dB}} = \frac{1+\dfrac{g_m A_{vb} R_Z}{\left(1+\dfrac{R_2}{R_1}\right)}}{2\pi R_Z C_Z}$$

The gain–bandwidth product is given by

$$GBW = \frac{\left(1+\dfrac{R_2}{R_1}\right)\left[1+\dfrac{g_m A_{vb} R_Z}{\left(1+\dfrac{R_2}{R_1}\right)}\right]}{2\pi R_Z C_Z}$$

C: Transconductance of the Current-Feedback Op-Amp Input Stage



© 2003 by CRC Press LLC

$$v_{\text{in}} = v_1 - v_2$$

$$i_{\text{out}} = I_{CI} - I_{C2}$$

$$I_{C1} = I_{S1} e^{\frac{v_{BE1}}{v_T}}$$

$$I_{C2} = I_{S2} e^{\frac{v_{BE2}}{v_T}}$$

$$V_{BE1} = V_{DQ1} + v_{\text{in}}$$

$$V_{BE2} = v_{\text{in}} - V_{DQ2}$$

$$I_{C1} = I_{S1} e^{\left(\frac{V_{DQ1}}{V_T} + \frac{v_{\text{in}}}{v_T}\right)}$$

$$I_{C2} = I_{S2} e^{\left(\frac{V_{DQ1}}{V_T} - \frac{v_{\text{in}}}{v_T}\right)}$$

$$I_{C1} = I_{CQ1} e^{\frac{v_{\text{in}}}{v_T}}$$

$$I_{C2} = I_{CQ2} e^{-\frac{v_{\text{in}}}{v_T}}$$

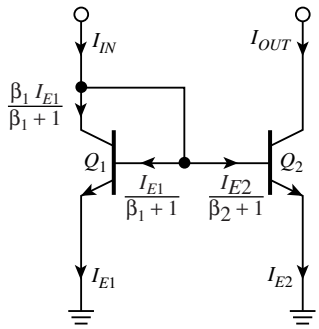
Assuming matched transistors then, $I_{CQ1} = I_{CQ2} = I_{CQ}$

$$i_{\text{out}} = I_{C1} - I_{C2} = I_{CQ}\left[e^{+\left(\frac{v_{\text{in}}}{v_T}\right)} - e^{-\left(\frac{v_{\text{in}}}{v_T}\right)}\right]$$

$$\frac{i_{\text{out}}}{I_{CQ}} = y = \left[e^{x} - e^{-x}\right] = 2\sinh(x)$$

where $x = + v_{\text{in}}/V_T$.

D: Transfer Function of Widlar Current Mirror



$$I_{\text{IN}} = I_{E1} + \frac{I_{E2}}{\beta_2 + 1}$$

$$I_{\text{IN}} = \frac{I_{E1}(\beta_2 + 1) + I_{E2}}{\beta_2 + 1}$$

© 2003 by CRC Press LLC

$$I_{\text{OUT}} = \beta_2 I_{B2}$$

$$I_{\text{OUT}} = \frac{\beta_2 I_{E2}}{\beta_2 + 1}$$

$$\frac{I_{\text{OUT}}}{I_{\text{IN}}} = \frac{\left(\beta_2 I_{E2}\right)\left(\beta_2 + 1\right)}{\left(\beta_2 + 1\right)\left[I_{E1}\left(\beta_2 + 1\right) + I_{E2}\right]}$$

$$\frac{I_{\text{OUT}}}{I_{\text{IN}}} = \frac{\beta_2 I_{E2}}{I_{E1}\left(\beta_2 + 1\right) + I_{E2}}$$

$$\frac{I_{\text{OUT}}}{I_{\text{IN}}} = \frac{1}{\dfrac{I_{E1}\left(\beta_2 + 1\right)}{I_{E2}\beta_2} + \dfrac{1}{\beta_2}}$$

For

$$\frac{I_{E1}}{I_{E2}} = \frac{I_{S1}\left(\dfrac{\beta_1 + 1}{\beta_1}\right) e^{\frac{v_{BE1}}{V_T}}}{I_{S2}\left(\dfrac{\beta_2 + 1}{\beta_2}\right) e^{\frac{v_{BE2}}{v_T}}}$$

Then, as $V_{BE1} = V_{BE2}$,

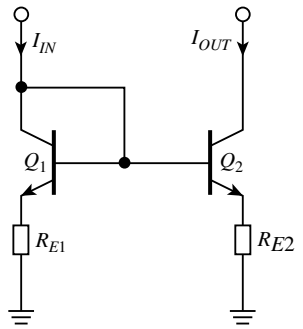
$$\frac{I_{E1}}{I_{E2}} = \frac{I_{S1}\left(\dfrac{\beta_1 + 1}{\beta_1}\right)}{I_{S2}\left(\dfrac{\beta_2 + 1}{\beta_2}\right)}$$

$$\frac{I_{\text{OUT}}}{I_{\text{IN}}} = \frac{1}{\dfrac{I_{S1}\left(\beta_1 + 1\right)}{I_{S2}\beta_1} + \dfrac{1}{\beta_2}}$$

Assume $\beta_1 = \beta_2 = \beta$, $I_{S1} = I_{S2}$. Then

$$\frac{I_{\text{OUT}}}{I_{\text{IN}}} = \frac{\beta}{\beta + 2}$$

E: Transfer Function of Widlar Current Mirror with Emitter Degeneration Resistors



© 2003 by CRC Press LLC

Assuming that $\beta \gg 1$, then

$$V_{BE1} + I_{IN}R_1 = V_{BE2} + I_{out}R_2$$

$$I_{out} = \frac{I_{IN}R_1}{R_2} + \frac{\left(V_{BE1} - V_{BE2}\right)}{R_2}$$

$$\frac{I_{OUT}}{I_{IN}} = \frac{R_1}{R_2} + \frac{\left(V_{BE1} - V_{BE2}\right)}{I_{IN}R_2}$$

$$\frac{I_{OUT}}{I_{IN}} = \frac{R_1}{R_2} + \frac{V_T \ln\left(\frac{I_{IN}}{I_{S1}}\frac{I_{S2}}{I_{OUT}}\right)}{I_{IN}R_2}$$

$$\frac{I_{OUT}}{I_{IN}} = \frac{R_1}{R_2} + \frac{V_T\left(\ln\frac{I_{IN}}{I_{OUT}} + \frac{\Delta V_{BE}}{V_T}\right)}{I_{IN}R_2}$$

$$\frac{I_{OUT}}{I_{IN}} = \frac{R_1}{R_2} + \frac{V_T\left(\ln\frac{I_{IN}}{I_{OUT}}\right)}{I_{IN}R_2} + \frac{\Delta V_{BE}}{I_{IN}R_2}$$

Assuming that the term $V_T[\ln(I_{IN}/I_{OUT})]/I_{IN}R_2$ is small compared with the other terms, then

$$\frac{I_{OUT}}{I_{IN}} = \frac{R_1}{R_2} + \frac{\Delta V_{BE}}{I_{IN}R_2}$$

57.2 Bipolar Noise

B. M. Wilamowski

Bipolar transistors and other electronic devices generate internal electrical noise. This limits the device operation at a small-signal range. There are a few different sources of noise, such as thermal noise, shot noise, flicker noise or 1/*f* noise, burst noise or "popcorn noise," and avalanche noise [1], [6].

Thermal Noise

Thermal noise is created by random motion of charge carriers due to the thermal excitation [1]. This noise is sometimes known as the Johnson noise. The thermal motion of carriers creates a fluctuating voltage on the terminals of each resistive element. The average value of this voltage is zero, but the power on its terminals is not zero. The internal noise voltage source or current source is described by Nyquist equation

$$\overline{v_n^2} = 4kTR\Delta f \qquad \overline{i_n^2} = \frac{4kT\Delta f}{R} \tag{57.75}$$

where k is the Boltzmann constant, T is absolute temperature, and $4kT$ is equal to 1.66×10^{-20} V· C at room temperature. The thermal noise is proportional to the frequency bandwidth Δf. It can be represented by the voltage source in series with resistor R, or by the current source in parallel to the resistor R. The maximum noise power can be delivered to the load when $R_L = R$. In this case, maximum noise power in the load is $kT\Delta f$. The noise power density $dP_n/df = kT$, and it is independent of frequency. Thus, the thermal noise is the white noise. The rms noise voltage and the rms noise current are proportional to the square root of the frequency bandwidth Δf. The thermal noise is associated with every physical resistor in the circuit. In a bipolar transistor, the thermal noise is generated mainly by series base, emitter, and collector resistances.

Shot Noise

Shot noise is associated with the carrier injection through the pn junction. In each forward biased junction, there is a potential barrier that can be overcome by the carriers with higher thermal energy. This is a random process and the noise current is given by

$$\overline{i_n^2} = 2qI\Delta f \tag{57.76}$$

where q is the electron charge and I is the forward junction current. The shot noise depends on the thermal energy of carriers near the potential barrier. Similar to the thermal noise, the shot noise has constant and frequency-independent noise power density. It is also the white type of noise. Shot noise is usually considered as a current source connected in parallel to the small-signal junction resistance.

Flicker — 1/*f* Noise

Flicker noise in bipolar transistors is associated mainly with generation-recombination centers [2]–[4]. Free carries are randomly trapped and released by these centers. This is a relatively slow process and it cannot be seen at high frequencies. The flicker noise is always associated with a current and is approximated by

© 2003 by CRC Press LLC

$$\overline{i_n^2} = K_F I^{A_F} \frac{\Delta f}{f} \tag{57.77}$$

where K_F is the flicker-noise coefficient and A_F is the flicker-noise exponent. Both K_F and A_F are device dependent. With modern technology, the number of trapping centers can be significantly lowered, thus the effect of flicker noise is meaningfully reduced. The $1/f$ nature of the flicker noise is such that sometimes this noise component is considered to be responsible for the long term device parameter fluctuation.

Other Types of Noise

The burst or "popcorn" noise is another type of noise at low frequencies [3], [4]. This noise is not fully understood, but it seems that it is related to the heavy-metal ion contamination. The burst noise looks, on an oscilloscope, like a square wave with the constant magnitude, but with random pulse widths. It has significant effect at low frequencies. In audio amplifiers, the burst noise sounds as random shoots, which are similar to the sound associated with making popcorn. Obviously, bipolar transistors with large burst noise must not be used in audio amplifiers and in other analog circuitry. The burst noise is often approximated by

$$\overline{i_n^2} = K_B \frac{i_D^{A_B}}{1 + \left(\frac{f}{f_B}\right)^2} \Delta f \tag{57.78}$$

where K_B, A_B, and f_B are experimentally chosen parameters, which usually vary from one device to another. Furthermore, a few different sources of the burst noise can exist in a single transistor. In such a case, each noise source should be modeled by a separate Eq. (57.78) with different parameters (usually different corner frequency f_B).

The avalanche noise is another noise component, which can be found in bipolar transistors. For large reverse voltages on the collector junction, the collector current can be multiplied by the avalanche phenomenon. Carriers in the collector-base junctions gain energies in high electrical field, then losing this energy during collision with the crystal lattice. If the energy gained between collisions is large enough, then during collision another pair of carriers (electron and hole) can be generated. This way, the collector current can be multiplied. This is a random process and obviously the noise source is associated with the avalanche carrier generation. The magnitude of the avalanche noise is usually much larger than any other noise component. Fortunately, the avalanche noise exists only in the pn junction biased with a voltage close to the breakdown voltage. The avalanche phenomenon is often used to build the noise sources [5].

Noise Characterization

Many different methods are used in literature for noise characterization. Sometimes the noise is characterized by an equivalent noise resistance, sometimes by an equivalent noise temperature, sometimes by an equivalent rms noise voltage or current or sometimes by a noise figure.

Equivalent Noise Voltage and Current

The equivalent noise voltage or current is the most commonly used method for modeling the noise in semiconductor devices. The equivalent diagram of the bipolar transistor, including various noise components, is shown in Fig. 57.64. The noise components are given by

$$\overline{i_B^2} = \frac{4kT\Delta f}{r_B} \quad \overline{i_E^2} = \frac{4kT\Delta f}{r_E} \quad \overline{i_C^2} = \frac{4kT\Delta f}{r_C}$$
$$\overline{i_c^2} = 2qI_C\Delta f \tag{57.79}$$

© 2003 by CRC Press LLC

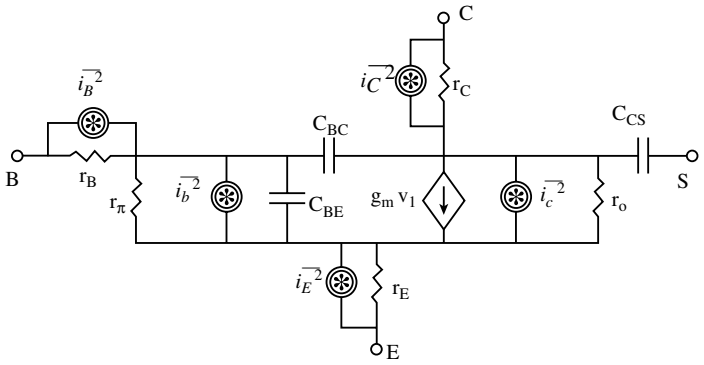

FIGURE 57.64 Equivalent diagram of the bipolar transistor, which includes noise sources.

$$\overline{i_b^2} = 2qI_B\Delta f + K_F\frac{I_B^{A_F}}{f}\Delta f + K_B\frac{I_B^{A_B}}{1+\left(\dfrac{f}{f_B}\right)^2}\Delta f$$

Thermal noise is associated with physical resistors only, such as base, emitter, and collector series resistances. The small-signal equivalent resistances, such as r_π and r_0, do not exhibit thermal noise. The shot noise is associated with both collector and base currents. It was found experimentally that the flicker and the burst noise are associated with base current. The typical noise characteristic of a bipolar transistor is shown in Fig. 57.65. The corner frequency of the flicker noise can vary from 100 Hz to 1 MHz.

Equivalent Noise Resistance and Noise Temperature

The noise property of a two-port element can be described by a noise current source connected in parallel to the output terminals, as Fig. 57.66(a) shows. Knowing that noise current can be expressed as the shot noise of the dc device current [(57.76)], the two-port noise can be expressed by means of an equivalent dc noise current

$$I_{eq} = \frac{\overline{i_n^2}}{2q\Delta f} \tag{57.80}$$

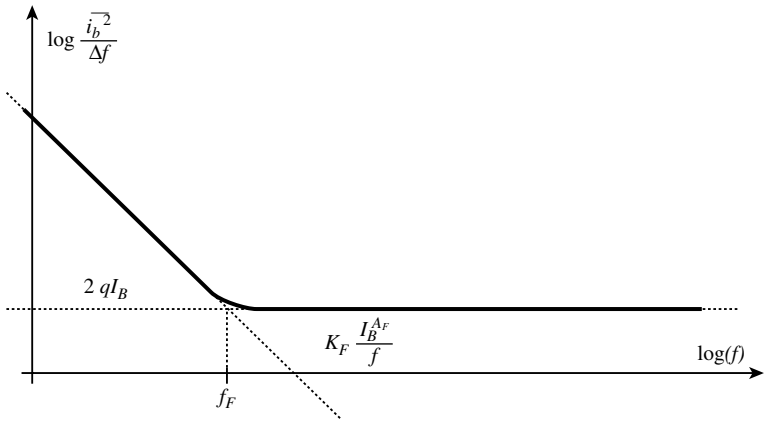

FIGURE 57.65 Bipolar noise as a function of frequency.

© 2003 by CRC Press LLC

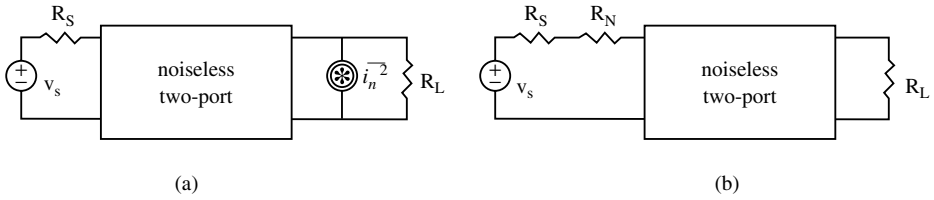

FIGURE 57.66 Noise characterization for two-ports: (a) using the noise source at the output, (b) using noise resistance R_N at the input.

Another way to model the two-port noise in the two-port is to use the thermal noise at the input. This can be done using an additional "noisy" resistor connected to the input, as Fig. 57.66(b) shows:

$$R_n = \frac{\overline{v_{n1}^2}}{4kT\Delta f} = \frac{\overline{v_{n2}^2}}{A_v^2 4kT\Delta f} \tag{57.81}$$

where A_v is the voltage gain of the two-part, and v_{n1}^2 and v_{n2}^2 are equivalent noise voltage sources at the input and the output, respectively. The equivalent noise resistance is not a very convenient way to represent the noise property of the two-port. This additional resistance R_n must not be on the circuit diagram for small-signal analysis. To overcome this difficulty the concept of the equivalent noise temperature was introduced. This is a temperature increment of the source resistance required to obtain the same noise magnitude at the output if this source resistance is the only noise source. The noise temperature can be calculated from the simple formula

$$T_n = \frac{R_n}{R_s} 290 \text{ K} \tag{57.82}$$

where R_n and R_s are shown in Fig. 57.66(b). It is customary to use 290 K as the reference room temperature for the noise temperature calculations.

Noise Figure

The noise figure is the ratio of the output noise of the actual two-port to the output noise of the ideal noiseless two-port when the resistance of the signal source R_s is the noise source.

$$F = 10 \log\left(\frac{\text{total output noise}}{\text{output noise due to the source resistance}}\right) \tag{57.83}$$

The noise figure F is related to the noise resistance and the noise temperature in the following way:

$$F = 10 \log\left(1 + \frac{R_n}{R_s}\right) = 10 \log\left(1 + \frac{T_n}{290 \text{ K}}\right) \tag{57.84}$$

The noise figure F is the most common method of noise characterization.

58.1 Introduction

A few years ago, the world of wireless communications and its applications started to grow rapidly. The main cause for this event was the introduction of digital coding and digital signal processing in wireless communications. This digital revolution is driven by the development of high-performance, low-cost, CMOS technologies that allow for the integration of an enormous amount of digital functions on a single die. This allows, in turn, for the use of sophisticated modulation schemes, complex demodulation algorithms, and high-quality error detection and correction systems, resulting in high-performance lossless communication channels.

Today, the digital revolution and the high growth of the wireless market also bring many changes to the analog transceiver front-ends. The front-ends are the interface between the antenna and the digital modem of the wireless transceiver. They have to detect very weak signals (μV) which come in at a very high frequency (1 to 2 GHz) and, at the same time, they have to transmit at the same high-frequency high power levels (up to 2 W). This requires high-performance analog circuits, like filters, amplifiers, and mixers which translate the frequency bands between the antenna and the A/D-conversion and digital signal processing. Low cost and a low power consumption are the driving forces and they make the analog front-ends the bottleneck for future RF design. Both low cost and low power are closely linked to the trend toward full integration. An even further level of integration renders significant space, cost, and power reductions. Many different techniques to obtain a higher degree of integration for receivers, transmitters, and synthesizers have been presented over the past years.[1-3] This chapter introduces and analyzes some advantages and disadvantages and their fundamental limitations.

© 2003 by CRC Press LLC

Parallel to the trend to further integration, there is the trend to the integration of RF circuitry in CMOS technologies. The mainstream use for CMOS technologies is the integration of digital circuitry. The use of these CMOS technologies for high-performance analog circuits yields, however, many benefits. The technology is, of course — if used without any special adaptations toward analog design — cheap. This is especially true if one wants to achieve the ultimate goal of full integration: the complete transceiver system on a single chip, with both the analog front-end and the digital demodulator implemented on the same die. This can only be achieved in either a CMOS or a BiCMOS process. BiCMOS has better devices for analog design, but its cost will be higher, not only due to the higher cost per area, but also due to the larger area that will be needed for the digital part. Plain CMOS has the extra advantage that the performance gap between devices in BiCMOS and nMOS devices in deep sub-micron CMOS, and even nMOS devices in the same BiCMOS process, is becoming smaller and smaller due to the much higher investments in the development of CMOS than bipolar. The f_T's of the nMOS devices are getting close to the f_T's of npn devices.

Although some research had been done in the past on the design of RF in CMOS technologies,[4] it is only in the few years that real attention has been given to its possibilities.[5,6] Today several research groups at universities and in industry are researching this topic.[2,3,7,9] As bipolar devices are inherently better than CMOS devices, RF CMOS is by some seen as a possibility for only low-performance systems, with reduced specification (like ISM),[8,10] or that the CMOS processes need adaptations, like substrate etching under inductors.[7] Others feel, however, that the benefits of RF CMOS can be much bigger and that it will be possible to use plain deep sub-micron CMOS for the full integration of transceivers for high-performance applications, like GSM, DECT, and DCS 1800.[2,3] First, this chapter analyzes some trends, limitations, and problems in technologies for high-frequency design. Second, the down-converter topologies and implementation problems are addressed. Third, the design and trends toward fully integrated low-phase noise PLL circuits are discussed. Finally, the design of fully integrated up-converters is studied.

58.2 Technology

Active Devices

Due to the never-ending progress in technology and the requirement to achieve a higher degree of integration for DSP circuits, sub-micron technologies are nowadays considered standard CMOS technologies. The trend is even toward deep sub-micron technologies (e.g., transistor lengths of 0.1 μm. Using the square law relationship for MOS transistors to calculate the f_t of a MOS device no longer holds, due to the high electrical fields. Using a more accurate model, which includes the mobility degradation due to the high electrical fields, results in

$$f_t = \frac{g_m}{2\pi C_{gs}} = \frac{\mu}{2\pi 2/3L^2} \frac{\left(V_{gs} - V_t\right)}{\left(1 + 2\left(q + \frac{\mu}{v_{\max} L}\right)\left(V_{gs} - V_t\right)\right)} \tag{58.1}$$

Hence, by going to deep sub-micron technologies, the square law benefit in L for speed improvement drastically reduces due to the second term in the denominator of Eq. (58.1). Even for very deep sub-micron technologies, the small signal parameter g_m has no square law relationship anymore:

© 2003 by CRC Press LLC

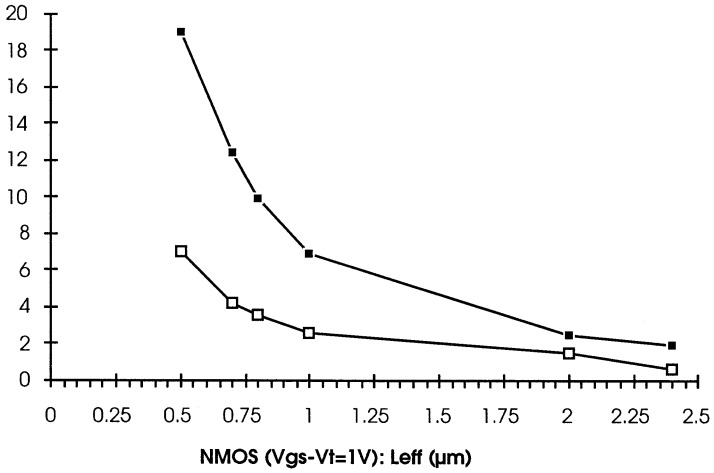

FIGURE 58.1 Comparison of f_t and f_{max}.

$$g_m = \frac{\mu C_{ox} W \left(V_{gs} - V_t\right)}{L\left(1 + 2\left(\theta + \frac{\mu}{v_{\max} L}\right)\left(V_{gs} - V_t\right)\right)} \tag{58.2}$$

with transistor lengths smaller than approximately

$$L < \frac{\mu}{v_{\max}} \frac{1}{\frac{1}{2\left(V_{gs} - V_t\right)} - q} \approx 0.12\,\mu\text{m} \tag{58.3}$$

with $\mu/v_{max} = 0.3$, $V_{gs} - V_t = 0.2$ (boundary of strong inversion), and $\theta = 0.06$, the transistor has only the weak inversion and the velocity saturation area. This will result in even higher biasing currents in order to achieve the required g_m and will result in higher distortion and intermodulation components, which will be further discussed in the trade-off of low-noise amplifier designs.

Furthermore, the speed increase of deep sub-micron technologies is reduced by the parasitic capacitance of the transistor, meaning the gate-drain overlap capacitances and drain-bulk junction capacitances. This can clearly be seen in Fig. 58.1 in the comparison for different technologies of the f_t and the f_{max} defined as the 3-dB point of a diode-connected transistor.[11] The f_{max} is more important because it reflects the speed limitation of a transistor in a practical configuration. As can be seen, the f_t rapidly increases; but for real circuit designs (f_{max}), the speed improvement is only moderate.

Passive Devices

The usability of a process for RF design does not only depend on the quality of the active devices, but also, more and more, on the availability of good passive devices. The three passive devices (resistors, capacitors, and inductors) are discussed.

Low-ohmic resistors are available today in all CMOS technologies and their parasitic capacitance is such that they allow for more than high enough bandwidth (i.e., more than 2 to 3 GHz). A more

© 2003 by CRC Press LLC

important passive device is the capacitor. In RF circuits, capacitors can be used for ac-coupling. This allows dc-level shifting between different stages, resulting in a more optimal design of each stage and in the ability to use lower power supply voltages. The quality of a capacitor is mainly determined by the ratio between the capacitance value and the value of the parasitic capacitance to the substrate. Too high a parasitic capacitor loads the transistor stages, thus reducing their bandwidth, and it causes an inherent signal loss due to a capacitive division. Capacitors with ratios lower than 8 are, as a result, difficult to use in RF circuit design as coupling devices.

The third passive device, the inductor, is gaining more and more interest in RF circuit design on silicon. The use of inductors allows for a further reduction of the power supply voltage and for compensation of parasitic capacitances by means of resonance, resulting in higher operating frequencies. The problem is that the conducting silicon substrate under a spiral inductor reduces the quality of the inductor. Losses occur due to capacitive coupling to the substrates, and eddy currents induced in the substrate will also result in losses and in a reduction of the effective inductance value. This problem can be circumvented by using extra processing steps that etch away the substrate under the spiral inductor,[23] having the large disadvantage that it eliminates all the benefits of using a standard CMOS process. It is therefore important that in CMOS, spiral inductors are used without any process changes and that their losses are accurately modeled. In Reference 12, it is shown that spiral inductors can be accurately modeled and that they can be used in CMOS RF circuit design. As an example, Section 58.4 discusses all the different possibilities for the use of inductors in the design of VCOs. It shows that high-performance VCOs can be integrated with spiral inductors, even on lossy substrates, without requiring any external component.

58.3 The Receiver

Receiver Topologies

The heterodyne or IF receiver is the best known and most frequently used receiver topology. In the IF receiver, the wanted signal is down-converted to a relatively high intermediate frequency. A high quality passive bandpass filter is used to prevent a mirror signal to be folded upon the wanted signal on the IF frequency. Very high performances can be achieved with the IF receiver topology, especially when several IF stages are used (e.g., 900 MHz to 300 MHz, 300 MHz to 70 MHz, 70 MHz to 30 MHz, 30 MHz to 10 MHz). The main disadvantage of the IF receiver is the poor degree of integration that can be achieved as every stage requires going off-chip and requires the use of a discrete bandpass filter. This is both costly (the cost of the discrete filters and the high pin-count for the receiver chip) and power consuming (often the discrete filters have to be driven by a 50-Ω signal source).

The homodyne or zero-IF receiver, introduced as an alternative to the IF receiver, can achieve a much higher degree of integration. The zero-IF receiver uses a direct, quadrature down-conversion of the wanted signal to the baseband. In this case, the wanted signal has itself as mirror signal and sufficient mirror signal suppression can therefore be achieved, even with a limited quadrature accuracy (e.g., 3° phase accuracy and 1-dB amplitude accuracy). Theoretically, there is thus no discrete high-frequency bandpass filter required in the zero-IF receiver, allowing in this way the realization of a fully integrated receiver. The limited performance of the LNA and the mixers reveals, however, that — although not for mirror signal suppression — a high-frequency bandpass filter is still required. The reason why LNAs and mixers require bandpass filtering and how this can be prevented, is explained later.

In the zero-IF receiver, down-conversion can be performed in a single stage (e.g., directly from 900 MHz to the baseband), giving large benefits toward full integration, low cost, and low power consumption.[13] The problem with the zero-IF receiver, however, is its poor performance compared to IF receivers. The zero-IF receiver is intrinsically very sensitive to parasitic baseband signals like dc-offset voltages and cross talk products caused by RF and LO self-mixing. It is precisely these drawbacks that have kept the zero-IF receiver from being used on a large scale in new wireless applications. The use of the zero-IF receiver has therefore been limited to either low-performance applications like pagers and ISM[10] or as a second stage in a combined IF–zero-IF receiver topology.[14,15] It has, however, been shown

© 2003 by CRC Press LLC

that by using dynamic nonlinear dc-correction algorithms, implemented in the DSP, the zero-IF topology can be used for high-performance applications like GSM and DECT.[1,16]

In recent years, new receiver topologies, like the quasi-IF receiver[3] and the low-IF receiver[2] have been introduced for use in high-performance applications. The quasi-IF receiver uses a quadrature down-conversion to an IF frequency, followed by a further quadrature down-conversion to the baseband. The channel selection is done with the second local oscillator on the IF frequency, giving the advantage that a fixed-frequency first local oscillator can be used. The disadvantages of the quasi-IF receiver are that, with a limited accuracy of the first quadrature down-converter (e.g., a phase error of 3 degrees), the mirror signal suppression is not good enough and an HF filter that improves the mirror signal suppression is still necessary. A second disadvantage is that a high IF is required in order to obtain a high enough ratio between the IF frequency and the full band of the application. Otherwise, the tunability of the second VCO has to be too large. Unfortunately, a high IF requires a higher power consumption. Moreover, the first stage of mixers cannot be true down-conversion mixers in the sense that they still need to have a relatively high output bandwidth. To conclude, multistage topologies inherently require more power.

The low-IF receiver performs a down-conversion from the antenna frequency directly down to — as the name already indicates — a low IF (i.e., in the range a few 100 kHz).[2] Down-conversion is done in quadrature and the mirror signal suppression is performed at low frequency, after down-conversion, in the DSP. The low-IF receiver topology is thus closely related to the zero-IF receiver. It can be fully integrated (it does not require an HF mirror signal suppression filter) and uses a single-stage direct-down-conversion. The difference is that the low-IF does not use baseband operation, resulting in a total immunity to parasitic baseband signals, resolving in this way the main disadvantage of the zero-IF receiver. The drawback is that the mirror signal is different from the wanted signal in the low-IF receiver topology; but by carefully choosing the IF frequency, an adjacent channel with low signal levels can be selected for which the typical mirror signal suppression (i.e., a phase accuracy of 3°) is sufficient.

Full Integration

With newly developed receiver topologies such as the zero-IF receiver and the low-IF receiver, the need disappears for the use of external filters that suppress the mirror signal (see previous section). This does not mean, however, that there would not be any HF filtering required anymore. Filtering before the LNA is, although not for mirror signal suppression, still necessary to suppress the blocking signals. Moreover, between the LNA and the mixer, filtering may be necessary in order to suppress second and third harmonic distortion products that are introduced by the LNA. Due to the use of a switching down-converter or the nonlinearities of the mixer and local oscillator harmonics, these distortion products will be down-converted to the same frequency as the wanted signal. The latter problem can be eliminated by using either a very good blocking filter before the LNA (resulting in small signals after the LNA) or by using a highly linear LNA. The use of linear down-converters (i.e., based on the multiplication with a sinusoidal local oscillator signal) reduces of course the problem as well.

In mobile communications systems, very high, out-of-band signals may be present. In order to prevent saturation of the LNA, these signals must be suppressed with an HF filter that passes only the signals in the band of the application. In the GSM system, for example, the ratio between the largest possible out-of-band signal and the lowest detectable signal is 107 dB. Without a blocking filter, the LNA and the mixer must be able to handle this dynamic range. For the LNA, this means that the input should be able to handle an input signal of 0 dBm (i.e., the –1 dB compression point P_{-1dB} should be about 0 dBm), while having a noise figure of 6 dB. Consequently, this means that the IP3 value should be +10 dBm (IP3 ≈ P_{-1dB} + 10.66 dB). The IMFDR3 (intermodulation free dynamic range) of an LNA or mixer for a given channel bandwidth is given by:

$$\text{IMFDR3} = \frac{2}{3}\left[\text{IP3} + 174\,\text{dB} - 10\log\left(\text{BW}\right) - \text{NF}\right] \tag{58.4}$$

© 2003 by CRC Press LLC

The required IMFDR3 for an LNA is thus (for a 200-kHz bandwidth) 80 dB. CMOS down-converters can be made very linear by using MOS transistors in the linear region,[2,6,17] much more linear than the bipolar cross-coupled multipliers. IP3 values of +45 dBm and noise figures of 18 dB have been demonstrated for CMOS realizations.[2,6] This results in an IMFDR3 for a 200-kHz bandwidth of more than 95 dB. The consequence is that the IMFDR3 spec of 80 dB (i.e., without blocking filter) is achievable for the mixer. In this manner, CMOS opens the way to the development of a true fully integrated single-chip receiver for wireless systems that does not require a single external component, not even a blocking filter. In order to achieve this goal, highly linear mixers that multiply with a single sine must be used. However, the noise performance of mixers is intrinsically worse than the noise of an amplifier, and the use of an LNA is still necessary. In order to be able to cope with the blocking levels, the LNA will have to be highly linear and its gain will have to be reduced from a typical value of, for example, 18 dB to 12 dB. The mixers' noise figure will then have to be lowered by about 6 dB too. This will require a higher power consumption from the down-conversion mixer, but the benefit would be that the receiver can then be fully integrated.

The Down-Converter

The most-often used topology for a multiplier is the multiplier with cross-coupled variable transconductance differential stages. The use of this topology or related topologies (e.g., based on the square law) in CMOS is limited for high-frequency applications. Two techniques are used in CMOS: the use of the MOS transistor as a switch and the use of the MOS transistor in the linear region.

The technique often used in CMOS down-conversion for its ease of implementation is subsampling on a switched-capacitor amplifier.[5,18,19] Here, the MOS transistor is used as a switch with a high input bandwidth. The wanted signal is commutated via these switches. Subsampling is used in order to be able to implement these structures with a low-frequency op-amp. The switches and the switched capacitor circuit run at a much lower frequency (comparable to an IF frequency or even lower). The clock jitter must, however, be low so that the high-frequency signals can be sampled with a high enough accuracy. The disadvantage of subsampling is that all signals and noise on multiples of the sampling frequency are folded upon the wanted signal. The use of a high-quality HF filter in combination with the switched-capacitor subsampling topology is therefore absolutely necessary.

Figure 58.2 shows the block diagram of a fully integrated quadrature down-converter realized in a 0.7-μm CMOS process.[2] The proposed down-converter does not require any external components, nor does it require any tuning or trimming. It uses a newly developed double-quadrature structure, which renders a very high performance in quadrature accuracy (less than 0.3 degrees in a very large passband). The down-converter topology is based on the use of nMOS transistors in the linear region.[2,6] By using capacitors on the virtual ground, a low-frequency op-amp can be used for down-conversion. The MOS transistors in the linear region result in very high linearity (input-referred IP3 is +27 dBm) for both the RF and the LO input. The advantages of such high linearity on both inputs are, as explained in the previous section, that the mixer can handle a very high IMFDR3, resulting in no need for any kind of HF filtering. This opens the way to the implementation of a fully integrated receiver.

The LNA

As denoted in the previous section, the HF down-conversion mixer tends to have a high noise floor; if the mixer is positioned directly behind the antenna, small antenna signals will be drowned in noise and the overall receiver sensitivity will be low. In order to increase the receiver sensitivity and the SNR at minimum antenna input power, the antenna signal has to be pushed above the noise floor of the mixer by means of a low noise amplifier (LNA). As long as the output noise of the LNA is greater than the input noise of the mixer, the sensitivity is fully determined by the LNA noise figure (NF). This is illustrated in Fig. 58.3.

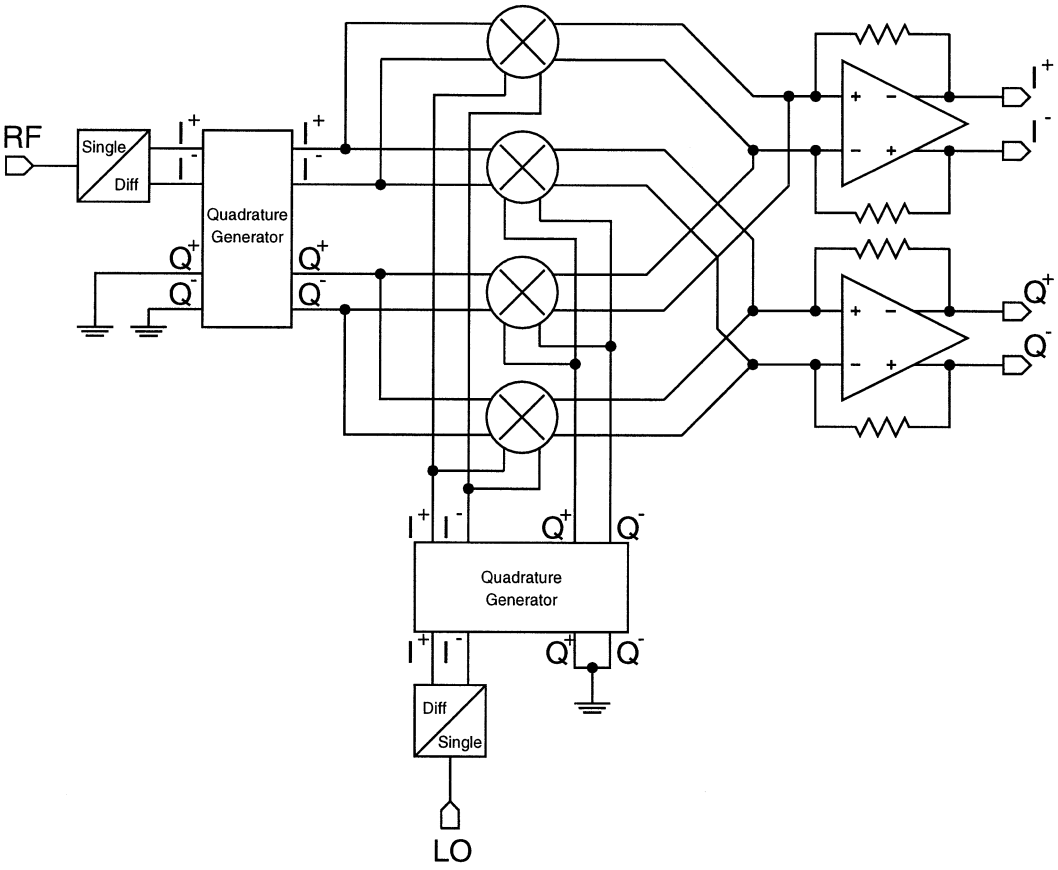

FIGURE 58.2 A double-quadrature down-conversion mixer.

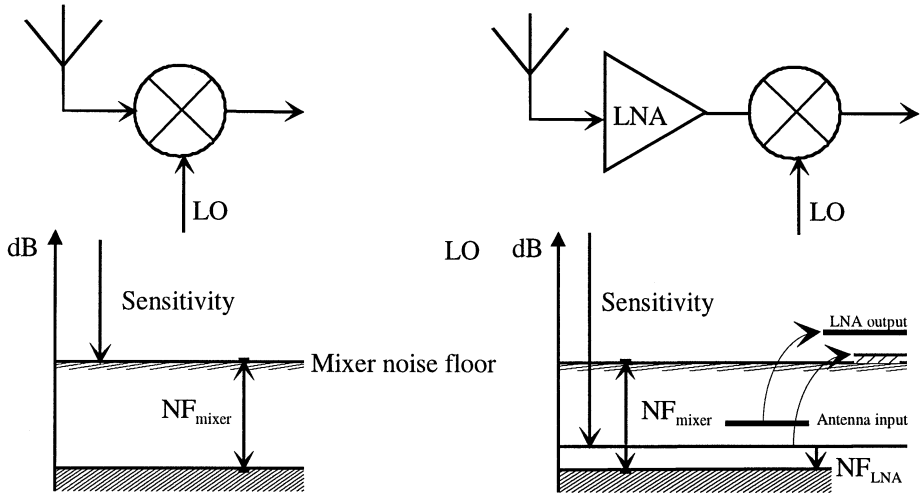

FIGURE 58.3 The benefit of using a low-noise amplifier.

© 2003 by CRC Press LLC

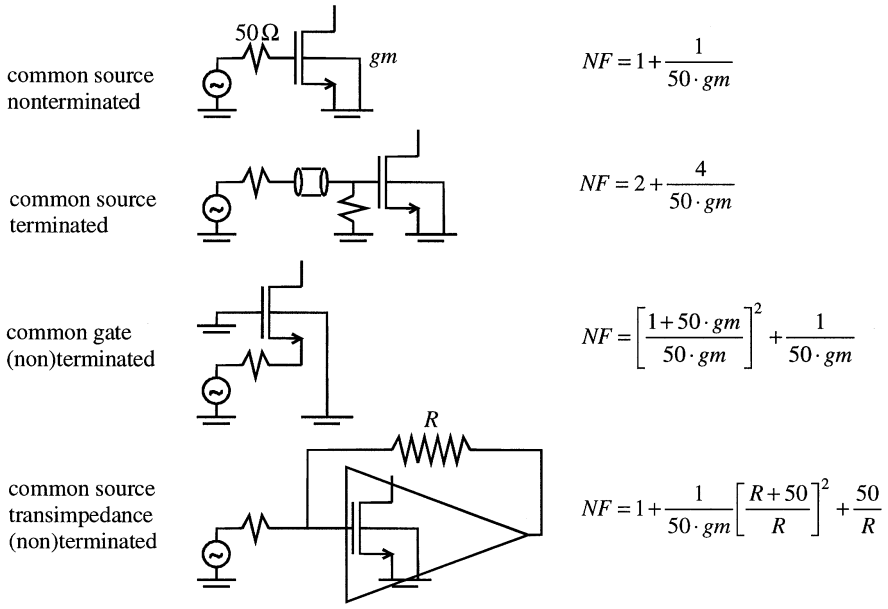

FIGURE 58.4 Noise figure of some common input structures.

The noise figure (NF) of a low-noise amplifier embedded in a 50-Ω system is defined as:

$$\mathrm{NF} = 10\log_{10}\left(\frac{\text{LNA output noise}}{\text{LNA output noise if the LNA itself was noiseless}}\right) \tag{58.5}$$

that is, the real output noise power (dv^2/Hz) of the LNA (consisting of the amplified noise of the 50-Ω source and including all the noise contributions of the amplifier itself to the output noise), divided by the amplified noise of the 50-Ω source only (dv^2/Hz). In this way, the noise figure can be seen as the deterioration of the SNR due to insertion of the non-ideal amplifier. The noise figure is generally dominated by the noise of the first device in the amplifier.

Figures 58.4 and 58.5 compare some common input structures regarding noise. As can be seen from the NF equations and the plotted noise figure as function of the g_m of the transistor for the different topologies, the non-terminated common-source input stage and the (terminated) transimpedance stage are superior as far as noise is concerned. For those circuits, the NF can be approximated as:

$$\left(NF - 1\right) = \frac{1}{50 \cdot g_m} = \frac{\left(V_{gs} - V_t\right)}{50 \cdot 2 \cdot I} \tag{58.6}$$

indicating that a low-noise figure needs a high transconductance in the first stage. In order to generate this transconductance with high power efficiency, a low $V_{gs} - V_t$ is preferred. However, this will result in a large gate capacitance. Together with the 50-Ω source resistance in a 50-Ω antenna system, the achievable bandwidth is limited by:

$$f_{3dB} \cong \frac{1}{2\pi \cdot 50\Omega \cdot C_{gs}} \tag{58.7}$$

Together with Eq. (58.6), this results in (f_T is the cutoff frequency of the input transistor)

© 2003 by CRC Press LLC

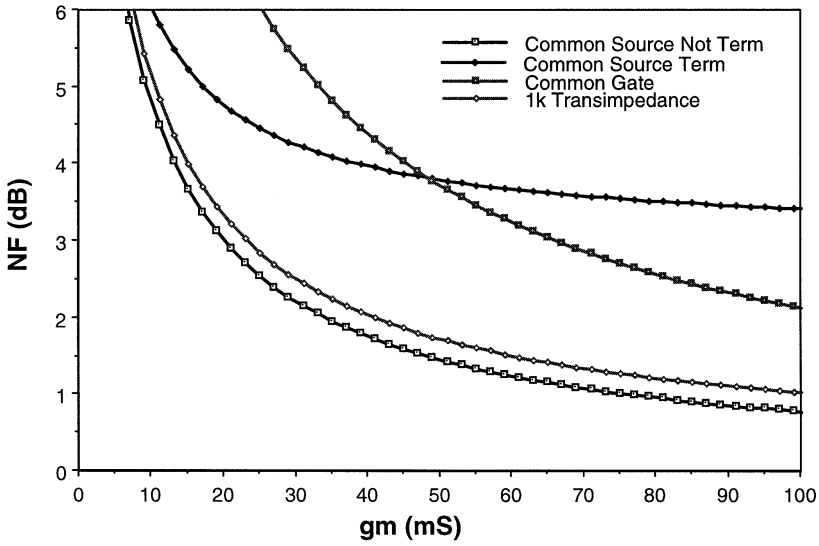

FIGURE 58.5 Performance comparison.

$$\left(\mathrm{NF}-1\right)=\frac{f_{3dB}}{f_T} \tag{58.8}$$

Due to overlap capacitances and Miller effect, this relationship becomes approximately (f_d is the 3-dB point of a transistor in diode configuration):[11]

$$\left(\mathrm{NF}-1\right)=\frac{f_{3dB}}{f_d} \tag{58.9}$$

This means that a low-noise figure can only be achieved by making a large ratio between the frequency performance of the technology (f_d) and the working frequency (f_{3dB}). Because for a given technology, f_d is proportional to $V_{gs} - V_t$, this requires a large $V_{gs} - V_t$ and, associated with it, a large power drain. Only by going to real deep sub-micron technologies, will the f_d be high enough to achieve GHz working frequencies with low $V_{gs} - V_t$ values. Only then can the power drain be reduced to an acceptable value.

In practice, the noise figure and the power transfer from the antenna to the LNA is further optimized by doing, respectively, noise and source impedance matching. These matching techniques often rely on inductors to cancel out parasitics by a resonance phenomenon to boost up the maximum working frequency; the LNA works in "overdrive" mode. Although these aspects are not discussed in this chapter, they are very important when designing LNAs for practical boundary conditions like antenna termination, etc.

In contrast to what one might think, there are still some drawbacks in using short-channel devices for low noise. The large electric field at the drain of a sub-micron transistor may produce hot carriers, having a noise temperature significantly above the lattice temperature.[20] This indicates that a good LDD (lightly doped drain) is as crucial for low noise as it is for device reliability.

At high antenna input powers, the signal quality mainly degrades due to in-band distortion components that are generated by third-order intermodulation in the active elements. The linearity performance of LNAs is generally described by the input-referred, third-order intercept point (IIP3), as can be seen in Fig. 58.6. IIP3 specifies the extrapolated input signal where third-order intermodulation products start to dominate the output.

© 2003 by CRC Press LLC

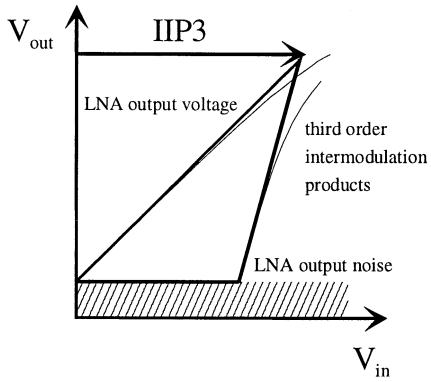

FIGURE 58.6 Linearity performance of an LNA.

As out-of-band signals are, in general, orders of magnitude larger than the wanted signal ("blocking levels"), the mixing of out-of-band signals toward an in-band intermodulation product must be avoided by all means. Therefore, it is very important to know the limiting factors and the dynamics of the most important linearity spec, that is, IIP3. Because the core of an amplifier always contains one or more active elements, we will focus on their internal distortion mechanisms.

Long-channel transistors are generally described by a quadratic model. Consequently, a one-transistor common-source amplifier ideally suffers only from second-order distortion and produces no third-order intermodulation products. As a result, high IP3 values should easily be achieved. In fact,

$$\mathrm{IM2} = \frac{1}{2}\frac{v}{V_{gs} - V_t} \quad \text{and} \quad \mathrm{IM3} = 0 \tag{58.10}$$

where v denotes the input amplitude of the amplifier.

However, when the channel length decreases toward deep sub-micron, this story no longer holds; third-order intermodulation starts to become important. To understand the main mechanism behind third-order distortion in a sub-micron CMOS transistor, we start from the equation for the drain current of a short-channel transistor,

$$I_{ds} = \frac{\mu_0 C_{ox}}{2n} \cdot \frac{W}{L} \cdot \frac{\left(V_{gs} - V_t\right)^2}{1 + \Theta \cdot \left(V_{gs} - V_t\right)} \tag{58.11}$$

with

$$\Theta = \theta + \frac{\mu_0}{L_{eff} \cdot v_{\max} \cdot n} \tag{58.12}$$

where θ stands for the mobility degradation due to the transversal electrical field (surface scattering at the oxide–silicon interface) and the $\frac{\mu}{L_{eff} \cdot v_{\max} \cdot n}$-term models the degradation caused by the longitudinal electric field (electrons reaching the thermal saturation speed). As the $_\theta$-term is small in today's technologies (increasingly better quality of the oxide–silicon interface), it can often be neglected relative to the longitudinal term. For a typical 0.5 μm CMOS technology, the Θ-parameter equals about 0.9.

It can be seen from Eq. (58.11) that for large values of $V_{gs} - V_t$, the current becomes a linear function of $V_{gs} - V_t$. The transistor is then operating in the velocity saturation region. For smaller vales of $V_{gs} - V_t$, the effect of Θ consists apparently of "linearizing" the quadratic characteristic; but in reality, the effect results in an intermodulation behavior that is worse than in the case of quadratic transistors. Indeed, we

© 2003 by CRC Press LLC

will have a slightly lower amount of second-order intermodulation, but it comes at the cost of third-order intermodulation.

The following equations for the intermodulation ratios *IMx* can be found[13] by calculating the Taylor expansion of the drain current around a certain $V_{gs} - V_t$ value:

$$\mathrm{IM2} = \frac{v}{V_{gs} - V_t} \cdot \frac{1}{(1+r)\cdot(2+r)} \tag{58.13}$$

and

$$\mathrm{IM3} = \frac{3}{4}\frac{v}{(V_{gs} - V_t)} \cdot \frac{v}{V_{sv}} \cdot \frac{1}{(1+r)^2\cdot(2+r)} \tag{58.14}$$

where

$$V_{sv} = \frac{1}{\Theta} \tag{58.15}$$

represents the transit voltage between strong inversion and velocity saturation and

$$r = \frac{V_{gs} - V_t}{V_{sv}} \equiv \Theta\cdot(V_{gs} - V_t) \tag{58.16}$$

denotes the relative amount of velocity saturation. The transit voltage V_{sv} depends only on technology parameters and is about 2 V for a 0.7-μm CMOS technology. For deep sub-micron processes (e.g., a 0.1-micron technology), this voltage becomes even smaller than 300 mV, which is very close to the $V_{gs} - V_t$ at the boundary of strong inversion.

Based on Eq. (58.14), one can directly derive an expression for IIP3:

$$\mathrm{IIP3} \cong 11.25 + 10\cdot\mathrm{Log}_{10}\left((V_{gs} - V_t)\cdot V_{sv}\cdot(1+r)^2\cdot(2+r)\right) \tag{58.17}$$

This value is normalized to 0 VdBm, the voltage that corresponds to a power of 0 dBm in a 50-Ω resistor. For the 0.5-μm technology that was mentioned before and a $V_{gs} - V_t$ value of 0.2 V, IIP3 equals +9.5 VdBm. It is worth noting that for a given L_{eff}, the intrinsic IIP3-value of a transistor is only a function of the gate overdrive.

In Fig. 58.7, the formula for IP3 is evaluated for a minimum-length transistor in three different technologies. As can be seen from the figure, for a given L_{eff}, the linearity becomes better with increasing gate overdrive. For small gate overdrives, the increase in IIP3 is proportional to the square root of $V_{gs} - V_t$. At high $V_{gs} - V_t$ values (near velocity saturation), the increase in IIP3 becomes even more pronounced. However, this region of operation exhibits a very low transconductance efficiency (g_m/I_{ds}), particularly for sub-micron transistors, where this parameter is given by

$$\frac{g_m}{I_{ds}} = \frac{2}{V_{gs} - V_t} \cdot \frac{1 + \Theta\cdot(V_{gs} - V_t)}{1 + 2\Theta\cdot(V_{gs} - V_t)} \tag{58.18}$$

The influence of L_{eff} on IIP3 can be seen in Fig. 58.7; For practical values of the gate overdrive, the linearity gets worse with decreasing gate length, because V_{sv} is proportional to L_{eff}. This may pose a

© 2003 by CRC Press LLC

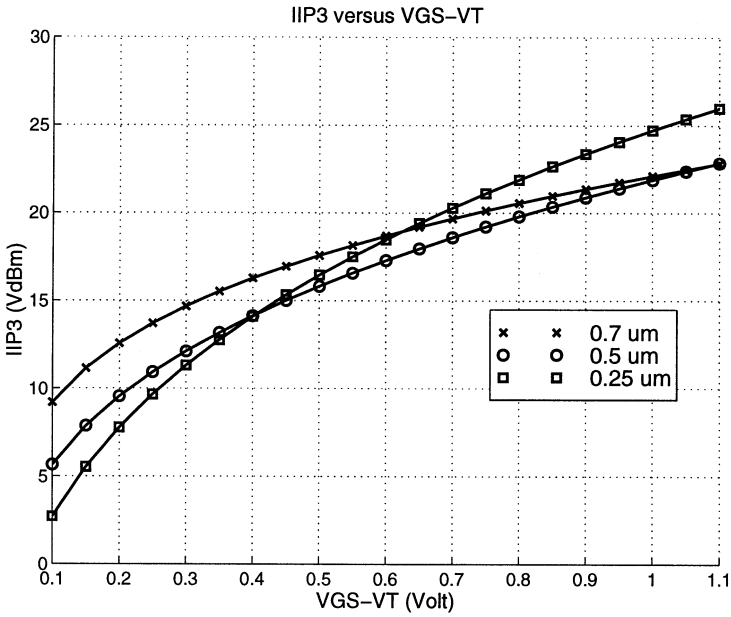

FIGURE 58.7 IIP3 vs. $V_{gs} - V_t$ for three different technologies.

problem when very small transistor lengths are required to reduce the power drain and a high IP3 is necessary to avoid the blocking filters. For large values of the gate overdrive, there is a point where the intermodulation performance of a short-channel transistor gets better compared to a large-channel one, because the first already enters the velocity saturation region. As mentioned before, this region of operation is not highly recommended.

Nevertheless, when a certain IIP3 is required, there are basically two methods to ensure this: using a high enough $V_{gs} - V_t$ or using some kind of feedback mechanism (e.g., source degeneration). It can be shown that for the same equivalent g_m and the same distortion performance, the required dc current is lower when local feedback at the source is applied. It comes, however, at the cost of a larger transistor width, eventually compromising the amplifier bandwidth.

58.4 The Synthesizer

Synthesizer Topology

The *frequency synthesizer* generates the local oscillator signal, responsible for the correct frequency selection in the up- and down-converters. Since the frequency spectrum in modern wireless communication systems must be used as efficiently as possible, channels are placed very close together. The signal level of the desired receiving channel can be made very small, whereas adjacent channels can have very large power levels. Therefore, the phase noise specifications for the LO signal are very high, which makes the design of the frequency synthesizer very critical.

Meanwhile, mobile communication means low power consumption, low cost, and low weight. This implies that a completely integrated synthesizer is desirable, where integrated means a standard CMOS technology without any external components or processing steps. Usually, the frequency synthesizer is realized as a phase-locked loop (PLL) as shown in Fig. 58.8. The most critical building blocks of a PLL for integration in CMOS are the building blocks that operate at high frequency: the voltage-controlled oscillator (VCO) and the prescaler. Both will be discussed in the following sections.

© 2003 by CRC Press LLC

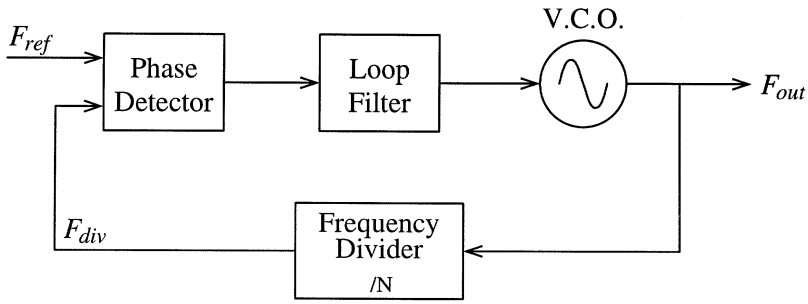

FIGURE 58.8 PLL-based frequency synthesizer.

As stated previously, the most important specification of a frequency synthesizer is low phase noise. The following formulae indicate how the noise of the different building blocks is transferred toward the synthesizer's output.

$$\frac{\theta_{out}(s)}{\theta_{vco}(s)} = \frac{N \cdot s}{N \cdot s + K_{pd} \cdot G_{lf}(s) \cdot K_{vco}} \tag{58.19}$$

$$\frac{\theta_{out}(s)}{\theta_{other}(s)} = \frac{N \cdot K_{pd} \cdot G_{lf}(s) \cdot K_{vco}}{N \cdot s + K_{pd} \cdot G_{lf}(s) \cdot K_{vco}} \tag{58.20}$$

with θ_{out} the synthesizer's output noise, θ_{vco} the phase noise of the VCO, θ_{other} the phase noise of the reference signal, the prescaler, the phase detector, and the loop filter, N the prescaler division factor, K_{pd} the phase detector gain, $G_{lf}(s)$ the loop filter transfer function, and K_{vco} the VCO gain.

With $G_{lf}(s)$ as the transfer function of a low-pass filter, the phase noise of the VCO is high-passed toward the output. The phase noise of the other components is low-passed. In other words, the VCO is the main contributor for out-of-band phase noise, while the other building blocks account for the in-band noise.

As can be seen, the choice of the loop bandwidth is critical for phase noise performance. In order to have enough suppression of phase noise at frequency offsets, important for communication standards (e.g., 600kHz for GSM and DCS-1800) and of spurious due to the reference signal, the loop bandwidth cannot be chosen very large (a few kHz typically). Also, for stability reasons, the loop bandwidth has to be small compared to the PLL reference frequency. To realize relatively small loop bandwidths, large capacitor and resistor values are necessary to implement the large time constant. In current commercial designs, the capacitors are often implemented off-chip, to limit the chip area. To go to full integration of the frequency synthesizer, a way must be found to implement the loop filter without the need for large amounts of capacitance. Several possibilities exist.

The first possibility is to increase the resistance needed to create the large time constant of a narrow low-pass filter, which means a decrease of capacitance. The disadvantage of this approach is the increase of loop filter phase noise. Hence, a trade-off between integrated capacitance and phase noise exists.

A more appealing approach is the one used in Reference 31. Here, a type-II fourth-order PLL is integrated, using a dual-path filter topology. The loop filter consists of two filter paths: one active filter path and one passive filter path. By combining the signals of both paths, a zero is realized without the need for an extra capacitor and resistor. The zero is necessary to provide enough phase margin for loop stability. The principle is explained in Fig. 58.9. In this way, the integrated capacitance is small enough to be integrated on-chip, without degrading the phase noise performance. The total chip area was only 1.9 μm by 1.6 μm.

© 2003 by CRC Press LLC

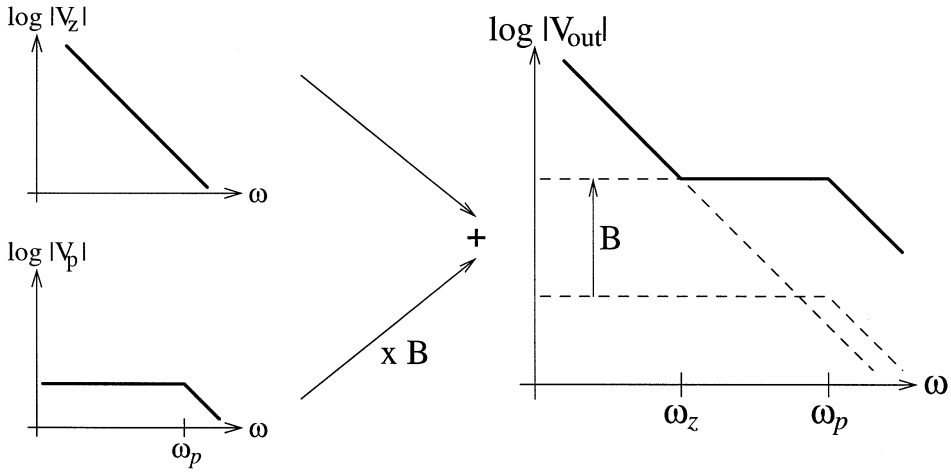

FIGURE 58.9 Dual-path filter principle.

A third possibility is increasing the reference frequency. As a consequence, the loop bandwidth can be made larger, with still enough suppression of the reference spurious noise. This means less integrated capacitance and a better PLL settling time. In addition, the prescaler's division factor *N* will be decreased. As can be seen in Eq. (58.20), the phase noise of the phase detector, the loop filter, the reference signal, and the prescaler is multiplied by *N*. In other words, increasing the reference frequency also results in better in-band phase noise. One disadvantage exists. The prescaler can only divide by integer values, so the smallest frequency step that can be synthesized is equal to the reference frequency. In GSM and DCS-1800 systems, this would mean that the reference frequency must be 200 kHz in order to select all possible channels. This problem can be circumvented by the use of the fractional-N technique. This technique allows the use of fractional division factors by very fast switching between different integer division factors. By combining fractional-N with delta-sigma modulation,[32] the spurs generated by the switching action are shaped to high-frequency noise. This noise can then be filtered by the PLL loop filter.

The Oscillator

As stated above, the *oscillator* will be the main source of out-of-band phase noise. Therefore, its design is one of the most critical parts in the integration of a frequency synthesizer for high-quality communication standards. For the realization of a gigahertz VCO in a sub-micron CMOS technology, two options exist: ring oscillators or oscillators based on the resonance frequency of an LC-tank. The inductor in this LC-tank can be implemented as an active inductor or a passive one. It has been shown that for ring oscillators[21] as well as active LC-oscillators,[22] the phase noise is inversely related to the power consumption.

$$\text{Ring osc. (Ref. 21):}\quad L\{\Delta\omega\} \sim kTR\left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = \frac{1}{R}$$
$$\text{Active - LC (Ref. 22):}\quad L\{\Delta\omega\} \sim \frac{kT}{2\omega C}\cdot\left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = 2\omega C \tag{58.21}$$

Therefore, the only viable solution to a low-power, low-phase-noise VCO is an LC-oscillator with a passive inductor. In this case, the phase noise changes proportionally with the power consumption:

© 2003 by CRC Press LLC

$$\text{Passive-LC (Ref. 22):}\quad L\{\Delta\omega\} \sim kTR\left(\frac{\omega}{\Delta\omega}\right)^2 \quad \text{with} \quad g_m = R(\omega C)^2 \tag{58.22}$$

As could be expected, the only limitation in this oscillator is the integrated passive inductor. Equation (58.22) shows that for low phase noise, the resistance R (i.e., the equivalent series resistance in the LC-loop) must be as small as possible. A low resistance also means low losses in the circuit and thus low power needed to compensate for these losses. Capacitors are readily available in most technologies. But since the resistance R will be dominated by the contribution of the inductors' series resistance, the inductor design is critical. Three solutions exist.

Spiral inductors on a silicon substrate usually suffer from high losses in this substrate, which limit the obtainable Q-factor. Recently, techniques have been developed to etch this substrate away underneath the spiral coil in a post-processing step.[7,23] The cavity created by such an etching step can clearly be seen in Fig. 58.10. However, since there is an extra etching step required after normal processing of the ICs, this technique is not allowed for mass production.

For extremely low phase noise requirements, the concept of bondwire inductors has been investigated. Since a bondwire has a parasitic inductance of approximately 1 nH/mm and a very low series resistance, very-high-Q inductors can be created. Bondwires are always available in IC technology, and can therefore be regarded as being standard CMOS components. Two inductors, formed by four bondwires, can be combined in an enhanced LC-tank[22] to allow a noise/power trade-off. A microphotograph of the VCO is shown in Fig. 58.11.[25] The measured phase noise is as low as –115 dBc/Hz at an offset frequency of 200 kHz from the 1.8-GHz carrier. The power consumption is only 8 mA at 3 V supply. Although chip-to-chip bonds are used in mass commercial products,[28] they are not characterized on yield performance for mass production. Therefore, the industry is reluctant with regard to this solution.

The most elegant solution is the use of a spiral coil on a standard silicon substrate, without any modifications. Bipolar implementations do not suffer from substrate losses because they usually have a

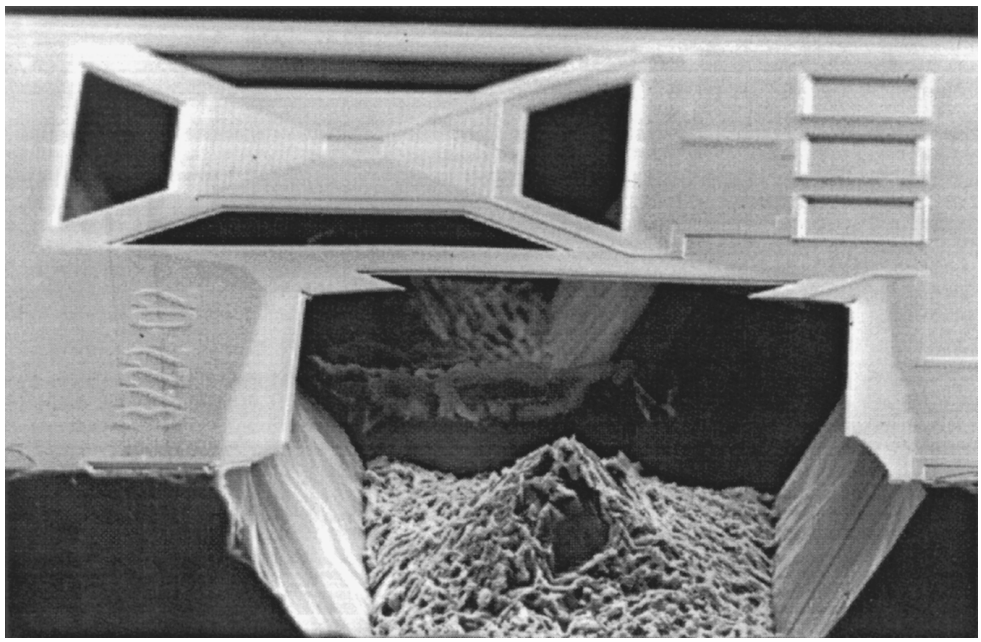

FIGURE 58.10 Etched spiral inductor.

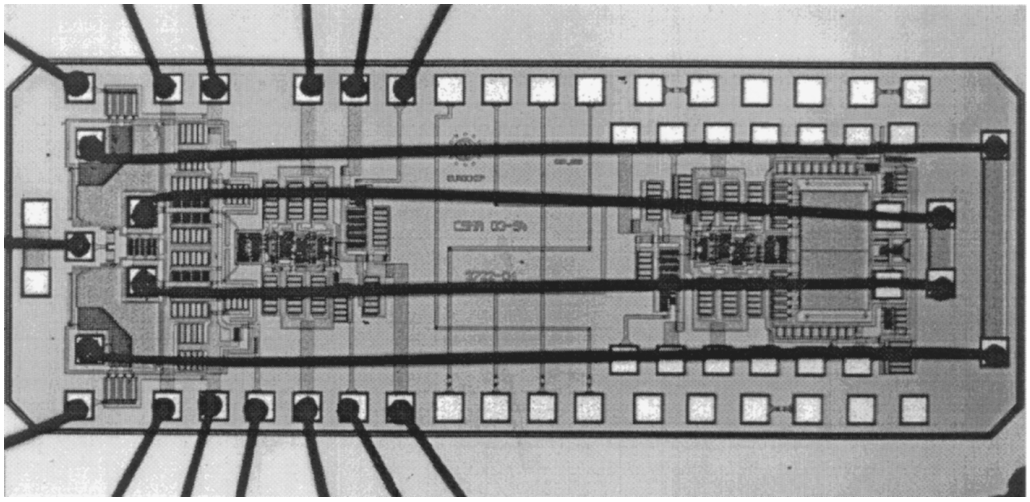

FIGURE 58.11 Microphotograph of the bondwire LC-oscillator.

high-ohmic substrate.[24] Most sub-micron CMOS technologies use a highly doped substrate, and therefore have large induced currents in the substrate, which is responsible for the high losses. The effects present in these low-ohmic substrates can be investigated with finite-element simulations. The finite-element simulations also take the losses in the metal conductors into account. Three phenomena contribute to these losses. The first is the dc series resistance of the metal. The others are high-frequency effects, the skin effect, and eddy currents. Due to the skin effect, the metal turns are only partially used for conduction of the high frequency current. Eddy currents are generated by the changing magnetic field that crosses the metal lines, resulting in an increased resistance, especially in the inner turns of the inductors. This analysis can lead to a coil design optimized for a certain technology. A coil was implemented, using the above analysis, in a spiral-inductor LC-oscillator. The technology is a standard two-metal layer, 0.4-μm CMOS technology. With a power consumption of only 11 mW, a phase noise of –122.5 dBc/Hz at 600 kHz offset of the 1.8 GHz carrier has been obtained.[29] A microphotograph is shown in Fig. 58.12.

The Prescaler

To design a high-speed, dual-modulus prescaler, a new architecture has been developed that is based on the 90° phase relationship between the master and the slave outputs of an M/S toggle-flip-flop.[26] This architecture is shown in Fig. 58.13. No additional logic is present in the high frequency path to realize the dual-modulus division, as is the case in classic prescalers, based on synchronous counters. Here, the dual-modulus prescaler is as fast as an asynchronous fixed divider. Using this new principle, a 1.75-GHz input frequency has been obtained at a power consumption 24 mW and 3 V power supply. At 5 V power supply, input frequencies above 2.5 GHz can even be processed in a standard 0.7-μm CMOS technology. By going to sub-micron technologies, even higher frequencies can be obtained at low power consumption.

Fully Integrated Synthesizer

The fully integrated VCO and dual-modulus prescaler make it possible to integrate a complete LO synthesizer in a standard CMOS technology, without tuning, trimming, or post-processing, that achieves modern telecom specs. Using the dual-path filter topology for minimizing the necessary integrated capacitance, a type-II, fourth-order, fully integrated PLL frequency synthesizer for DCS-1800 applications has been realized. The PLL is implemented in a standard 0.4-μm CMOS, achieving a phase noise of –121 dBc/Hz at 600 kHz offset frequency, while consuming only 51 mW from a 3-V power supply. The

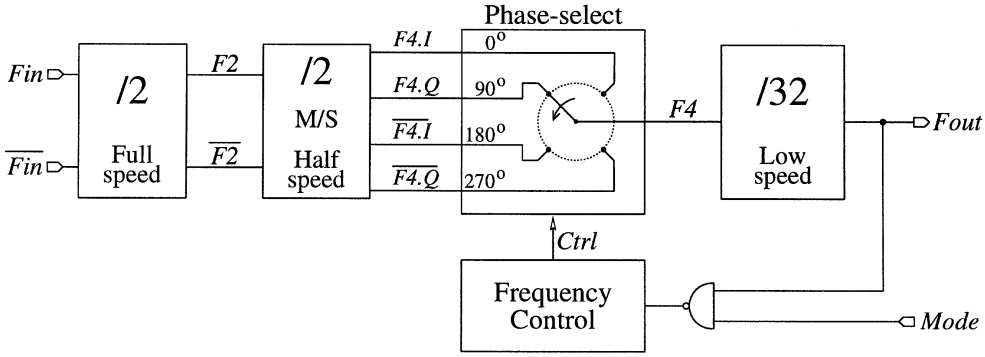

FIGURE 58.13 New dual-modulus prescaler architecture.

integrated capacitance could be decreased to less than 1 nF, for a loop bandwidth of 45 kHz, resulting in a chip area of 1.7 μm by 1.9 μm. A chip microphotograph is shown in Fig. 58.14.

58.5 The Transmitter

For communication systems like GSM, two-way communication is required and a transmitter circuit must be implemented to achieve a full transceiver system. In the open literature, most reported mixer circuits in CMOS are down-conversion mixers. However, as will be explained in the first section below, there is a huge difference between receivers. This implies that a lot of research for the development of CMOS transmitter circuits still needs to be done.

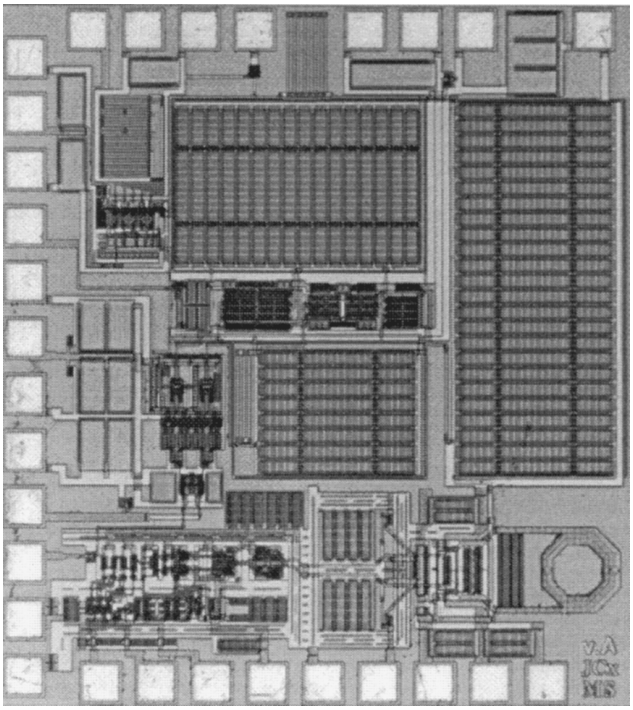

FIGURE 58.14 A fully integrated frequency synthesizer.

Down-Conversion vs. Up-Conversion

The modulation of the baseband signals on the local oscillator carrier frequency requires an up-conversion mixer topology. In classical bipolar transceiver implementations, the up- and down-converter mixer use typically the same four-quadrant topology. However, some fundamental differences exist between up- and down-converters, which can be exploited to derive optimal dedicated mixer topologies.

In a down-conversion topology, the two input signals are at a high frequency (e.g., 900 MHz for GSM systems) and the output signal is a low-frequency signal of maximum a few MHz for low-IF or zero-IF receiver systems. This low-frequency output signal can easily be processed making optimal use of the advantages of feedback circuits. Also, high-frequency spurious signals (e.g., LO feedthrough) can be filtered.

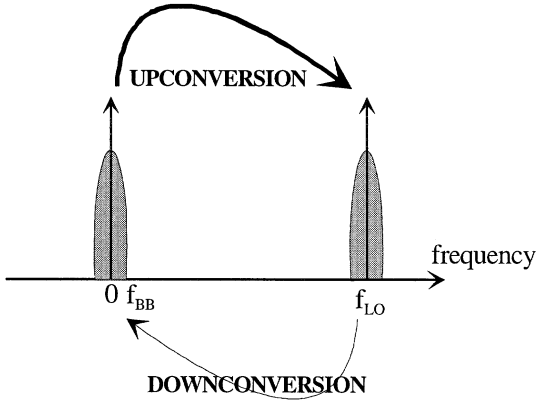

FIGURE 58.15 The difference between up-conversion and down-conversion.

© 2003 by CRC Press LLC

For up-conversion mixers, the situation is totally different. The high frequent local oscillator (LO) and the low frequent baseband (BB) input signal are multiplied to form a high frequent (RF) output signal. All further signal processing has to be performed at high frequencies, which is very difficult and power consuming when using current sub-micron CMOS technologies. Furthermore, all unwanted signals (like the intermodulation products and LO-leakage) have to be limited to a specified level (e.g., below –30 dBc) as they cannot be filtered.

Also, the specifications have to be interpreted differently for both kinds of mixer circuits: for example, an important specification for down-conversion mixers is the conversion gain G_c, defined as the ratio between the output signal and the RF input signal. As for a down-conversion mixer, the RF input signal is fixed — and usually very small; G_c is a good measure of the circuit performance. For an up-conversion mixer, the situation is different. G_c would be the ratio between the RF output signal and the baseband signal. However, in this case, both the input ports, the baseband signal, and the LO signal are free design parameters. As it is easier and more power-friendly to amplify the low-frequency signal, a large baseband signal is preferred. Because of this extra design parameter, it should be better to compare up-conversion circuits based on, for example, the same distortion level or on the same output power level.

CMOS Mixer Topologies

Switching Modulators

Many published CMOS mixer topologies are based on the traditional variable transconductance multiplier with cross-coupled differential modulator stages. Since the operation of the classical bipolar cross-coupled differential modulator stages is based on the translinear behavior of the bipolar transistor, the MOS counterpart can only be effectively used in the modulator or switching mode. Large LO-signals have to be used to drive the gates and this results in a huge LO-feedthrough. In CMOS down-converters, this is already a problem; in Reference 9, for example, the output signal level is –23 dBm with an LO-feedthrough signal of –30 dBm, which represents a suppression of only –7 dB. This gives rise to very severe problems in direct up-conversion topologies. Moreover, by using a square wave modulating LO signal, 30% of the signal power is present at the third-order harmonic. This unwanted signal can only be filtered with an extra external output blocking filter.

In CMOS, the variable transconductance stage is typically implemented using a differential pair biased in the saturation region. To avoid distortion problems, large $V_{gs} - V_t$ values or a large source degeneration resistance have to be used, which results in large power drain and noise problems, especially compared with the bipolar converter circuits. This can be avoided by replacing the bottom differential pair by a pseudo-differential topology with MOS transistors in the linear region.[17]

Linear MOS Mixers

Next, an intrinsically linear CMOS mixer topology is presented. The modulation is performed by biasing MOS transistors in the linear region. The circuit is focused on a real single-ended output topology, which avoids the use of external combining and the circuits have been optimized based on the analysis of the non-linearities of the mixer structure. The understanding of the origins of the distortion, results in a better compromise between the linearity, the output signal power, and the power consumption. Therefore, the results of the linearity analysis and some guidelines to optimize the circuit performance are also presented in this section. The general design ideas will be illustrated by numerical data from realized chips[33,34]

Figure 58.16 shows the four up-conversion mixers M1a, M1b, M1c, and M1d and the single-ended output current buffer. The realized mixer topology is based on an intrinsic linear mixer circuit that converts the baseband and LO voltages into modulated currents.

Each mixer transistor converts a quadrature LO voltage and baseband voltage to a linearly modulated current. The expression for the drain-source current for a MOS transistor in the linear region is given by:

$$I_{ds} = \beta\left[\left(V_{gs} - V_t\right)V_{ds} - \frac{V_{ds}^2}{2}\right] \tag{58.23}$$

© 2003 by CRC Press LLC

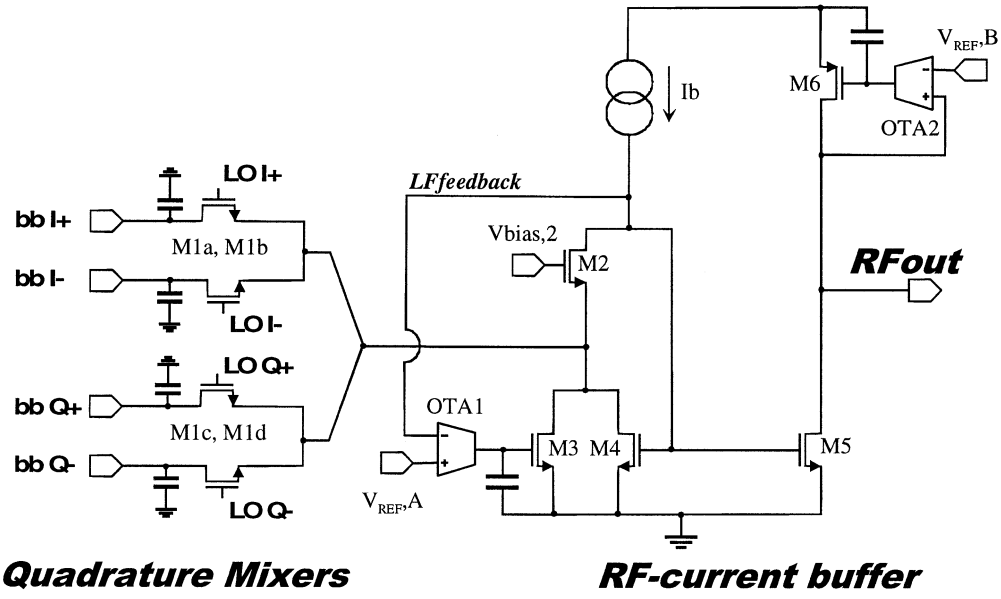

FIGURE 58.16 Schematic of the quadrature up-conversion mixers and output driver.

This equation is rewritten in terms of dc and ac terms as:

$$I_{ds} = \beta\left(V_{ds} + v_{ds}\right)\left(V_{gs} - V_t - \frac{V_d - V_s}{2} + v_g - \frac{v_d + v_s}{2}\right) \tag{58.24}$$

The differential baseband voltage is applied at the drain/source of the mixer transistors M1a and M1b, and the LO signal is applied at the gates of the mixers. Equation (58.24) shows that only two high-frequency components (products with the LO signal v_g) occur in the signal current of each mixer transistor: $\beta V_{DS} v_g$ and $\beta v_{ds} v_g$. The last term is the wanted mixed signal. The first term is proportional to the product of the dc drain-source voltage and the gate (LO) signal. Hence, it is situated at the oscillator frequency. This unwanted signal has been eliminated by applying zero dc drain-source voltage over the mixer transistor. In this way, only the wanted frequency component is formed by each mixer transistor.

The voltage-to-current conversion is performed balanced. The currents are immediately added at the common node, which is made virtual ground by the very low input impedance of the buffer stage (Fig. 58.16).

Quadrature modulation is performed by summing the four modulated currents of each mixer transistor. The resulting single-ended signal current is given by Eq. (58.25).

$$I_{mixer} = \delta\beta\left(v_{bb,I}^2 + v_{bb,Q}^2 + 2 v_{lo} v_{bb}\left(SSB\right)\right) \tag{58.25}$$

where:

δ = A reduction factor due to the degeneration by the finite input conductance of the output stage
β = $\mu C_{ox} W/L$
$v_{bb,I}$ and $v_{bb,Q}$ = the baseband I and Q voltage signals, respectively
v_{lo} = the local oscillator voltage

© 2003 by CRC Press LLC

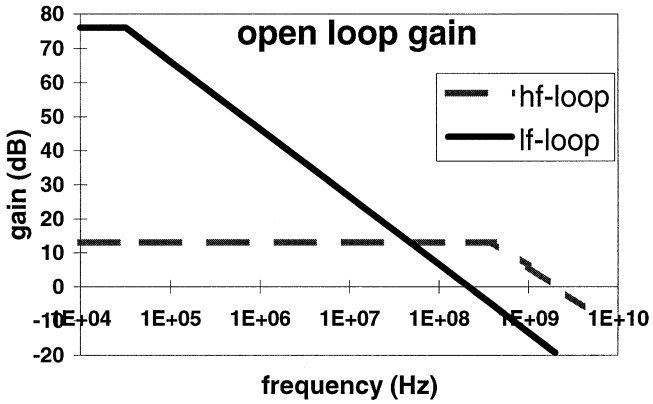

FIGURE 58.17 Open-loop conversion gain of the feedback loops.

The modulated current contains a low frequent square baseband signal and the wanted RF single side band (SSB) mixing product.

The mixer has been designed to have all distortion and intermodulation components, including LO-feedthrough, lower than –30 dBc, which is typical for wireless GSM, DECT, and DCS applications.

An essential improvement in the RF mixer design is the implementation of large on-chip capacitors to the ground at the baseband nodes of the mixer transistors. In this way, the modulated RF current flows through the capacitor and not through the bonding wires, which form a considerable impedance at GHz frequency. The RF signal linearity and amplitude becomes independent of the bonding wire matching and length as the RF signal remains on-chip. Also, a degeneration of the high-frequency signal current by the output impedance of the baseband signal source is prevented by this low impedance.

The Low-Frequency Feedback Loop.

The low-frequency feedback loop, which consists of OTA1 and transistors M2 and M3, suppresses the low-frequency (square baseband) signals to enlarge the dynamic range of the output stage and to prohibit intermodulation products of the unwanted low, frequent, square, baseband mixer current with the high-frequency signal. It also lowers the input impedance of the output stage at low frequencies. The operation can be further explained and illustrated by the numerical data given in Reference 33 and Fig. 58.17. The LF loop has a gain bandwidth of 500 MHz and a high dc gain, which is obtained by using a cascoded OTA structure. The large gain results in a very small (<1 Ω) LF input impedance. In this way, no LF voltage signal is formed at the summing node. This is absolutely essential to obtain a linear operation of the mixer as an additional voltage signal is also up-converted. This structure offers the advantage that the LF and HF modulated current components are separated, and only the high-frequency component of the signal current is mirrored to the output. The dc current through M3 needs to be sufficiently large to reject all the LF current generated in the mixer transistors.

The High-Frequency Current Buffer.

The high-frequency current buffer (M2, M4) ensures a very low input impedance at high frequencies to realize the virtual ground node and mirrors the RF current component (~vlo·vbb) to the output. In Reference 33, a 2.0-GHz GBW was obtained by designing gm_4 = 14 mS, consuming 5 mA dc current, and the parasitic capacitance at node 2 = 1.1 pF. As the loop gain is unity at 2 GHz, the input impedance of the output driver is determined by $1/g_m2$ = 12 Ω (Fig. 58.18). This low impedance also ensures the stability of the HF feedback loop. The pole at node 1, determined by the parasitic capacitance at the summing node and this input impedance, is at more than 3 times the GBW of HF feedback loop. For the second-order feedback system, this results in a phase margin of more than 68°.

© 2003 by CRC Press LLC

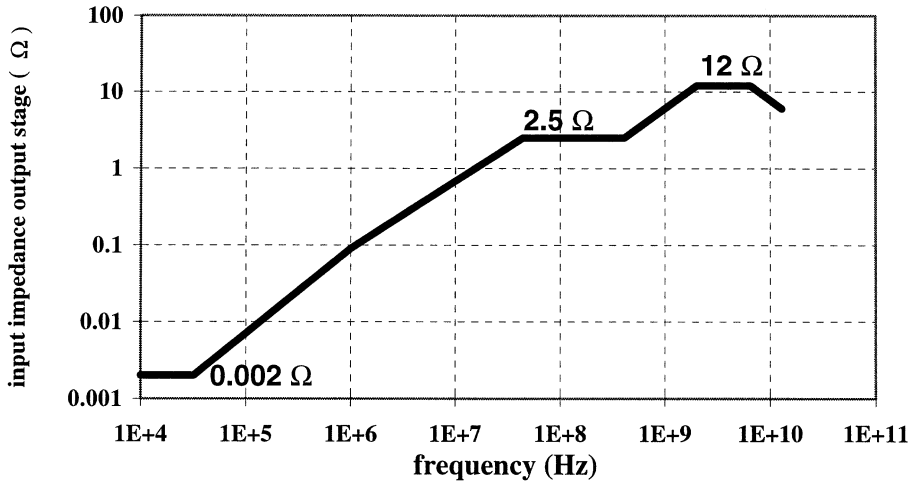

FIGURE 58.18 Input impedance on the virtual ground summing node.

Analysis of the Non-Linearities and the LO-Feedthrough

To obtain an optimal tradeoff between distortion, power consumption, frequency performance, signal power, and distortion, a profound analysis of the causes of the non-linearities is indispensable.

First, the intrinsic non-linearity of the voltage-to-current conversion by the mixer transistors is examined. As the LO feedthrough is also an unwanted signal in the signal band, it is also covered in this section.

A non-ideal virtual ground at the summing node has severe consequences for the modulated signal. A finite output conductance of the baseband signal has similar influences on the linearity of the output signal. These elements are investigated.

Intrinsic Non-Linearity of the Mixer Transistors.

Equations (58.24) and (58.25), which describe the generated current, are only valid if a very low impedance is seen at the drain and source nodes of the mixer transistors. If this condition is fulfilled, no unwanted high-frequency mixing components seem to appear in the modulated current. However, both in measurements and in simulations, a significant unwanted signal is noticed at oscillator frequency (f_{lo}) ± 3 times the baseband frequency (f_{bb}). As this signal originates from a product $v_{lo} \cdot v_{bb}^3$, the magnitude of this distortion component is expected to have the same third-order relationship to the baseband signal. However, only a second-order magnitude relationship is perceived if the virtual ground condition is fulfilled. An explanation for this effect has been searched and the result is described in the paragraphs that follow.

The observed phenomenon is a result of the short-channel effects in a MOS transistor. Both the mobility and the threshold voltage are affected by the gate-source and drain-source voltage. However, the calculated impact of the V_t dependency on the signal is an order of magnitude lower than the observed effect.

The distortion component can be explained by exploring the drain-source voltage dependency of μ_{eff} in the β factor. The expressions for β and μ_{eff} in the linear region are given by:

$$\beta = \mu_{eff} C_{ox} W/L, \text{ where } \mu_{eff} = \frac{\mu_0}{1 + \vartheta\left(V_{gs} - V_t\right) + \frac{\mu_0}{V_{max} L} V_{ds}} \tag{58.26}$$

where: μ_{eff} = The effective mobility
μ_0 = The surface mobility
ϑ = The empirical mobility modulation factor
V_{max} = The maximum drift velocity

© 2003 by CRC Press LLC

If the summing node is made virtual ground and zero dc drain-source voltage is applied, drain and source of each mixer transistor alternate when a sinusoidal signal is applied. If the applied baseband signal is positive, the virtual ground node is the source of that mixer transistor; if the signal is negative, this node is the drain. Mathematically, the source and drain voltages of a mixer transistor can be described as:

$$v_s = \frac{v_{bb} - |v_{bb}|}{2} \qquad v_d = \frac{v_{bb} + |v_{bb}|}{2} \tag{58.27}$$

Equation (58.27) can be transformed to:

$$\mu_{eff} = \frac{\mu_0}{1 + \vartheta\left(V_{gs} - V_t\right)_{dc} + \vartheta\left(v_{lo} - \frac{v_{bb}}{2}\right) + \left(\frac{\mu_0}{V_{max}L} + \frac{\theta}{2}\right)|v_{bb}|} \tag{58.28}$$

Substituting v_{bb} by $A\sin(\omega_{bb}t)$ and making the Fourier series expansion of $|v_{bb}|$ results in Eq. (58.29):

$$\mu_{eff} = \frac{\mu_0}{B\left(1 + \frac{\vartheta}{B}v_{lo} - \frac{\vartheta A}{2B}\sin\left(\omega_{bb}t\right) + C\cos\left(2\omega_{bb}t\right) + D\cos\left(4\omega_{bb}t\right) + \ldots\right)}$$

where:

$$A\sin\left(\omega_{bb}t\right) = \text{The baseband signal}$$

$$\begin{aligned} B &= 1 + \left(V_{gs} - V_t\right)_{DC} + \frac{2}{\pi}A\left(\frac{\mu_0}{V_{max}L} + \frac{\theta}{2}\right) \\ &\approx 1 + \left(V_{gs} - V_t\right)_{DC} \\ C &= \frac{A}{B}\frac{4}{\pi 3}\left(\frac{\mu_0}{V_{max}L} + \frac{\theta}{2}\right) \\ D &= \frac{A}{B}\frac{4}{\pi \cdot 3 \cdot 5}\left(\frac{\mu_0}{V_{max}L} + \frac{\theta}{2}\right) \end{aligned} \tag{58.29}$$

The equation for μ_{eff} shows that a second-order baseband frequency component ($\cos(2\,\omega_{bb}t)$) appears. In the dc reduction factor B, the third term is an order of magnitude smaller than 1. Hence, it appears that the magnitude C of the second-order component has only a first-order relationship to the baseband signal amplitude A. In the mixer voltage-to-current relationship, μ_{eff} is multiplied with $v_{lo} \cdot v_{bb}$. As a result, a mixing component at $f_{lo} \pm 3f_{bb}$ occurs. The magnitude of this signal is only second-order related to the amplitude of the baseband signal. This explains the observed effect.

In the amplitude C of this distortion component, $\frac{\mu_0}{V_{max}L}$ is dominant to $\frac{\theta}{2}$ for most sub-micron CMOS technologies. It is important to notice that the distortion is inversely proportional to the gate length. This implies that this effect will become even more important when going to deeper sub-micron technologies.

Oscillator Feedthrough.

As a direct up-conversion topology is used, the oscillator feedthrough cannot be filtered and, consequently, it has to be as low as the other in-band unwanted frequency components. A signal at oscillator

© 2003 by CRC Press LLC

frequency can have several origins: for example, capacitive feedthrough of the gate voltage or a component due to mixing of a dc drain-source voltage with the oscillator gate signal [see Eq. (58.23)]. The last is avoided by applying zero dc drain-source voltage over the mixer transistor, as stated earlier.

Due to the differential input voltages, the capacitive LO-feedthrough is canceled at the virtual ground node. However, this cancellation is never perfect, due to technology mismatch. The capacitive LO-feedthrough of one mixer transistor is given by [Eq. (58.30)].

$$i_{lo} = \left(\frac{C_{ox}}{2} + \frac{C_{ov}}{L} \right) WLv_{lo} 2\pi f \tag{58.30}$$

where: C_{ox} = The oxide capacitance
C_{ov} = The gate-drain overlap capacitance
v_{lo} = The amplitude of the LO signal
f = The LO frequency

When the asymmetry caused by mismatches in the differential mixer structure is taken into account, the expression for the capacitive LO-feedthrough current is given by:

$$\Delta\left(i_{lo}\right) = \delta\left(i_{lo}\right) i_{lo} \tag{58.31}$$

where $\delta(i_{lo})$ is the relative difference in the LO-feedthrough for the differential mixer transistors.

Based on Eqs. (58.25), (58.30), and (58.31), the ratio between the LO feedthrough current and the modulated signal is given in Eq. (58.32).

$$\frac{i_{signal}}{\Delta\left(i_{lo}\right)} = \frac{2\mu C_{ox} \frac{W}{L} v_{bb} v_{lo}}{\delta\left(i_{lo}\right)\left(\frac{C_{ox}}{2} + \frac{C_{ov}}{L} \right) WLv_{lo} 2\pi f} \tag{58.32}$$

This formula can be simplified to:

$$\frac{i_{signal}}{\Delta\left(i_{lo}\right)} = \frac{\mu C_{ox} v_{bb}}{\delta\left(i_{lo}\right)\left(\frac{C_{ox}}{2} + \frac{C_{ov}}{L} \right) L^2 \pi f} \tag{58.33}$$

Even in the case where the two LO-feedthrough currents are added instead of canceled ($\delta(i_{lo}) = 1$), a ratio of 30 dBc signal to LO-feedthrough is achieved with a 1-GHz oscillator signal and a 316 mV baseband signal. If a relative inaccuracy ($\delta(i_{lo})$) of, for example, 10% on the parameters is taken into account, 50 dBc can easily be accomplished. This analysis illustrates the strategy not to rely on cancelling of RF signals to achieve the requirements.

58.6 Toward Fully Integrated Transceivers

Combining all the preceding techniques has resulted in the recent development of single-chip CMOS transceiver circuits.[30] Figure 58.19 provides a microphotograph of the 0.25-μm CMOS transceiver test-circuit. The chip does not require a single external component, nor does it require any tuning or trimming. The objective of this design is to develop a complete system for wireless communications at 1.8 GHz that can be built with a minimum of surrounding components: only an antenna, a duplexer, a power amplifier,

and a baseband signal processing chip. The high level of integration is achieved using a low-IF topology for reception, a direct quadrature up-conversion topology for transmission, and an oscillator with on-chip integrated inductor. The presented chip has been designed for the DCS-1800 system, but the broadband nature of the LNA, the down-converter, the up-converter, and the output amplifier makes the presented techniques equally suited for use at other frequencies, for example, for use in a DCS-1900 or a DECT system. The presented circuit consumes 240 mW from a 2.5-V supply and occupies a die area of 8.6 mm^2.

58.7 Conclusions

The trends toward deep sub-micron technologies have resulted in the exploration by several research groups of the possible use of CMOS technologies for the design of RF circuits. Especially the development of new receiver topologies, such as quasi-IF and low-IF topologies, in combination with highly linear down-converters, has opened the way to fully integrated down-converters with no external filters or components. However, due to the moderate speed performance of the present sub-micron technologies, lower noise circuits in combination with less power drain have to be worked out. The trends toward deep sub-micron technologies will allow us to achieve those goals as long as the short-channel effects do not limit the performance concerning linearity and intermodulation problems.

Concerning synthesizers, in the last few years, high-performance, low phase noise, low power drain, fully integrated VCO circuits have been demonstrated. Starting with difficult post-processing techniques, research has resulted in the use of standard CMOS technologies using bondwires as inductors. Today, even low phase noise performances with optimized integrated spiral inductors in standard CMOS technologies without any post-processing, tuning, trimming, or external components have been announced. This opens the way toward fully integrated receiver circuits.

However, telecommunication systems are usually two-way systems, requiring transmitter circuits as well. It is only recently that CMOS up-converters with moderate output power have been announced in open literature. Again, thanks to the trends toward deep sub-micron technologies, fully integrated CMOS transmitter circuits with an acceptable power consumption will be feasible. This opens the way for fully integrated transceiver circuits in standard CMOS technologies.

59.1 Introduction

What Is and Why Phase-Locked?

Phase-locked loop (PLL) is a circuit architecture that causes a particular system to track with another one. More precisely, PLL synchronizes a signal (usually a local oscillator output) with a reference or an input signal in frequency as well as in phase.

Phase locking is a useful technique that can provide effective synchronization solutions in many data transmission systems such as optical communications, telecommunications, disk drive systems, and local networks, in which data is transmitted in baseband or passband. In general, only data signals are transmitted in most of these applications; namely, clock signals are not transmitted in order to save hardware cost. Therefore, the receiver should have some schemes to extract the clock information from the received data stream in order to recover transmitted data. The scheme is called a *timing recovery* or *clock recovery* circuit.

The cost of electronic interfaces in communication systems is higher in conjunction with the higher data rate. Hence, high-speed circuits are the practical issue of the high data rate systems implementation, and advanced VLSI technology plays an important role in cost reduction for the high-speed communication systems.

Basic Operation Concepts of Phase-Locked Loops (PLLs)

Typically, a PLL consists of three basic functional blocks: a phase detector (PD), a loop filter (LF), and a voltage-controlled oscillator (VCO). The PD detects the phase difference between the VCO output and the input signal, and generates a signal proportional to the phase error. The PD output contains a dc component and an ac component; the former is accumulated and the latter is filtered by the loop filter. The loop filter output that is near a dc signal is applied to the VCO. This almost dc control voltage

© 2003 by CRC Press LLC

changes the VCO frequency toward a direction to reduce the phase error between the input signal and the VCO. Depending on the type of loop filter used, the steady-state phase error will be reduced to zero or to a finite value.

PLL has an important feature: the ability to suppress both the noises superimposed on the input signal and generated by the VCO. The narrower the bandwidth of the PLL, the more effective jitter filtering the PLL can achieve. However, the error of the VCO frequency cannot be reduced rapidly. Although a narrow bandwidth is better for rejecting large amounts of input noise, it also prolongs the settling time in the acquisition process. So, there is a tradeoff between jitter filtering and fast acquisition.

Classification of PLL Types

Different PLL types are built from different classes of building blocks. The first PLL ICs appeared around 1965 and were purely analog devices. In the so-called "*linear PLLs*" (LPLLs), an analog multiplier (four-quadrant) is used as the phase detector, the loop filter is built from a passive or an active RC filter, and the voltage-controlled oscillator is used to generate the output signal of the PLL. In most cases, the input signal to this linear PLL is a sine wave, whereas the VCO output signal is a symmetrical square wave.

The classical *digital PLL* (DPLL) uses a digital phase detector, such as an XOR gate, a JK-flipflop, or a phase-frequency detector (PFD), with the remaining blocks still being the same as LPLL. In many aspects, the DPLL performance is similar to the LPLL.

The function blocks of the *all-digital PLL* (ADPLL) is implemented by purely digital circuits, and the signals within the loop are digital too. Digital versions of the phase detector are the same as DPLL. The digital loop filter is built from an ordinary up/down counter, N-before-M counter, or K-counter.[1] The digital counterpart of the VCO is the digital-controlled oscillator (DCO).[2,3]

Analogous to filter designs, PLLs can be implemented by software such as a microcontroller, microcomputer, or digital signal processing (DSP); this type of PLL is called *software PLL* (SPLL).

59.2 PLL Techniques

Basic Topology

A PLL is a feedback system that operates and minimizes the phase difference between two signals. Figure 59.1 is the basic function block of a PLL, which consists of a phase detector (PD), a loop filter, and a VCO. The PD works as a phase error amplifier. It compares the phase of the VCO output signal $u_o(t)$ with the phase of the reference signal $u_i(t)$ and develops an output signal $u_d(t)$, that is proportional to the phase error θ_e. Within a limited range,

$$u_d(t) = k_d \theta_e \tag{59.1}$$

where k_d represents the gain of the PD and the unit of k_d is volt/rad.

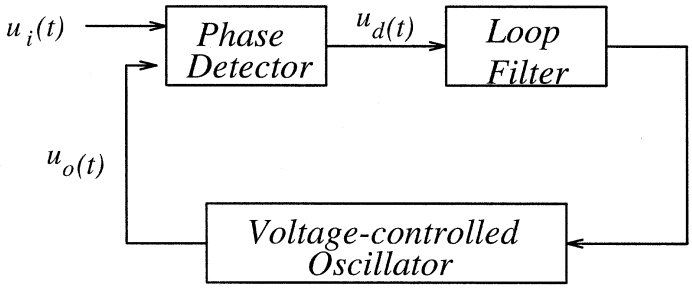

FIGURE 59.1 Basic block diagram of the PLL.

© 2003 by CRC Press LLC

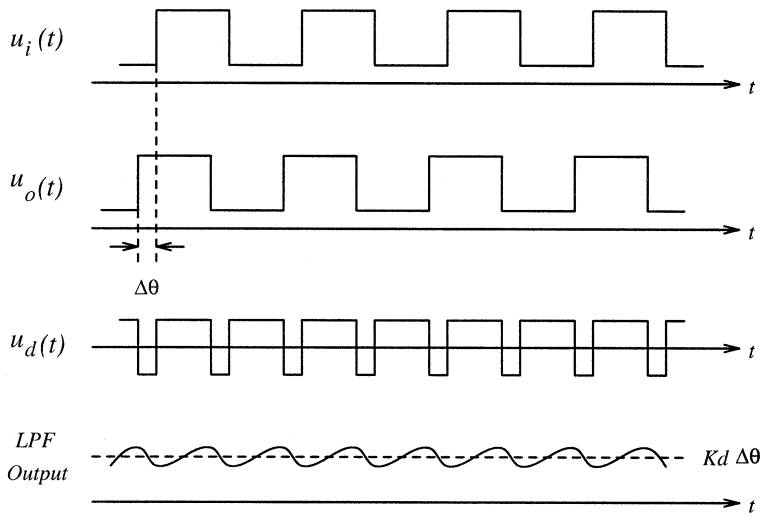

FIGURE 59.2 Waveforms in a PLL.

The output signal $u_d(t)$ of the PD consists of a dc component and a superimposed ac component. The latter is undesired and removed by the loop filter (LPF). Thus, the LPF generates an almost-dc control voltage for the VCO to oscillate at a frequency equal to the input frequency.

How the building blocks of the basic PLL work together will be explained in the following. First, the angular frequency ω_i of the input signal $u_i(t)$ is assumed equivalent to the central frequency ω_o of the VCO signal $u_o(t)$. Now, a small positive frequency step is applied to $u_i(t)$ at $t = t_o$ (shown in Fig. 59.2). $u_i(t)$ accumulates a phase faster than $u_o(t)$ of the VCO does. The PD then generates wider pulses increasingly, which results in a higher dc voltage at the LPF output to increase the VCO frequency. Depending on the type of the loop filter, the final phase error will be reduced to zero or to a finite value.

It is important to note from the descriptions in the above that the loop locks only after two conditions are satisfied: (1) ω_i and ω_o are equal and (2) the phase difference between the input $u_i(t)$ and the VCO output $u_o(t)$ settles to a steady-state value. If the phase error varies with time so fast that the loop is unlocked, the loop must keep on the transient process, which involves both *frequency acquisition* and *phase acquisition*.

To design a practical PLL system, it is required to know the status of the responses of the loop if (1) the input frequency is varied slowly (tracking process), (2) the input frequency is varied abruptly (lock-in process), and (3) the input and the output frequencies are not equal initially (acquisition process). Using linear PLL as an example, these responses will be shown in the following subsections.

Loop Order of the PLL

Second-Order Loop

The loop order of the PLL depends on the characteristics of the loop filter; therefore, the loop filter is a key component that affects the PLL dynamic behavior. Figure 59.3 shows three types of loop filters that are widely used. Figure 59.3(a) is a passive lead-lag filter; the associate transfer function $F(s)$ is given by

$$F(s) = \frac{1 + s\tau_2}{1 + s(\tau_1 + \tau_2)} \tag{59.2}$$

where $\tau_1 = R_1C$ and $\tau_2 = R_2C$. Figure 59.3(b) shows an active lead-lag filter; its transfer function is

© 2003 by CRC Press LLC

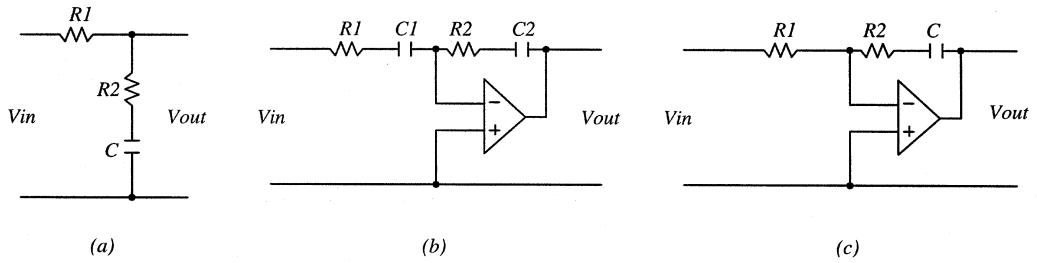

FIGURE 59.3 (a) Passive lead-lag filter, (b) active lead-lag filter, and (c) active PI filter.

$$F(s) = k_a \frac{1+s\tau_2}{1+s\tau_1} \tag{59.3}$$

where $\tau_1 = R_1C_1$, $\tau_2 = R_2C_2$, and $k_a = -\frac{C_1}{C_2}$. A PI filter is shown in Fig. 59.3(c), where PI stands for *Proportional and Integral* action. The transfer function is given by

$$F(s) = \frac{1+s\tau_2}{s\tau_1} \tag{59.4}$$

where $\tau_1 = R_1C$ and $\tau_2 = R_2C$. Their Bode diagrams are shown in Fig. 59.4 respectively. High-order filters could be used in some applications, but additional filter poles introduce a phase shift. High-order systems are not trivial generally to maintain a stable system.

Figure 59.5 shows the linear block diagram of the PLL. According to control theory, the closed loop transfer function of PLL can be derived as

$$H(s) \triangleq \frac{\theta_o(s)}{\theta_i(s)} = \frac{k_d k_o F(s)}{s + k_d k_o F(s)} \tag{59.5}$$

where k_d with units V/rad is called the phase-detector gain, k_o is the VCO gain factor and has units rad/s-V. In addition to the phase transfer function, a phase-error transfer function $H_e(s)$ is defined as follows:

$$H_e(s) \triangleq \frac{\theta_e(s)}{\theta_i(s)} = \frac{s}{s + k_d k_o F(s)} \tag{59.6}$$

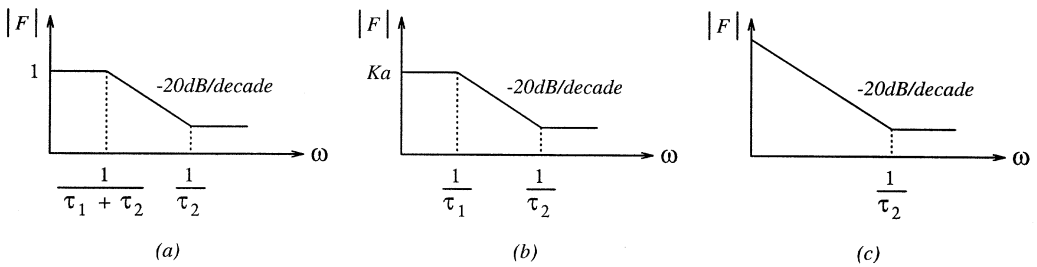

FIGURE 59.4 Bode diagrams of (a) passive lead-lag filter, (b) active lead-lag filter, and (c) active PI filter.

© 2003 by CRC Press LLC

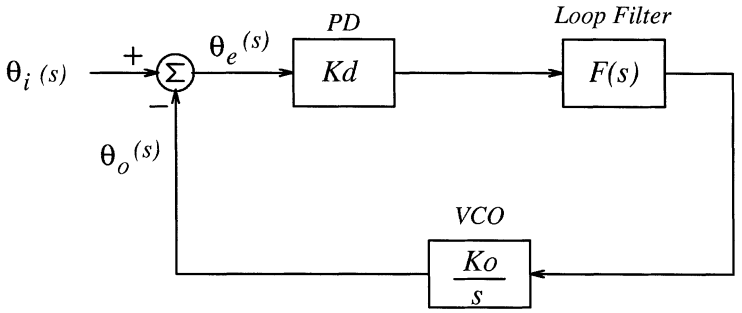

FIGURE 59.5 Linear model of PLL.

The transfer functions of the loop filters shown in Fig. 59.3 are substituted for $F(s)$ in Eq. (59.5) in order to analyze the phase transfer function. We obtain the phase transfer functions as follows:

For the passive lead-lag filter,

$$H(s) = \frac{k_d k_o \dfrac{1+s\tau_2}{\tau_1+\tau_2}}{s^2 + s\dfrac{1+k_d k_o \tau_2}{\tau_1+\tau_2} + \dfrac{k_d k_o}{\tau_1+\tau_2}} = \frac{\omega_n\left(2\zeta - \dfrac{\omega_n}{k_d k_o}\right)s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{59.7}$$

For the active lead-lag filter,

$$H(s) = \frac{k_d k_a k_o \dfrac{1+s\tau_2}{\tau_1}}{s^2 + s\dfrac{1+k_d k_a k_o \tau_2}{\tau_1} + \dfrac{k_d k_a k_o}{\tau_1}} = \frac{\omega_n\left(2\zeta - \dfrac{\omega_n}{k_d k_o k_a}\right)s + \omega}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{59.8}$$

For the active PI filter,

$$H(s) = \frac{k_d k_o \dfrac{1+s\tau_2}{\tau_1}}{s^2 + s\dfrac{k_d k_o \tau_2}{\tau_1} + \dfrac{k_d k_o}{\tau_1}} = \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{59.9}$$

where ω_n is the *natural frequency* and ξ is the *damping factor*. These two parameters are important to characterize a PLL. If the condition $k_d k_o \gg \omega_n$ or $k_d k_o k_o \gg \omega_n$ is true, this PLL system is called a *high-gain loop*. If the reverse is true, the system is a *low-gain loop*. Most practical PLLs are high-gain loops for good tracking performance. For a high-gain loop, Eqs. (59.7) to (59.9) become approximately

$$H(s) \approx \frac{2\zeta\omega_n s + \omega_n^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{59.10}$$

Similarly, assuming a high-gain loop, the approximate expression of the phase-error transfer function $H_e(s)$ for all three loop filter types becomes

© 2003 by CRC Press LLC

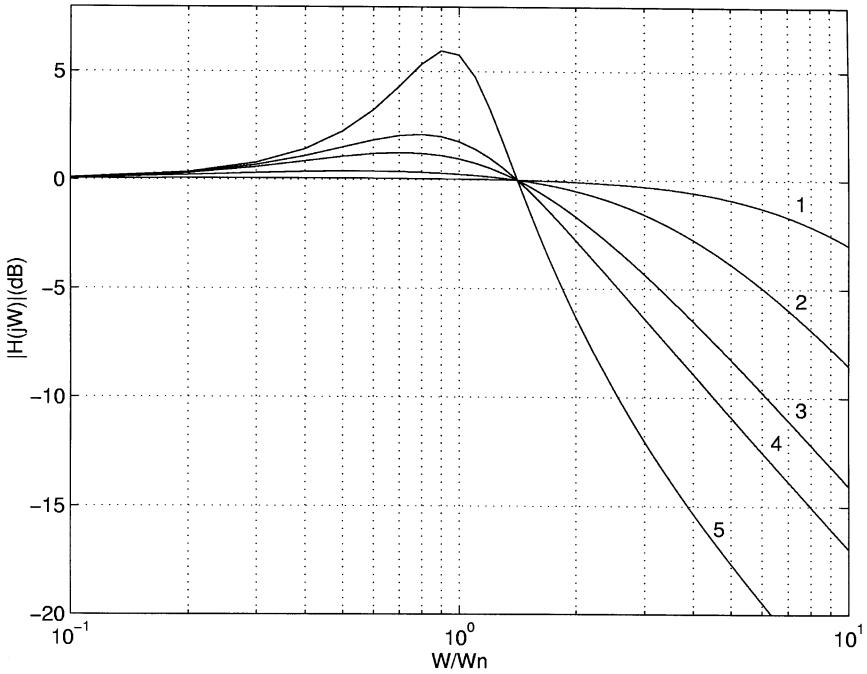

FIGURE 59.6 Frequency responses of the phase transfer function $H(j\omega)$ for different damping factors. Trace 1: ζ = 5, Trace 2: ζ = 2, Trace 3: ζ = 1, Trace 4: 5 = 0.707, Trace 5: 3 = 0.3.

$$H_e(s) \approx \frac{s^2}{s^2 + 2s\zeta\omega_n + \omega_n^2} \tag{59.11}$$

Because the highest power of s in the denominator of the transfer function is 2, the loop is known as the second-order loop.

The magnitude of the frequency responses of $H_e(s)$ for a high-gain loop with several values of damping factor are plotted in Fig. 59.6. It shows that the loop performs a low-pass filtering on the input phase signal. That is, the second-order PLL is able to track both phase and frequency modulations of the input signal as long as the modulation frequency remains within the frequency band roughly between zero and ω_n.

The magnitude of the frequency responses of $H_e(s)$ are plotted in Fig. 59.7. A high-pass characteristic is derived. It indicates that the second-order PLL tracks the low-frequency phase error but cannot track high-frequency phase error.

The transfer function $H(s)$ has a –3dB frequency, ω_{-3db}. ω_{-3db} stands for the closed-loop bandwidth of the PLL. The relationship between ω_{-3db} and ω_n is presented here to provide a comparison with the familiar concept of bandwidth. In the high-gain loop case, by setting $|H(j\omega)| = \frac{1}{\sqrt{2}}$ and solving for ω, we find that

$$\omega_{-3db} = \omega_n \left[2\zeta^2 + 1 + \sqrt{\left(2\zeta^2 + 1\right)^2} \right]^{\frac{1}{2}} \tag{59.12}$$

The relationship between ω_{-3db} and ω_n for different damping factors is plotted in Fig. 59.8.[4]

Other-Order Loop

The second-order PLL with a lead-lag loop filter is commonly used because the lead-lag filter has two time constants to determine the natural frequency and the damping factor independently. Therefore, a

© 2003 by CRC Press LLC

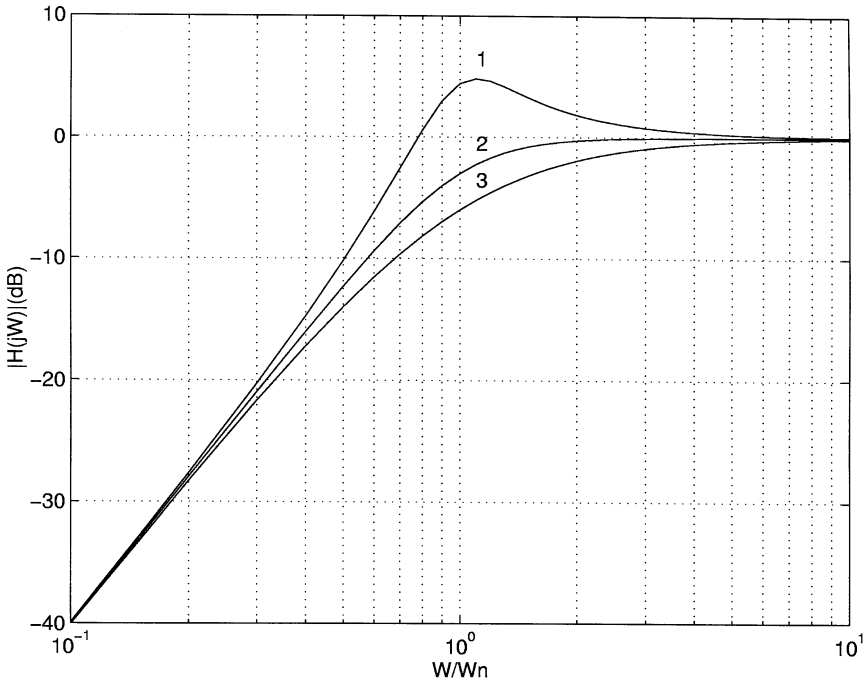

FIGURE 59.7 Frequency responses of the phase-error transfer function $H_e(j\omega)$ for different damping factors. Trace 1: $\zeta = 0.3$, Trace 2: $\zeta = 0.707$, Trace 3: $\zeta = 1$.

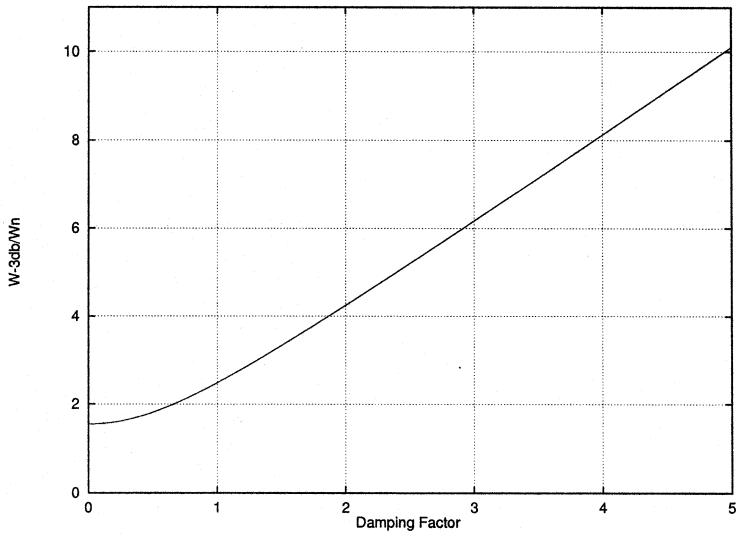

FIGURE 59.8 ω_{-3db} bandwidth of a second-order loop vs. different damping factors.

high dc loop gain for good tracking, while maintaining an overdamped PLL system, can be achieved. No loop filter and single pole loop filter cases are discussed briefly in the following for completeness.

If the loop filter is left out, a first-order loop is obtained. As shown in Fig. 59.5, set $F(s) = 1$ and the closed-loop transfer function can be derived as

© 2003 by CRC Press LLC

$$H(s) = \frac{k}{s+k} \tag{59.13}$$

where $k = k_d k_o$. If it is necessary to design a high dc gain loop for fast tracking, then the bandwidth of the PLL must be wide enough because the dc loop gain k is the only parameter available, which is not suitable for noise suppression. Therefore, fast tracking and narrow bandwidth are incompatible in a first-order loop.

Another commonly used loop filter is the passive lag filter. The transfer function is

$$F(s) = \frac{1}{1+s\tau} \tag{59.14}$$

The closed-loop transfer function can be derived as

$$H(s) = \frac{\frac{k_d k_o}{\tau}}{s^2 + \frac{1}{\tau}s + \frac{k_d k_o}{\tau}} = \frac{\tau\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{59.15}$$

where $\omega_n = \sqrt{\frac{k_d k_o}{\tau}}$ and $\zeta = \frac{1}{2\sqrt{\tau k_d k_o}}$. Although there are two parameters (τ and $k = k_o k_d$) available, three loop parameters must be determined (ω_n, ξ,k). That is if it is necessary to have a large dc loop gain and a narrow bandwidth, the loop will be severely underdamped and the transient response will be poor.

A high-order filter is used for critical applications because it provides better noise filtering. However, it is difficult to design a high-order loop due to some problems such as loop stability.

Tracking Process

The linear model of a PLL shown in Fig. 59.5 is suitable for analyzing the tracking performance of a PLL that is initially locked, but with small phase error. If the phase error changes so abruptly that the PLL loses lock, a large phase error will be induced, even if it happens only momentarily. The unlock condition is a non-linear process that cannot be analyzed by a linear model. The acquisition process will be described later.

At first, consider a step phase error applied to the input. The input phase signal is $\theta_i(t) = \Delta\theta u(t)$, the Laplace transform of the input is $\theta_i(s) = \frac{\Delta\theta}{s}$, which is substituted into Eq. (59.11) to get

$$\theta_e(s) = \frac{\Delta\theta}{s} \frac{s^2}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{59.16}$$

According to the final value theorem of the Laplace transform,

$$\lim_{t\to\infty} \theta_e(t) = \lim_{s\to 0} s\theta_e(s) = 0$$

In other words, the loop will eventually track on the step phase change without steady-state phase error.

Applying a step change of frequency $\Delta\omega$ to the input, the input phase change is a ramp (i.e., $\theta_i(t) = \Delta\omega t$); therefore, $\theta_i(s) = \frac{\Delta\omega}{s^2}$. Substituting $\theta_i(s)$ in Eq. (59.6) and applying the final value theorem, one obtains

$$\begin{aligned} \theta_v &= \lim_{t\to\infty} \theta_e(t) = \lim_{s\to 0} s\theta_e(s) \\ &= \lim_{s\to 0} \frac{\Delta\omega}{s + k_d k_o F(s)} \end{aligned} \tag{59.17}$$

© 2003 by CRC Press LLC

$$= \frac{\Delta\omega}{k_d k_o F(0)}$$

$$= \frac{\Delta\omega}{k_v}$$

θ_v is called the *velocity error* or *static phase error*.[4] Because the input frequency almost never agrees exactly with the VCO free-running frequency, there is a frequency difference $\Delta\omega$ between the two. From Eq. (59.17), if the PLL has a high dc loop gain, (i.e., $k_d k_o F(0) \gg \Delta\omega$), the steady-state phase error to a step frequency error input approaches zero. This is the reason why a high-gain loop has a good tracking performance. Now the advantage of a second-order loop using an active loop filter of high dc gain is evident. The active lead-lag loop filter with a high dc gain will make the steady-state phase error approach zero and the noise bandwidth narrow simultaneously, which is impossible in a first-order loop.

If the input frequency is changed linearly with time at a rate of $\Delta\dot{\omega}$, which is $\theta_i(t) = \frac{1}{2}\Delta\dot{\omega}t^2$, so $\theta_i(s) = \frac{\Delta\dot{\omega}}{s^3}$. According to a high-gain loop and applying the final value theorem of Laplace transform, then

$$\begin{aligned}\theta_a &= \lim_{t\to\infty}\theta_e(t) = \lim_{s\to 0} s\theta_e(s) \\ &= \frac{\Delta\dot{\omega}}{\omega_n^2}\end{aligned} \tag{59.18}$$

θ_a is called an *acceleration error* (sometimes called *dynamic tracking error* or *dynamic lag*).[4]

In some applications, PLL needs to track an accelerating phase error without static tracking error. The expression of the static phase error when frequency ramp is applied

$$\theta_e(s) = \lim_{s\to 0} \frac{\Delta\omega}{s\left(s + k_d k_o F(s)\right)} \tag{59.19}$$

For θ_e to be zero, it is necessary to make $F(s)$ be a form of $\frac{G(s)}{s^2}$, where $G(0) \neq 0$. $\frac{G(s)}{s^2}$ implies that the loop filter has two cascade integrators. This is a third-order loop. In order to eliminate the static acceleration error, a third-order loop is very useful for some special applications, such as satellites and missiles systems.

Based on Eq. (59.18), a large natural frequency ω_n is used to reduce the static tracking phase error in a second-order loop; however, a wide natural frequency has an undesired noise filtering performance. In contrast, the zero tracking phase error for a frequency ramp error is concordant with a small loop bandwidth in a third-order loop.

The preceding analysis on tracking process is under the assumption that the phase error is relatively small and the loop is linear. If the phase error is large enough to make the loop drop out of lock, the linear assumption is invalid. For a sinusoidal-characteristic phase detector, the exact phase expression of Eq. (59.17) should be

$$\sin\theta_v = \frac{\Delta\omega}{k_v} \tag{59.20}$$

The sine function has solutions when $\Delta\omega \le k_v$. Therefore, there is no solution if $\Delta\omega > k_v$. This is the case when the loop loses lock and the output of the phase detector will be beat notes signal rather than a dc control voltage. Therefore, k_v can be used to define the *hold range* of the PLL; that is

© 2003 by CRC Press LLC

$$\Delta\omega_H = \pm k_v = k_o k_d F(0) \tag{59.21}$$

The hold range is the frequency range in which a PLL is able to maintain lock *statically*. Namely, if input frequency offset exceeds the hold range statically, the steady-state phase error would drop out of the linear range of the phase detector and the loop loses lock. The hold range expressed in Eq. (59.21) is not correct when some other components in PLL are saturated earlier than the phase detector. k_v is a function of k_o, k_d, and $F(0)$. The dc gain $F(0)$ of the loop filter depends on the filter type. Then, hold range $\Delta\omega_H$ can be $k_o k_d$, $k_o k_d k_a$, and ∞ for passive lead-lag filter, active lead-lag filter, and active PI filter, respectively. When the PI filter is used, the real hold range is actually determined by the control range of the VCO.

Considering the dynamic phase error θ_a in a second-order loop, the exact expression for a sinusoidal characteristic phase detector is

$$\sin\theta_a = \frac{\Delta\dot{\omega}}{\omega_n^2} \tag{59.22}$$

which implies that the maximum change rate of the input frequency is ω_n^2. If the rate exceeds ω_n^2, the loop will fall out of lock.

Lock-in Process

The *lock-in* process is defined as PLL locks within one single beat note between the input and the output (VCO output) frequency. The maximum frequency difference between the input and the output that the PLL can lock within one single beat note is called the *lock-in range* of the PLL.

Figure 59.9 is the case in which a frequency offset $\Delta\omega$ is less than the lock-in range. Then, PLL will lock within one single beat note between ω_i and ω_o, and the lock-in process happens. In Fig. 59.10(b), the frequency offset $\Delta\omega$ between input (ω_i) and output (ω_o) is larger than the lock-in range; hence, the lock-in process will not take place, at least not instantaneously.

The magnitude of the lock-in range can be derived approximately in the following. Suppose the PLL is unlocked initially. The input frequency ω_i is $\omega_o + \Delta\omega$. If the input signal $v_i(t)$ is a sine wave and given by

$$v_i(t) = A_i \sin(\omega_o t + \Delta\omega t) \tag{59.23}$$

and the VCO output signal $v_o(t)$ is usually a square wave written as a Walsh function[5]

$$v_o(t) = A_o W(\omega_o t) \tag{59.24}$$

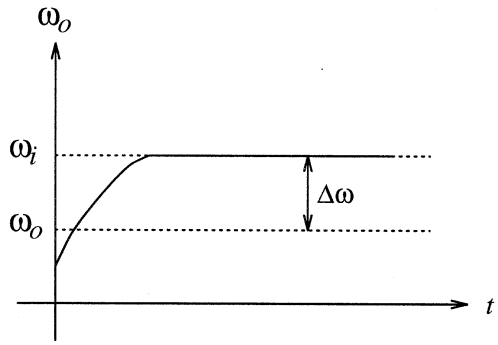

FIGURE 59.9 Lock-in process of the PLL.

© 2003 by CRC Press LLC

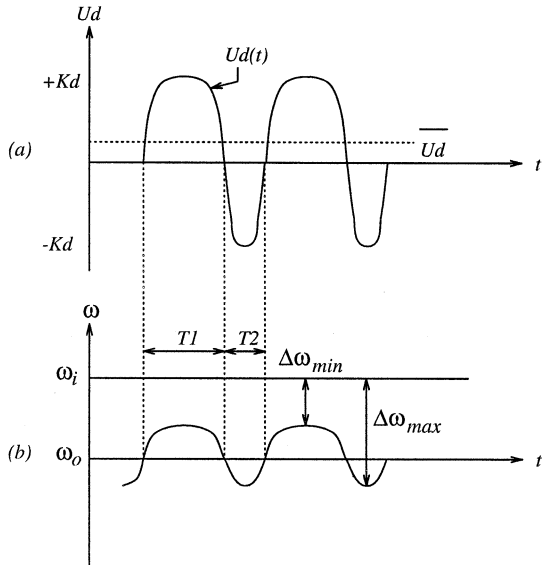

FIGURE 59.10 Pull-in process of the PLL.

$v_o(t)$ can be replaced by the Fourier Series,

$$v_o(t) = A_o\left[\frac{4}{\pi}\cos(\omega_o t) + \frac{4}{3\pi}\cos(3\omega_o t) + \ldots\right] \tag{59.25}$$

So, the phase detector output v_d is

$$\begin{aligned} v_d(t) = v_i(t)v_o(t) &= A_i A_o\left[\frac{2}{\pi}\sin(\Delta\omega t) + \ldots\right] \\ &= k_d \sin(\Delta\omega t) + \textit{high-frequency terms} \end{aligned} \tag{59.26}$$

The high-frequency components can be filtered out by the loop filter. The output of the loop filter is given by

$$v_f(t) \approx k_d\left|F(\Delta\omega)\right|\sin(\Delta\omega t) \tag{59.27}$$

The peak frequency deviation based on Eq. (59.27) is equal to $k_d k_o|F(\Delta\omega)|$. If the peak deviation is larger than the frequency error between ω_i and ω_o, the lock-in process will take place. Hence, the lock-in range is given by

$$\Delta\omega_L = k_d k_o\left|F(\Delta\omega_L)\right| \tag{59.28}$$

The lock-in range is always larger than the corner frequency $\frac{1}{\tau_1}$ and $\frac{1}{\tau_2}$ of the loop filter in practical cases. An approximation of the loop filter gain $F(\Delta\omega_L)$ is shown as follows:

© 2003 by CRC Press LLC

For the passive lead-lag filter,

$$F\left(\Delta\omega_L\right) \approx \frac{\tau_2}{\tau_1 + \tau_2}$$

For the active lead-lag filter,

$$F\left(\Delta\omega_L\right) \approx k_a \frac{\tau_2}{\tau_1}$$

For the active PI filter,

$$F\left(\Delta\omega_L\right) \approx \frac{\tau_2}{\tau_1}$$

τ_2 is usually much smaller than τ_1, and the $F(\Delta\omega_L)$ can be further approximated as follows:

For the passive lead-lag filter,

$$F\left(\Delta\omega_L\right) \approx \frac{\tau_2}{\tau_1}$$

For the active lead-lag filter,

$$F\left(\Delta\omega_L\right) \approx k_a \frac{\tau_2}{\tau_1}$$

For the active PI filter,

$$F\left(\Delta\omega_L\right) \approx \frac{\tau_2}{\tau_1}$$

Substituting the preceding equations into Eq. (59.28) and assuming a high-gain loop,

$$\Delta\omega_L = 2\zeta\omega_n \tag{59.29}$$

can be obtained for all three types of loop filters shown in Fig. 59.3.

Acquisition Process

Suppose that the PLL does not lock initially, and the input frequency is $\omega_i = \omega_o + \Delta\omega$, where ω_o is the initial frequency of VCO. If the frequency error $\Delta\omega$ is larger than the lock-in range, the lock-in process will not happen. Consequently, the output signal $u_d(t)$ of the phase detector shown in Fig. 59.10(a) is a sine wave that has a frequency $\Delta\omega$. The ac phase detector output signal $u_d(t)$ passes through the loop filter. Then the output $u_f(t)$ of the loop filter modulates the VCO frequency. As shown in Fig. 59.10(b), when ω_o increases, the frequency difference between ω_i and ω_o becomes smaller and vice versa.Therefore,

© 2003 by CRC Press LLC

the phase detector output $u_d(t)$ becomes asymmetric. That is, the duration of positve half-periods of the phase detector output is larger than the negative ones. The average value $\overline{u_d(t)}$ of the phase detector output therefore goes to slightly positive. Then the frequency of VCO will be pulled up until it reaches the input frequency. This phenomenon is called a *pull-in process*.

Because the pull-in process is a non-linear behavior, the mathematical analysis is quite complicated. According to the results in Reference 1, the pull-in range and the pull-in time depend on the type of loop filter. For an active lead–lag filter with a high-gain loop, the pull-in range is

$$\Delta\omega_P \approx \frac{4\sqrt{2}}{\pi}\sqrt{\zeta\omega_n k_o k_d} \tag{59.30}$$

and the pull-in time is

$$T_P \approx \frac{\pi^2}{16}\frac{\Delta\omega_0^2 k_a}{\zeta\omega_n^3} \tag{59.31}$$

where $\Delta\omega 0$ is the initial frequency error. Equations (59.30) and (59.31) will be modified for different types of phase detectors.[1]

Aided Acquisition

The PLL bandwidth is always too narrow to lock a signal of large frequency error. Furthermore, the frequency acquisition is slow and impractical. Therefore, there are aided frequency-acquisition techniques to solve this problem, such as the frequency-locked loop (FLL) and bandwidth-widening methods.

The frequency-locked loop, which is very similar to a PLL, is composed of a frequency discriminator, a loop filter, and a VCO. PLL is a coherent mechanism to recover a signal buried in noise. FLL, in contrast, is a non-coherent scheme that cannot distinguish between signal and noise. Therefore, an FLL can only be useful to provide signal frequency, which usually implies that the input signal power must exceed the noise.

The major difference between PLL and FLL is the phase detector and the frequency discriminator. The frequency discriminator is the frequency detector in the FLL. It generates a voltage proportional to the frequency difference between the input and the VCO. The frequency difference will be driven to zero in a negative feedback fashion. If a linear frequency detector is employed, it can be shown that the frequency-acquisition time is proportional to the logarithm of the frequency error.[6] In the literature, some frequency detectors like the quadricorrelator,[7] balance quadricorrelator,[8] rotational frequency detector,[9] and frequency delimiter[10] are disclosed.

Delay-Locked Loop

Two major approaches for adjustable timing elements are VCO and voltage-controlled delay line (VCDL). Figure 59.11 shows a typical delay-locked loop (DLL)[11,12] that replaces the VCO of a PLL with a VCDL. The input signal is delayed by an integer multiple of the signal period because the phase error is zero when the phase difference between V_{in} and V_o approaches a multiple of the signal periods. The VCDL usually consists of a number of cascaded gain stages with variable delay. Delay lines, unlike ring oscillators, cannot generate a signal; therefore, it is difficult to make frequency multiplication in a DLL.

In a VCO, the output "frequency" is proportional to the input control voltage. The phase transfer function contains a pole, which is $H(s) = \frac{k_o}{s}$ (k_o is the VCO gain). In a VCDL, the output "phase" is proportional to the control voltage, and the phase transfer function is $H(s) = k_{VCDL}$. So, the DLL can be easily stabilized with a simple first-order loop filter. Consequently, DLLs have much more relaxed trade-offs

© 2003 by CRC Press LLC

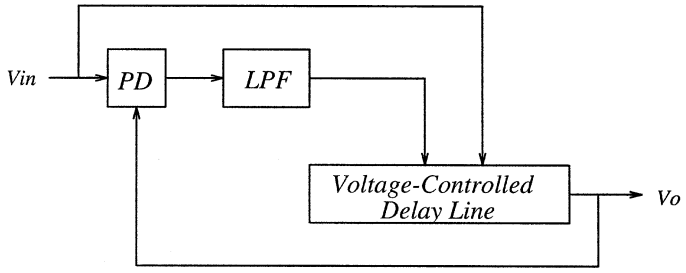

FIGURE 59.11 DLL block diagram.

among gain, bandwidth, and stability. This is one of the two important advantages over PLLs. Another advantage is that delay lines typically introduce much less jitter than a VCO.[13] Because a delay chain is not configured as a ring oscillator, there is no jitter accumulation because the noise does not contribute to the starting point of the next clock cycle.

Charge-Pump Phase-Locked Loop

A charge-pump PLL usually consists of four major blocks as shown in Fig. 59.12. The phase detector is a purely phase-frequency detector. The charge-pump circuit converts the digital signals UP, DN, and null (neither up nor down) generated by the phase detector into a corresponding charge-pump current I_p, $-I_p$, and zero. The loop filter is usually a passive RC circuit converting the charge-pump current into an analog voltage to control the VCO. So, the purpose of the "charge-pump" is to convert the logic state of the phase-frequency detector output into an analog signal suitable for controlling the voltage-controlled oscillator. The linear model of a charge-pump PLL is shown in Fig. 59.13. The k_d is the equivalent gain of a charge-pump circuit and a loop filter, which is shown in Fig. 59.14. If the loop bandwidth is much smaller than the input frequency, the detailed behavior within a single cycle can be ignored. Then, the state of a PLL can be assumed to be only changed by a small amount during each input cycle. Actually, the "average" behavior over many cycles is interesting. Then, the average current charging the capacitor is given by

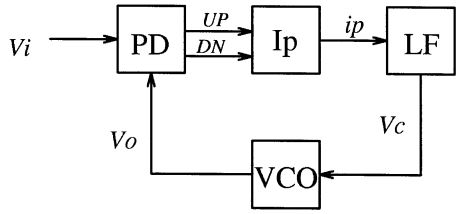

FIGURE 59.12 Charge-pump PLL diagram.

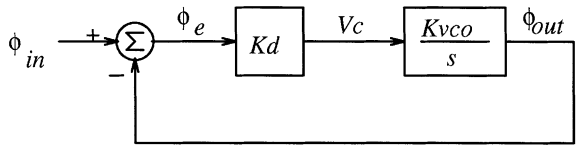

FIGURE 59.13 The linear model of charge-pump PLL.

© 2003 by CRC Press LLC

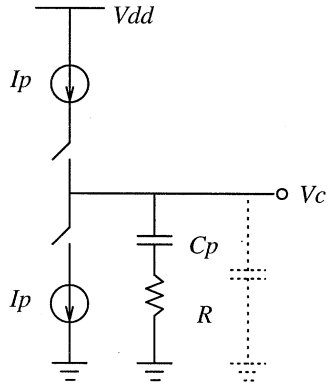

FIGURE 59.14 The schematic of a loop filter

$$\begin{aligned} I_{avg} &= \frac{Q}{T} = \frac{I\Delta t}{T} \\ &= \frac{I\left(\frac{\phi e}{2\pi}\right)T}{T} \\ &= \frac{I\phi_e}{2\pi} \end{aligned} \tag{59.32}$$

And the average k_d in Fig. 59.13 is

$$k_d \triangleq \frac{v_c}{\phi_e} = \frac{I}{2\pi}\left(R + \frac{1}{C_p s}\right) \tag{59.33}$$

The closed-loop transfer function can be obtained as

$$\begin{aligned} H(s) \triangleq \frac{\phi_{out}}{\phi_{in}} &= \frac{k_d \frac{k_{vco}}{s}}{1 + \frac{k_d k_{vco}}{s}} \\ &= \frac{\frac{I}{2\pi C_p}\left(RC_p s + 1\right)k_{vco}}{s^2 + \frac{I}{2\pi}k_{vco}Rs + \frac{Ik_{vco}}{2\pi C_p}} \end{aligned} \tag{59.34}$$

Generally, a second-order system is characterized by the natural frequency $f_n = \frac{\omega_n}{2\pi}$ and the damping factor ζ. So,

$$\begin{aligned} \omega_n &= \sqrt{\frac{I}{2\pi C_p}k_{vco}}\ rad\ \sec \\ \zeta &= \frac{RC_p}{2}\omega_n \end{aligned} \tag{59.35}$$

© 2003 by CRC Press LLC

For the stability consideration, there is a limitation of a normalized natural frequency F_N:[14]

$$F_N \triangleq \frac{f_n}{f_i} < \frac{\sqrt{1+\zeta^2}-\zeta}{\pi} \tag{59.36}$$

In the single-ended charge pump, the resistor added in series with the capacitor shown in Fig. 59.14 can introduce "ripple" in the control voltage V_c even when the loop is locked.[15] The ripple control voltage modulates the VCO frequency and results in phase noise. This effect is especially undesired in frequency synthesizers. In order to suppress the ripple, a second-order loop filter, as shown in Fig. 59.14 with a shunt capacitor in dotted lines, is used. This configuration introduces a third pole in the PLL. Stability issues must be taken care of. Gardner[15] provides criteria for the stability of the third-order PLL.

An important property of any PLL is the static phase error that arises from a frequency offset $\Delta\omega$ between the input signal and the free-running frequency of the VCO. According to the analysis of Reference 15, the static phase error is

$$\theta_v = \frac{2\pi\Delta\omega}{k_o I_p F(0)} rad \tag{59.37}$$

To eliminate the static phase error in conventional PLLs, an active loop filter with a high dc gain ($F(0)$ is large) is preferred. But the charge-pump PLL allows zero static phase error without the need for a large dc gain of the loop filter. This effect arises from the input open circuit during the "null" state (charge-pump current is zero). Real circuits will impose some resistive loading R_s in parallel to the loop filter. Therefore, the static phase error, from Eq. (59.37) will be

$$\theta_v = \frac{2\pi\Delta w}{k_o I_p R_s} rad \tag{59.38}$$

The shunt resistive loading most likely comes from the input of a VCO control terminal. Compared with the static phase error of a conventional PLL as expressed in Eq. (59.17), the same performance can be obtained from a charge-pump PLL without a high dc-gain loop filter.[16]

PLL Noise Performance

In high-speed data recovery applications, better performance of the VCO and the overall phase-locked loop itself is desired. The random variations of the sampling clock, so-called jitter, is the critical performance parameter.

Jitter sources of PLL, when using a ring voltage-controlled oscillator, mainly come from the input and the VCO itself. The ring oscillator jitter is associated with the power supply noise, the substrate noise, $1/f$ noise, and the thermal noise. The former two noise sources can be reduced by fully differential circuit structure. $1/f$ noise, on the other hand, can be rejected by the tracking capability of the PLL. Therefore, the thermal noise is the worst noise source. From the analysis in Reference 17, the one-state RMS timing jitter error of the ring oscillator normalized to the time delay per stage can be shown as

$$\frac{\Delta\tau_{rms}}{t_d} \approx \sqrt{\frac{2KT}{C_L}}\left(\sqrt{1+\frac{2}{3}a_v}\right)\frac{1}{V_{pp}} \tag{59.39}$$

where C_L is the load capacitance, $\sqrt{1+\frac{2}{3}a_v}$ is called the noise contribution factor ς, a_v is the small-signal gain of the delay cell, and Vpp is the VCO output swing. From Eq. (59.39), for a fixed output bandwidth, higher gain contributes larger noise.

© 2003 by CRC Press LLC

Because the ring oscillator is a feedback architecture, the noise contribution of a single delay cell may be amplified and filtered by the following stage. To consider two successive stages, Eq. (59.39) can be rearranged as:[17]

$$\frac{\Delta\tau_{rms}}{t_d} \approx \sqrt{\frac{2KT}{C_L}} \frac{1}{\left(V_{gs} - V_t\right)} \varsigma \tag{59.40}$$

Therefore, the cycle-to-cycle jitter of the ring oscillator in a PLL can be predicted[17] by

$$\overline{\left(\Delta\tau_N\right)^2} = \frac{KT}{I_{ss}} \frac{a_v \varsigma^2}{\left(V_{gs} - V_t\right)} T_o \tag{59.41}$$

where I_{ss} is the current of the delay cell, and T_o is the output period of the VCO. Based on Eq. (59.41), designing a low jitter VCO, $(V_{gs} - V_t)$ should be as large as possible. For fixed delay and fixed current, a lower gain of each stage is better for jitter performance, but the loop gain must satisfy the Barkhausen criterion. From the viewpoint of VCO jitter, a wide bandwidth of the PLL can correct the timing error of the VCO rapidly.[13] If the bandwidth is too wide, the input noise jitter may be so large that it dominates the jitter performance of the PLL. Actually, this is a tradeoff.

For a phase-locked loop design, the natural frequency and the damping factor are the key parameters to be determined by designers. If the signal-to-noise ratio $(\text{SNR})_i$ is defined, then the output signal-to-noise ratio $(\text{SNR})_o$ can be obtained:[4]

$$\left(\text{SNR}\right)_o = \left(\text{SNR}\right)_i \frac{B_i}{2B_L} \tag{59.42}$$

where B_i is the bandwidth of the prefilter and B_L is the noise bandwidth. Hence, the B_L can be derived using Eq. (59.42). And the relationship of B_L with ω_n and ζ is

$$B_L = \frac{\omega_n}{2}\left(\zeta + \frac{1}{4\zeta}\right) \tag{59.43}$$

Therefore, the ω_n and ζ can be designed to satisfy the $(\text{SNR})_o$ requirement.

Besides the system and circuit designs, jitter can be reduced in the board level design. Board jitter can be alleviated by better layout and noise decoupling schemes like such as appending proper decouple and bypass capacitances.

PLL Design Considerations

A PLL design starts with specifying the key parameters such as natural frequency ω_n, lock-in range $\Delta\omega_L$, damping factor ζ, and the frequency control range which depend significantly on applications. Design procedures based on a practical example will be described as follows:

Step 1. Specify the damping factor ζ. The damping factor of the PLL determines the responses of phase or frequency error steps applied to the input. ζ should be considered to achieve fast response, small overshoot, and minimum noise bandwidth B_L. If ζ is very small, large overshoot will occur and the overshoot causes phase jitter.[18] If ζ is too large, the response will become sluggish.

Step 2. Specify the lock-in range $\Delta\omega_L$ or the noise bandwidth B_L. As shown in Eqs. (59.29) and (59.43), the natural frequency ω_n depends on $\Delta\omega_L$and ζ (or B_L and ζ). If the noise is not the key issue of

© 2003 by CRC Press LLC

the PLL, one can ignore the noise bandwidth and specify the lock-in range. Where noise is of concern, one should specify B_L first, and keep the lock-in range of the PLL.

Step 3. Calculate the ω_n according to Step 2. If the lock-in range has been specified, Eq. (59.29) indicates that

$$\omega_n = \frac{\Delta\omega_L}{2\zeta} \tag{59.44}$$

If the noise bandwidth has been specified, Eq. (59.43) indicates the natural frequency as

$$\omega_n = \frac{2B_L}{\zeta + \frac{1}{4}\zeta} \tag{59.45}$$

Step 4. Determine the VCO gain factor k_o and the phase detector gain k_d. k_o and k_d are both characterized by circuit architectures and they must achieve the requirement of the lock-in range specified in Step 2. For example, if k_o or k_d is too small, the PLL will fail to achieve the desired lock-in range.

Step 5. Choose the loop filter. Different types of loop filters are available, as shown in Fig. 59.3. Eqs. (59.7) to (59.9), ω_n and ζ (specified previously) are used to derive the time constants of the loop filter.

59.3 Building Blocks of the PLL Circuit

Voltage-Controlled Oscillators

The function of a voltage-controlled oscillator (VCO) is to generate a stable and periodic waveform whose frequency can be varied by an applied control voltage. The relationship between the control voltage and the oscillation frequency depends upon the circuit architecture. A linear characteristic is generally preferred because of its wider applications. As a general classification, VCOs can be roughly categorized into two types by the output waveforms: (1) *harmonic oscillators* that generate nearly sinusoidal outputs, and (2) *relaxation oscillators* that provide square or triangle outputs. In general, a harmonic oscillator is composed of an amplifier that provides an adequate gain and a frequency-selective network that feeds a certain output frequency range back to the input. LC-tank oscillators and crystal oscillators belong to this type.

Relaxation oscillators are the most commonly used oscillator configuration in monolithic IC design because they can operate in a wide frequency range with a minimum number of external components. According to the mechanism of the oscillator topology employed, relaxation oscillators can be further categorized into three types: (1) grounded capacitor VCO,[19] (2) emitter-coupled VCO, and (3) delay-based ring VCO.[20] The operation of the first two oscillators is similar in the sense that time duration spent in each state is determined by the timing components and charge/discharge currents. The delay-based ring VCO operates quite differently since the timing relies on the delay in each of the gain stages that are connected in a ring configuration.

Generally, harmonic oscillators have the following advantages: (1) superior frequency stability, which includes the frequency stability with temperature, power supply, and noise; and (2) good frequency accuracy control, because the oscillation frequency is determined by a tank circuit or a crystal.

Nevertheless, harmonic oscillators are not compatible with monolithic IC technology and their frequency turning range is limited. On the contrary, relaxation oscillators are easy to implement in monolithic ICs. Since frequency is normally proportional to a controlled-current or -voltage and inversely proportional to timing capacitors, the frequency of oscillation can be varied linearly over a very wide

© 2003 by CRC Press LLC

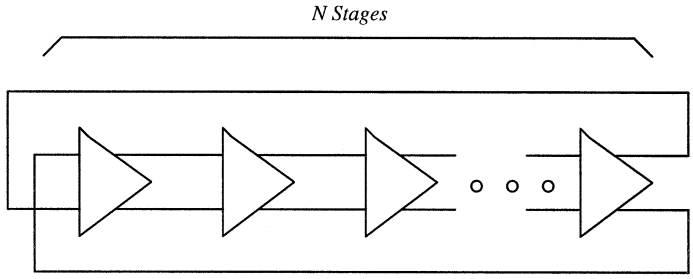

FIGURE 59.15 Ring oscillator.

range. Coming from the ease of frequency tuning, the drawbacks of such oscillators are poor frequency stability and frequency inaccuracy.

Recently, the ring oscillator has received considerable attentions in high-frequency PLL applications for clock synchronization and timing recovery. Since they can provide high-frequency oscillation with simple digital-like circuits that are compatible with digital technology, they are suitable for VLSI implementations.

In order to achieve high rejection of power supply and substrate noises, both the signal path and the control path of a VCO must be fully differential. A common ring oscillator topology in monolithic PLLs is shown in Figure 59.15. The loop oscillates with a period equal to $2NT_d$, where T_d is the delay of each stage. The oscillation can be obtained when the total phase shift is zero and the loop gain is greater or equal to unity at a certain frequency. To vary the frequency of oscillation, the effective number of stages or the delay of each stage must be changed. The first approach is called "delay interpolating" VCO,[20] where a shorter delay path and a longer delay path are used in parallel. The total delay is tuned by increasing the gain of one path and decreasing the other, and the total delay is a weighted sum of the two delay paths. The second approach is to vary the delay time of each stage to adjust the oscillation frequency. The delay of each stage is tuned by varying the capacitance or the resistance seen at the output node of each stage. Because the tuning range of the capacitor is small and the maximum oscillation frequency is limited by the minimum value of the load capacitor, it makes the "resistive tuning" a better alternative technique. The resistive tuning method provides a large, uniform frequency tuning range and lends itself easily to differential control. In Figure 59.16(a), the on-resistance of the triode PMOS loads are adjusted by V_{cont}. The more V_{cont} decreases, the more the delay of the stage drops; because the time constant at the output node decreased, the small-signal gain decreases too. The circuit eventually fails to oscillate when the loop gain at the oscillation frequency is less than unity. In Fig. 59.16(b), the delay of the gain stage is tuned by adjusting the tail current, but the small-signal gain remains constant. So, the circuit is better than Fig. 59.16(a). As shown in Fig. 59.16(c),[21] the PMOS current source with a pair of cross-coupled diode loads provides a differential load impedance that is independent of common-mode voltage. This makes the cell delay insensitive to common-mode noise. Figure 59.16(d) is a poor delay cell for a ring oscillator because the tuning range is very small.

The minimum number of stages that can be used while maintaining reliable operation is an important issue in a ring oscillator design. When the number of stages decreases, the required phase shift and dc gain per stage increases. Two-stage bipolar ring oscillators can be designed reliably,[22] but CMOS implementations cannot. Thus, CMOS ring oscillators typically utilize three or more stages.

Phase and Frequency Detectors

The phase detector type has influence on the dynamic range of PLLs. Hold range, lock-in range, and pull-in range are analyzed in Section 59.2, based on the multiplier phase detector. Most other types of phase detectors have a greater linear output span and a larger maximum output swing than a sinusoidal characteristic phase detector. A larger tracking range and a larger lock limit are available if the linear

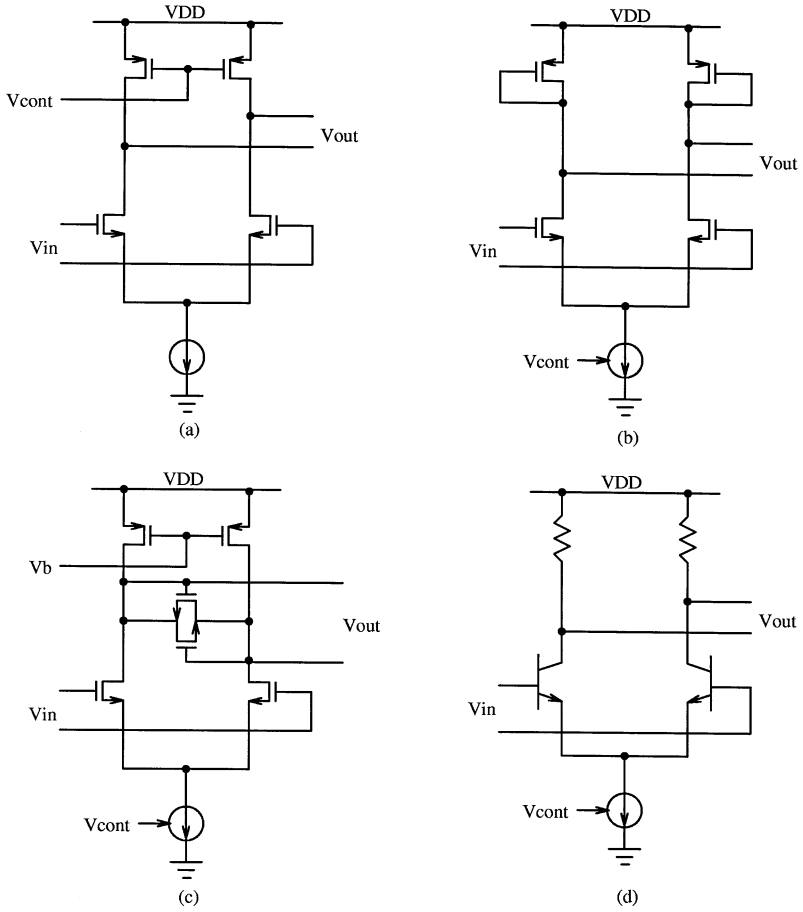

FIGURE 59.16 The gain stages using resistive tuning.

output range of the PD increases. The three widely used phase detectors are XOR PD, edge-triggered JK-flipflop, and PFD (phase-frequency detector). The characteristics of these phase detectors are plotted in Fig. 59.17.

The XOR phase detector can maintain phase tracking when the phase error θ_e is confined in the range of

$$\frac{-\pi}{2} < \theta_e < \frac{\pi}{2}$$

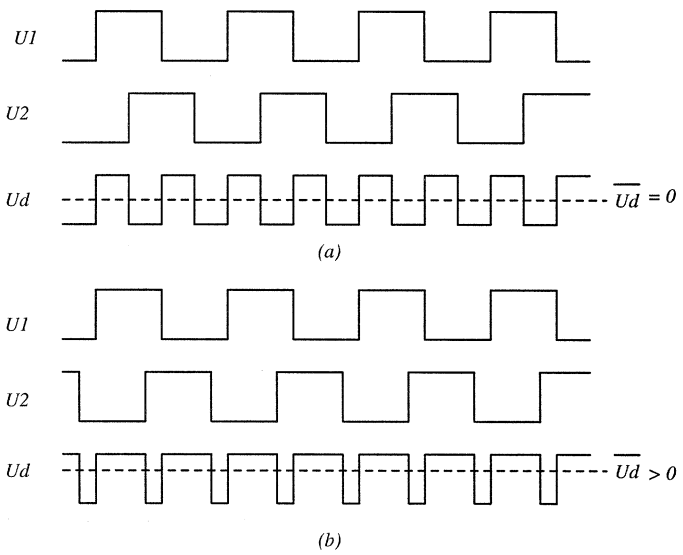

FIGURE 59.18 Waveforms of the signals for the XOR phase detector: (a) waveforms at zero phase error, and (b) waveforms at positive phase error.

as shown in Fig. 59.17(a). The zero phase error takes place when the input signal and the VCO output are quadrature in phase as shown in Fig. 59.18(a). As the phase difference deviates from $\frac{\pi}{2}$, the output duty cycle is no longer 50%, which provides a dc value proportional to the phase difference as shown in Fig. 59.18(b). But the XOR phase detector has a steady-state phase error if the input signal or the VCO output are asymmetric.

The JK-flipflop phase detector shown in Fig. 59.19, also called a two-state PD, is barely influenced by the asymmetric waveform because it is edge-triggered. The zero phase error happens when the input signal and the VCO output are out-of phase as illustrated in Fig. 59.19(a). As shown in Fig. 59.17(b), the JK-flipflop phase detector can maintain phase tracking when the phase error is within the range of

$$-\pi < \theta_e < \pi$$

Here, a positive edge appearing at the "J" input triggers the flipflop into "high" state (Q = 1), and the rising edge of u_2 drives Q to zero. Figure 59.19(b) shows the output waveforms of the JK-flipflop phase detector for $\theta_e > 0$.

The PFD output depends not only on the phase error, but also on the frequency error. The characteristic is shown in Fig. 59.17(c). When the phase error is greater than 2π, the PFD works as a frequency detector. The operation of a typical PFD is as follows, and the waveforms are shown in Fig. 59.20. If the frequency of input A, ω_A, is less than the frequency of input B, ω_B, then the PFD produces positive pulses at Q_A, while Q_B remains at zero. Conversely, if $\omega_A > \omega_B$, the positive pulses appear at Q_B while $Q_A = 0$. If $\omega_A = \omega_B$, then the PFD generates pulses at either $Q_A$or Q_B with a width equal to the phase difference between the two inputs. The outputs $Q_A$and Q_B are usually called the "up" and "down" signals, respectively. If the input signal fails, which usually happens at the NRZ data recovery applications during missing or extra transmissions, the output of the PFD would stick on the high state (or low state). This condition may cause the VCO to oscillate fast or slow abruptly, which results in noise jitter or even losing lock. This problem can be remedied by additional control logic circuits to make the PFD output toggle back and forth between the two logic levels with 50% duty cycle,[18] the loop is interpreted as zero phase error. The "rotational FD" described by Messerschmitt can also solve this issue.[9] The output of a PFD can be converted to a dc control voltage by driving a three-state charge-pump, as described in Section 59.2.

59.4 PLL Applications

Clock and Data Recovery

In data transmission systems such as optical communications, telecommunications, disk drive systems, and local networks, data is transmitted on baseband or passband. In most of these applications, only data signals are transmitted by the transmitter; clock signals are not transmitted in order to save hardware cost. Therefore, the receiver should have some scheme to extract the clock information from the received data stream and regenerate transmitted data using the recovery clock. This scheme is called *timing recovery* or *clock recovery*.

To recover the data correctly, the receiver must generate a synchronous clock from the input data stream, and the recovered clock must synchronize with the bit rate (the baud of data). The PLL can be used to recover the clock from the data stream, but some special design considerations must be addressed. For example, because of the random nature of data, the choice of phase-frequency detectors is restricted. In particular, a three-state PD is not proper; because of missing data transitions, the PD will interpret the VCO frequency to be higher than the data frequency, and the PD output stays on "down" state to make the PLL lose lock, as shown in Fig. 59.21. Thus, the choice of phase-frequency detector for random binary data requires a careful examination of their responses when some transitions are absent. One useful method is the rotational frequency detector described in Reference 9. The random data also causes the PLL to introduce undesired phase variation in the recovered clock; this is called *timing jitter* and is an important issue of the clock recovery.

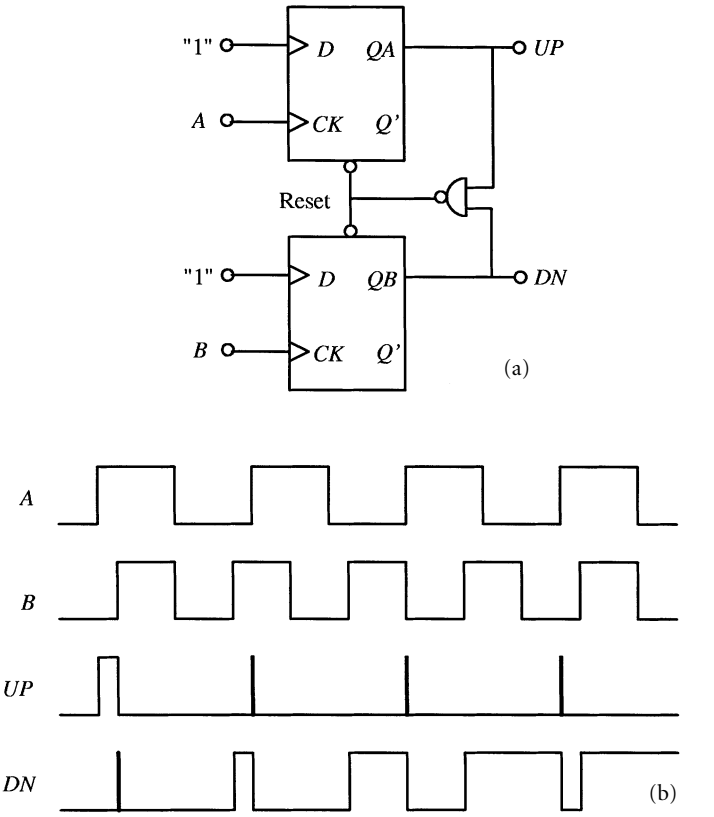

FIGURE 59.20 (a) PFD diagram and (b) input and output waveforms of PFD.

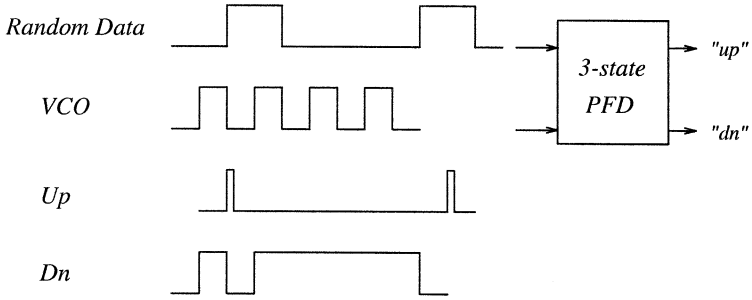

FIGURE 59.21 Response of a three-state PD to random data.

Data Format

Binary data is usually transmitted in a NRZ (Non-Return-to-Zero) format, as shown in Fig. 59.22(a), because of the consideration of bandwidth efficiency. In NRZ format, each bit has a duration of T_B (bit period). The signal does not go to zero between adjacent pulses representing 1's. It can be shown[23] in that the corresponding spectrum has no line component at $f_B = \frac{1}{T_B}$; most of the spectrum of this signal lines below $\frac{f_B}{2}$. The term "non-return-to-zero" distinguishes from another data type called "return-to-zero" (RZ), as shown in Fig. 59.22(b), in which the signal goes to zero between consecutive bits. Therefore,

© 2003 by CRC Press LLC

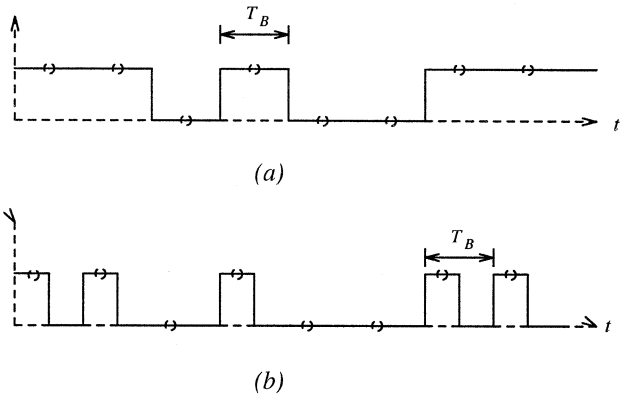

FIGURE 59.22 (a) NRZ data and (b) RZ data.

the spectrum of RZ data has a frequency component at f_B. For a given bit rate, RZ data needs wider transmitting bandwidth; therefore, NRZ data is preferable when channel or circuits bandwidth is a concern.

Due to the lack of a spectral component at the bit rate of NRZ format, a clock recovery circuit may lock to spurious signals or fail to lock at all. Thus, a non-linear process at NRZ data is essential to create a frequency component at the baud rate.

Data Conversion

One way to recover a clock from NRZ data is to convert it to RZ-like data that has a frequency component at bit rate, and then recover clock from data using a PLL. Transition detection is one of the methods to convert NRZ data to RZ-like data. As illustrated in Fig. 59.23(a), the edge detection requires a mechanism to sense both positive and negative data transitions. In Fig. 59.23(b), NRZ data is delayed and compared with itself by an exclusive-OR gate; therefore, the transition edges are detected. In Fig. 59.24, the NRZ data V_i is first differentiated to generate pulses corresponding to each transition. These pulses are made to be all positive by squaring the differentiated signal $\dot{v}_i$. The result is the signal V_i' that looks just like RZ data, where pulses are spaced at an interval of T_B.

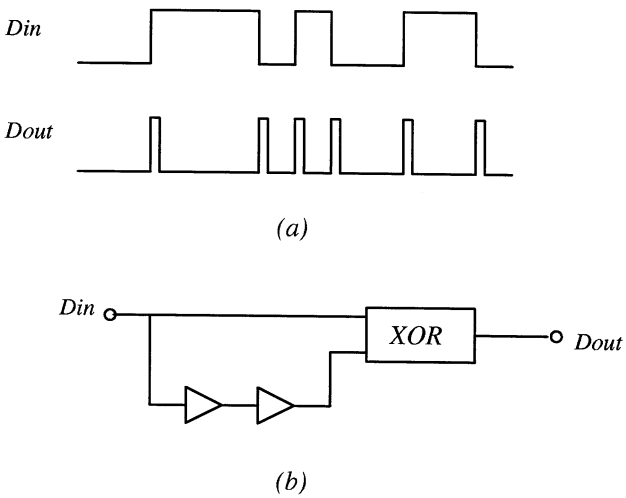

FIGURE 59.23 Edge detection of NRZ data.

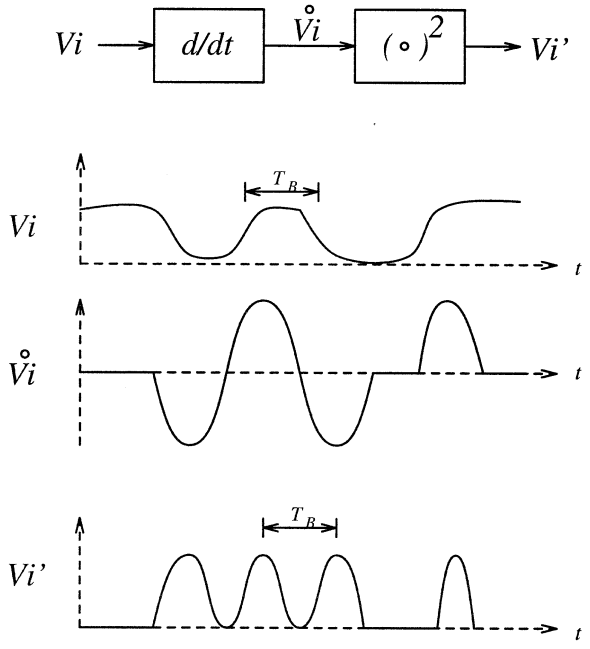

FIGURE 59.24 Converting NRZ to RZ-like signal.

Clock Recovery Architecture

Based on different PLL topologies, there are several clock recovery approaches. Here, the early-late and the edge-detector based methods are described.

Figure 59.25 shows the block diagram of the early-late method. If the input lags the VCO output, Fig. 59.26 shows the waveforms for this case. In Fig. 59.26, the early integrator integrates the input signal for the early-half period of the clock signal and holds it for remainder of the clock signal. On the other hand, the late integrator integrates the input signal for the late-half period of the clock signal and holds it for the next early-half period. The average difference between the absolute values of the late hold and the early hold voltage generated from a low-pass filter gives the control signal to adjust the frequency of the VCO. As mentioned previously, this method is popular for rectangular pulses. However, this method has some drawbacks. Since this method relies on the shape of pulses, a static phase error can be introduced if the pulse shape is not symmetric. In high-speed applications, this approach requires a fast settling integrator that limits the operating speed of the clock recovery circuit and the acquisition time cannot be easily controlled.

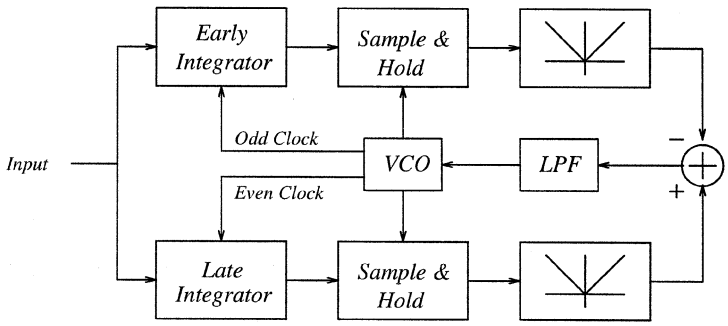

FIGURE 59.25 Early-late block diagram.

© 2003 by CRC Press LLC

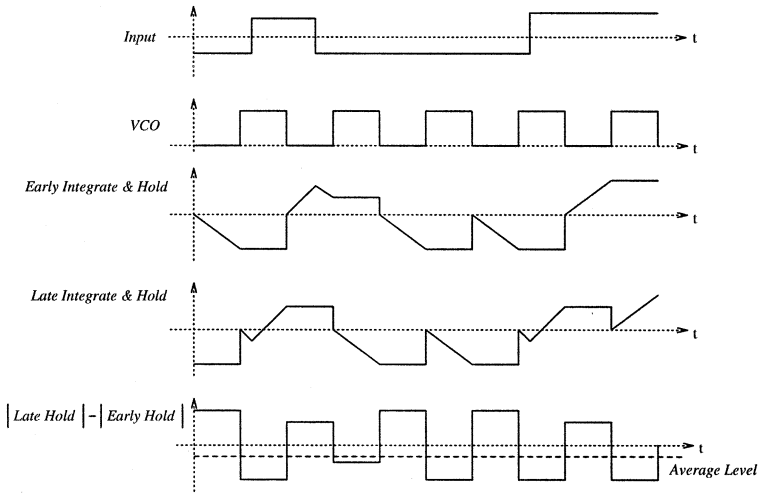

FIGURE 59.26 Clock waveforms for early-late architecture.

The most widely used technique for clock recovery in high-performance, wide-band data transmission applications is the edge-detection based method. The edge-detection method is used to convert data format such that the PLL can lock the correct band frequency. More details were given in the previous subsection. There are many variations of this method, depending on the exact implementation of each PLL loop component. The "quadricorrelator" introduced by Richman[7] and modified by Bellisio[24] is a frequency-difference discriminator and has been implemented in a clock recovery architecture. Figure 59.27 is a phase-recovery locked loop using edge-detection method and quadricorrelator to recover timing information from NRZ data.[25] As shown in Fig. 59.27, the quadricorrelator follows the edge-detector with a combination of three loops sharing the same VCO. Loop I and II form a frequency-locked loop that contains the quadricorrelator for frequency detection. Loop III is a typical phase-locked loop for phase alignment. The phase- and frequency-locked loops share the same VCO; the interaction between two loops is a very important issue. As described in Reference 25, when $\omega_1 \approx \omega_2$, the dc feedback signal produced by loop I and II approaches zero, and loop III dominates the loop performance. A composite frequency- and phase-locked loop is a good method to achieve fast acquisition and a narrow PLL loop

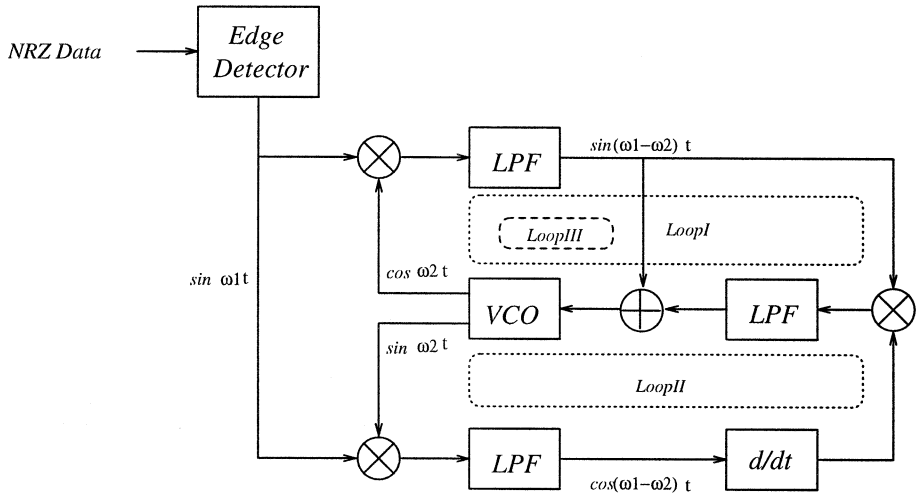

FIGURE 59.27 Quadricorrelator.

© 2003 by CRC Press LLC

bandwidth to minimize the VCO drift. Nevertheless, because the wide band frequency-locked loop can respond to noise and spurious components, it is essential to disable the frequency-locked loop when the frequency error gets into the lock-in range of the PLL to minimize the interaction. More clock recovery architectures are described in References 18, 20, 22, and 26–28.

Frequency Synthesizer

A frequency synthesizer generates any of a number of frequencies by locking a VCO to an accurate frequency source such as a crystal oscillator. For example, RF systems usually require a high-frequency local oscillator whose frequency can be changed in small and precise steps. The ability to multiply a reference frequency makes PLLs attractive for synthesizing frequencies.

The basic configuration used for frequency synthesis is shown in Fig. 59.28(a). This system is capable of generating an integer multiple frequency of a reference frequency. A quartz crystal is usually used as the reference clock source because of its low jitter characteristic. Due to the limited speed of a CMOS device, it is difficult to generate frequency directly in the range of GH_z or more. To generate higher frequencies, prescalers are used; they are implemented with other IC technologies such as ECL. Figure 59.28(b) shows a synthesizer structure using a prescaler V; the output frequency becomes

$$f_{out} = \frac{NVf_i}{M} \tag{59.46}$$

Because the scaling factor V is much greater than one, obviously, it is no longer possible to generate any desired integer multiple of the reference frequency. This drawback can be circumvented by using a so-called dual-modulus prescaler, as shown in Fig. 59.29. A dual-modulus prescaler is a divider whose division can be switched from one value to another by a control signal. The following shows that the dual-modulus prescaler makes it possible to generate a number of output frequencies that are spaced only by one reference frequency. The VCO output is divided by V/V+1 dual-modulus prescaler. The

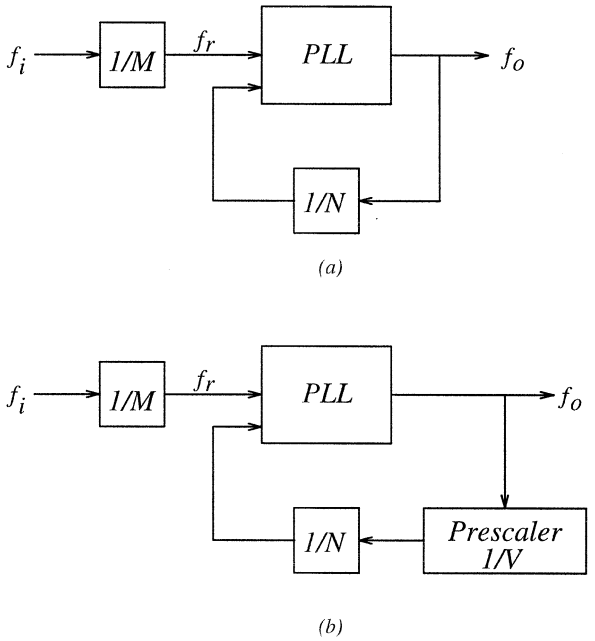

FIGURE 59.28 Frequency-synthesizer block diagrams: (a) basic frequency-synthesizer system; (b) system extends the upper frequency range by using an additional high-speed prescaler.

© 2003 by CRC Press LLC

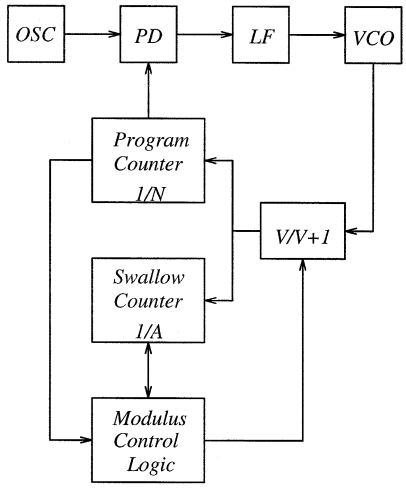

FIGURE 59.29 The block diagram of dual-modulus frequency synthesizer.

output of the prescaler is fed into a "program counter" $\frac{1}{N}$ and a "swallow counter" $\frac{1}{A}$. The dual-modulus prescaler is set to divide by V+1 initially. After "A" pulses out of the prescaler, the swallow counter is full and changes the prescaler modulus to V. After additional "N-A" pulses out of the prescaler, the program counter changes the prescaler modulus back to V+1, restarts the swallow counter, and the cycle is repeated. In this way, the VCO frequency is equal to $(V+1)A + V(N-A) = VN + A$ times the reference frequency. Note that N must be larger than A. If this is not the case, the program counter would be full earlier than $\frac{1}{A}$, and both counters would be reset. Therefore, the dual-modulus prescaler would never be switched from $V + 1$ to V. For example, if V = 64, then A must be in the range of 0 to 63 such that $N_{min} = 64$. The smallest realizable division ratio is

$$\left(N_{tot}\right)_{min} = N_{min} V = 4096 \tag{59.47}$$

The synthesizer of Fig. 59.29 is able to generate all integer multiples of the reference frequency, starting from $N_{tot} = 4096$. For extending the upper frequency range of frequency synthesizers, but still allowing the synthesis of lower frequency, the four-modulus prescaler is a solution.[1]

Based on the previous discussions, the synthesized frequency is an integer multiple of a reference frequency. In RF applications, the reference frequency is usually larger than the channel spacing for loop dynamic performance considerations, in which the wider loop bandwidth for a given channel spacing allows faster settling time and reduces the phase jitter requirements to be imposed on the VCO. Therefore, a "fractional" scaling factor is needed. Fractional division ratios of any complexity can be realized. For example, a ratio of 3.7 is obtained if a counter is forced to divide by 4 in seven cycles of each group of ten cycles and by 3 in the remaining three cycles. On the average, this counter effectively divides the input frequency by 3.7.

60.1 MOS Logic Circuits

John P. Uyemura

Introduction

MOS-based technology has become the default standard for high-density logic designs for several reasons. The most obvious is that MOSFETs can be made with side dimensions of <0.1 μm (10^{-7} m), allowing for complex logic functions to be constructed in small areas. The section is an investigation of the basics of designing and characterizing logic gates in an MOS technology.

MOSFET Models for Digital Circuits

The properties of digital logic gates are derived from a large-signal analysis of the circuits. Because transistor characteristics are intrinsically nonlinear, accurate analytic modeling becomes quite complicated, and closed-form solutions can be difficult to come by. To overcome this problem, simplified MOSFET models are used to estimate the circuit operation in first-cut designs. Once the basic operation is established, computer simulations are used to obtain more accurate information.

Square-law models are useful for understanding the operation of MOS logic circuits. Consider first an *n*-channel, enhancement-mode MOSFET that has a threshold voltage $V_{Tn} > 0$. As shown in Fig. 60.1, the primary device voltages are V_{DS}, V_{GS}, and V_{SB}. The value gate-source voltage V_{GS} relative to the threshold voltage V_{Tn} determines if drain current I_D flows. If V_{GS}, $< V_{Tn}$ then $I_D \approx 0$, establishing the condition of **cutoff**. Elevating the gate-source voltage to a value V_{GS}, $> V_{Tn}$ places the MOSFET into the **active region** where I_D will be nonzero if a drain-source voltage V_{DS} is applied; the value of I_D depends on the values of the device voltages.

To describe active operation, we introduce the drain-source saturation voltage $V_{DS,\,sat}$ defined by

$$V_{DS,sat} = V_{GS} - V_{Tn} \tag{60.1}$$

The threshold voltage is affected by the affected by the source-bulk (body) voltage V_{SB} by

$$V_{Tn} = V_{T0n} + \gamma\left(\sqrt{2|\phi_F| + V_{SB}} - \sqrt{2|\phi_F|}\right) \tag{60.2}$$

© 2003 by CRC Press LLC

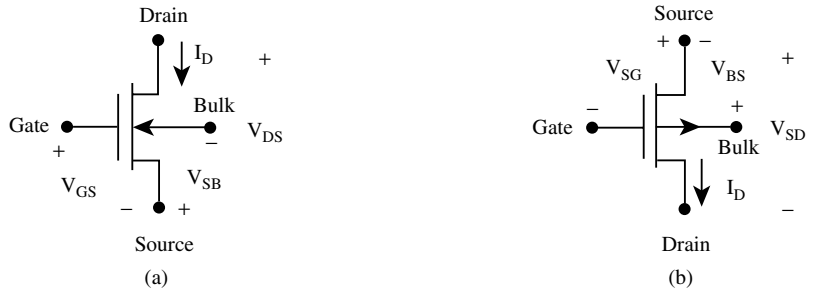

FIGURE 60.1 MOSFET symbols. (a) *n*-channel MOSFET; (b) *p*-channel MOSFET.

where V_{T0n} is the nFET zero-body-bias threshold voltage, γ is the body bias (or, body effect) coefficient, and ϕ_F is the bulk Fermi potential. When $V_{DS} \le V_{DS,\text{sat}}$, the MOSFET is nonsaturated with

$$I_D \approx \left(\frac{\beta_n}{2}\right)\left[2\left(V_{GS} - V_{Tn}\right)V_{DS} - V_{DS}^2\right] \tag{60.3}$$

In this equation β_n is the device transconductance given by $\beta_n = k_n'(\text{W/L})$, with k_n' the process transconductance in units of $[A/V^2]$, W the channel width, and L the channel length; the width-to-length (W/L) is called the **aspect ratio** of the transistor. The process transconductance is given by $k_n' = \mu_n C_{\text{ox}}$, where μ_n is the electron surface mobility and C_{ox} the oxide capacitance per unit area. For an oxide layer with thickness t_{ox}, the MOS capacitance per unit area is calculated from

$$C_{\text{ox}} = \frac{\varepsilon_{\text{ox}}}{t_{\text{ox}}} \tag{60.4}$$

where ε_{ox} is the oxide permittivity. In the current technologies t_{ox} is smaller than about 60 Å. If $V_{DS} \ge V_{DS\ \text{sat}}$, the MOSFET is saturated with

$$I_D \approx \left(\frac{\beta_n}{2}\right)\left(V_{GS} - V_{Tn}\right)^2 \tag{60.5}$$

This ignores several effects, most notably that of **channel-length modulation**, but is still a reasonable approximation for estimating basic performance parameters.

The structure of the MOSFET gives rise to several parasitic capacitances that tend to dominate the circuit performance. Two types of capacitors are contained in the basic model shown in Fig. 60.2. The contributions C_{GS} and C_{GD} are due to the MOS layering of the gate-oxide-semiconductor, which is the origin of the field effect. The total gate capacitance G_G is calculated from

$$C_G = C_{\text{ox}}\text{WL} \tag{60.6}$$

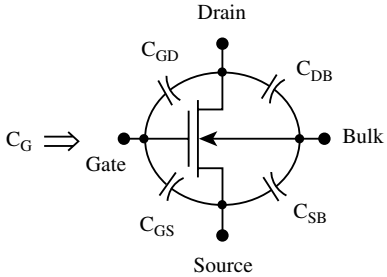

FIGURE 60.2 MOSFET capacitances.

© 2003 by CRC Press LLC

and the gate-source and gate-drain contributions can be approximated to first order by

$$C_{GD} \approx \frac{C_G}{2} \approx C_{GS} \tag{60.7}$$

Capacitors C_{DB} and C_{SB} are depletion contributions from the reverse-biased *pn* junction at the drain and source. These are nonlinear, voltage-dependent elements that decrease with increasing reverse voltage.

A *p*-channel MOSFET (pMOS or pFET) is the electrical complement of an *n*-channel device. An enhancement-mode pFET is defined to have a negative threshold voltage, i.e., $V_{Tp} < 0$. It is common to use device voltage of V_{SG}, V_{SD}, and V_{BS}, as shown in Fig. 60.1 to describe the operation. Cutoff occurs if $V_{SG} < |V_{Tp}|$, while the device is active if $V_{SG} \geq |V_{Tp}|$. The saturation voltage of the pFET is defined by

$$V_{SD,sat} = V_{SG} - |V_{Tp}| \tag{60.8}$$

With $V_{SG} \geq |V_{Tp}|$ and $V_{SG} < V_{SD,\,sat}$, the transistor is nonsaturated with

$$I_D \approx \left(\frac{\beta_p}{2}\right)\left[2\left(V_{SG} - |V_{Tp}|\right)V_{SD} - V_{SD}^2\right] \tag{60.9}$$

For the pFET, β_p is the device transconductance $\beta_p = k'_p$ (W/L); where $k'_p = \mu_p C_{ox}$ is the process transconductance, and (W/L) is the aspect ratio of the device. In complementary metal oxide-semiconductor inverters (CMOS) nFETs and pFETs are used in the same circuit, and it is important to note that $k'_n > k'_p$ due to the fact that the electron mobility is larger than the hole mobility, typically by a factor of 2 to 8.

It is often convenient to use the simplified MOSFET symbols shown in Fig. 60.3. The polarity of the transistor (nMOS or pMOS) is made explicit by the absence or presence of the gate inversion "bubble", as shown. These symbols do not show the bulk electrode explicitly, but it is important to remember that all nFETs have their bulks connected to the lowest voltage in the circuit (usually ground), while all pFET bulks are connected to the highest voltage (usually the power supply V_{DD}).

In digital circuit design, it is useful to model MOSFETs as voltage-controlled switches, as shown in Fig. 60.4. The MOSFET switches are controlled by a gate input signal *G*, which is taken to be a Boolean variable. Employing a positive logic convention, $G = 0$ corresponds to a low voltage (below V_{Tn}), while $G = 1$ is a high voltage. The operation of the FET switches is straightforward. An input of G = 0 places the nFET into cutoff, corresponding to an OPEN switch; $G = 1$ implies active operation, and the switch is CLOSED. The pFET has a complementary behavior, with $G = 0$ giving a CLOSED switch, and $G = 1$ giving an OPEN switch.

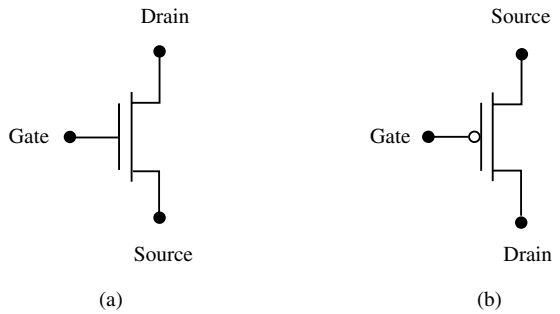

FIGURE 60.3 Simplified MOSFET symbols. (a) nMOSFET; (b) pMOSFET.

© 2003 by CRC Press LLC

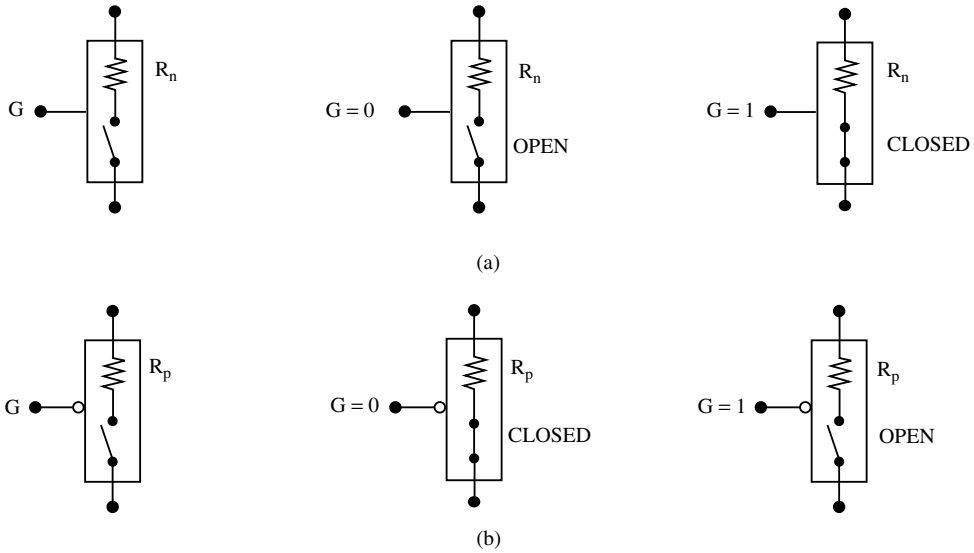

FIGURE 60.4 MOSFET switching models. (a) nFET switch model; (b) pFET switch model.

The switch models include parasitic drain-to-source resistance R_n and R_p, which are usually estimated using

$$R_n = \frac{1}{k_n'(W/L)_n(V_{DD} - V_{Tn})}$$
$$R_p = \frac{1}{k_p'(W/L)_p(V_{DD} - |V_{Tp}|)} \tag{60.10}$$

These equations illustrate the general dependence that the drain-source resistance R is inversely proportional to the aspect ratio (W/L). However, the MOSFET is at best a nonlinear resistor, so that these are only rough estimates. It is important to note the MOSFET parasitic capacitances C_{GS}, C_{GD}, C_{SB}, and C_{DB} must be included in the switching models when performing transient analysis.

The Digital Inverter

An ideal digital inverter is shown in Fig. 60.5. In terms of the Boolean variable A, the inverter accepts A and produces the complement $\overline{A}$. Electronic implementation of the inverter requires assigning voltage ranges for V_{in} and V_{out} to represent logic 0 and logic 1 states. These are chosen according to the DC **voltage transfer characteristics** (VTC) of the electronic circuit. A VTC is simply a plot of the output voltage V_{out} as a function of V_{in}; a general VTC is shown in Fig. 60.6.

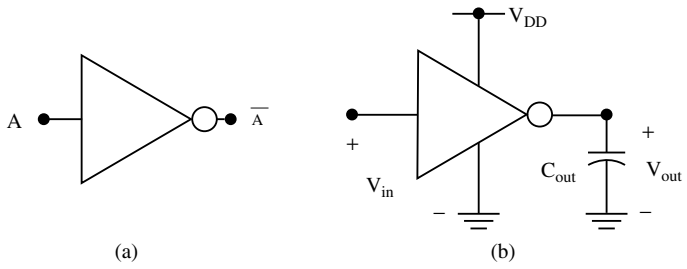

FIGURE 60.5 Basic inverter. (a) Ideal inverter symbol. (b) Electronic parameters.

© 2003 by CRC Press LLC

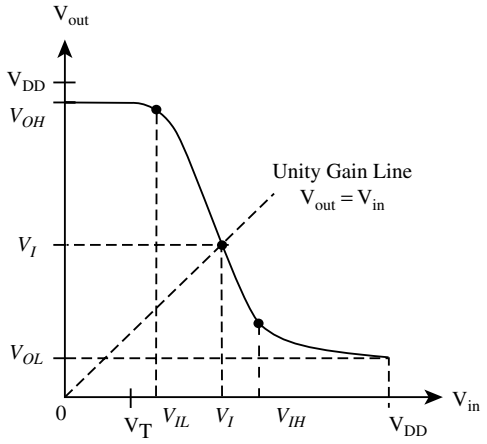

FIGURE 60.6 Inverter voltage transfer characteristics.

Consider first the output voltage V_{out}. The maximum value of V_{out} is denoted by V_{OH}, and is called the output high voltage. This is used to represent an ideal logic 1 output voltage. Conversely, the smallest value of V_{out} is denoted as V_{OL}, and is called the output low voltage. V_{OL} is the output logic 0 voltage. The logic swing of the inverter is then defined by $(V_{OH} - V_{OL})$. The range of input voltage V_{in} used to represent logic 0 and logic 1 input states is usually determined by points on the VTC at which the slope has a value of $(dV_{\text{out}}/dV_{\text{in}}) = -1$. Logic 0 voltages are those with values between 0 V and V_{IL}, the input low voltage. Similarly, voltages in the range from the input voltage V_{IH} to V_{OH} represent logic 1 input levels. The intersection of the VTC with the unity gain line defined by $V_{\text{out}} = V_{in}$ gives the inverter threshold voltage V_I; this represents the switching point of the circuit. The numerical value of V_{OH}, V_{OL} V_{IL}, V_{IHt}, and V_I are determined by the circuit and topology and the characteristics of the devices used in the circuit.

The transient characteristics of the gate are defined by two basic transition times. Figure 60.7 shows V_{in} and V_{out}, and the most important output switching intervals. The input voltage has been taken as an ideal step-like pulse. In a more realistic situation the input voltage is better approximated by a ramp or an exponential. The idealized pulse is used here because it allows a comparison among various circuits.

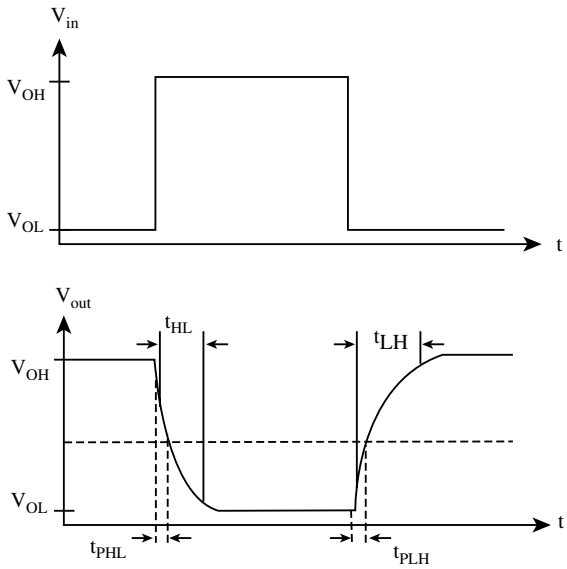

FIGURE 60.7 Inverter switching times.

© 2003 by CRC Press LLC

The most important switching properties of the inverter are the low-to-high time t_{LH}, and the high-to-low time t_{HL} as shown in Fig. 60.7. These represent the minimum response times of the inverter. Note that these time intervals are usually defined between the 10 and 90% voltages instead of the full logic swing. The maximum switching frequency is computed from

$$f_{\max} = \frac{1}{t_{LH} + t_{HL}} \tag{60.11}$$

The propagation delay t_P for the gate is the average time required for a change in the input to be seen at the output. It is computed using the time intervals t_{PHL} and t_{PLH} shown in the diagram from

$$t_P = \left(\frac{1}{2}\right)\left(t_{PHL} + t_{PLH}\right) \tag{60.12}$$

Note that the transition times for this parameter are measured to the 50% voltage.

nMOS Logic Gates

Early generations of MOS logic circuits were based on a single type of MOSFET. The Intel 4004, for example, used only pMOS transistors, while subsequent microprocessor chips such as the Intel 8088, the Zilog Z80, and the Motorola 6800 used only *n*-channel MOSFETs. Although all current MOS-based designs are implemented in CMOS, which employs both nMOS and pMOS devices, it is worthwhile to examine nMOS-only logic circuits. This provides an introduction to the basic characteristics of MOS logic circuits, many of which are used in even the most advanced CMOS techniques.

Several types of inverter circuits can be constructed using *n*-channel MOSFETs. Three configurations are shown in Fig. 60.8. Each circuit uses a switching transistor MD, known as the **driver**, which is controlled by the input voltage V_{in}. The VTC is determined by the **load** device that connects the drain of MD to the power supply V_{DD}. The MD can be viewed as the switched "pull-down" device, while the load serves as the "pull-up" device. In Fig. 60.8(a) a simple linear resistor with a value R_L is used as the load. The circuits in part (b) of the figure use an enhancement-mode (defined with $V_{Tn} > 0$) nMOSFET biased into saturation, while (c) has a depletion-mode nMOSFET (where $V_{Tn} < 0$) as an active load. Active loads provide better switching characteristics due to the nonlinearity of the device. In addition, MOSFETs are much smaller than resistors and process variations are not as critical because the circuit characteristics depend on the ratio of driver-to-load dimensions.

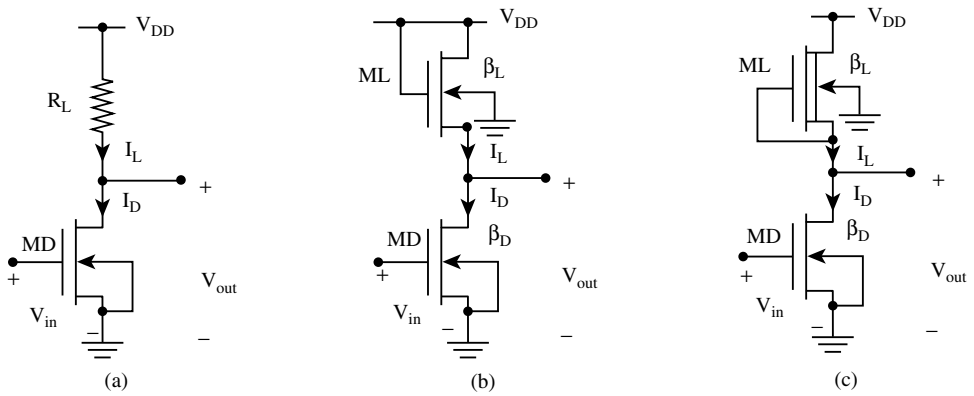

FIGURE 60.8 nMOS inverter circuits. (a) Resistor load; (b) saturated enhancement model MOSFET load; (c) depletion mode MOSFET load.

© 2003 by CRC Press LLC

Although the three nMOS inverter circuits are similar in structure, they have distinct switching properties. Consider the output voltage swing. Circuits (a) and (c) of the figure both have $V_{OH} \approx V_{DD}$, but the active load in (b) gives

$$V_{OH} = V_{DD} - V_{TL} \tag{60.13}$$

with the theshold voltage computed from

$$V_{TL} = V_{T0n} + \gamma\left(\sqrt{2|\phi_F| + V_{OH}} - \sqrt{2|\phi_F|}\right) \tag{60.14}$$

This is referred to as a **threshold voltage loss**, and is due to the fact that the load must have a minimum gate-source voltage of $V_{GSL} = V_{TL}$ to be biased into the active mode. Obviously, $V_{OH} < V_{DD}$ for this circuit.

The value of $V_{OL} > 0$ is determined by a ratio of driver parameters to load parameters. In circuit (a), this ratio is given by $R_L\beta_D$, which is inversely proportional to V_{OL}. This means a small V_{OL} requires that both the load resistance and the driver dimensions are large. In circuits (b) and (c), V_{OL} is set by the driver-to-load ratio $\beta_R = (\beta_D/\beta_L) = (W/L)_D/(W/L)_L$; increasing β_R decreases V_{OL}. For the depletion MOSFET load circuit in (c), the design equation is given by

$$\beta_R = \frac{|V_{TL}|^2}{2(V_{DD} - V_{TD})V_{OL} - V_{OL}^2} \tag{60.15}$$

A condition of $\beta_R > 1$ is generally required to achieve a functional inverter, implying that the driver MOSFET is always larger than the load device. Also, note that is not possible to achieve $V_{OL} = 0$ because this requires an infinite driver-to-load ratio.

The transient switching characteristics are obtained by including the output capacitance C_{out} as shown in Fig. 60.5 at the output. C_{out} consists of the input gate capacitance seen looking in the MOSFET of the next stage, and also has parasitic contributions from the MOSFETs and interconnects. By using a switch model for the driver, it is seen that the transient characteristics are determined by the time required to charge and discharge C_{out}. The high-to-low time t_{HL} represents the time it takes to discharge the capacitor through the driver MOSFET with a device transconductance value of β_D. A rough estimate is obtained using the RC time constant such that $t_{HL} \approx 2R_D\, C_{\text{out}}$, with R_D the equivalent resistance. Similarly, the low-to-high time t_{LH} is the time interval needed to charge C_{out} through the load device. With respect to Fig. 60.8 circuit (c) has the best transient response such that $t_{LH} \approx 2R_L\, C_{out}$, where R_L represents the equivalent resistance of the load MOSFET. nMOS circuits in the mid-1980s had inverter transition times on the order of a few nanoseconds. Because the DC design requires that $\beta_R = (\beta_D/\beta_L) > 1$, and the drain-source resistance of a MOSFET is inversely proportional to β, these circuits exhibit nonsymmetrical switching times with $t_{LH} > t_{HL}$. The propagation delay times can be estimated using $t_{PHL} \approx R_D\, C_{\text{out}}$ and $t_{PLH} \approx R_L\, C_{\text{out}}$ because these are measured relative to the 50% voltage levels.

MOS-based logic design allows one to easily construct other logic functions using the inverter circuit as a guide. For example, adding another driver MOSFET in parallel gives the NOR operation, while adding a series connected driver yields the NAND operation; these are shown in Fig. 60.9.

Complex logic gates for AOI (AND-OR-INVERT) and OAI (OR-AND-INVERT) canonical logic functions can be constructed using the simple rules

- nMOSFETs (or groups) in parallel provide the NOR operation
- nMOSFETs (or groups) in series provide the NAND operation

Examples are provided in Fig. 60.10. It should be noted that this type of circuit structuring is possible because the drain and source are interchangeable. The main problem that arises in design complex nMOS logic gates is that the circuit requires large driver-to-load ratios to achieve small V_{OL} values. The switching

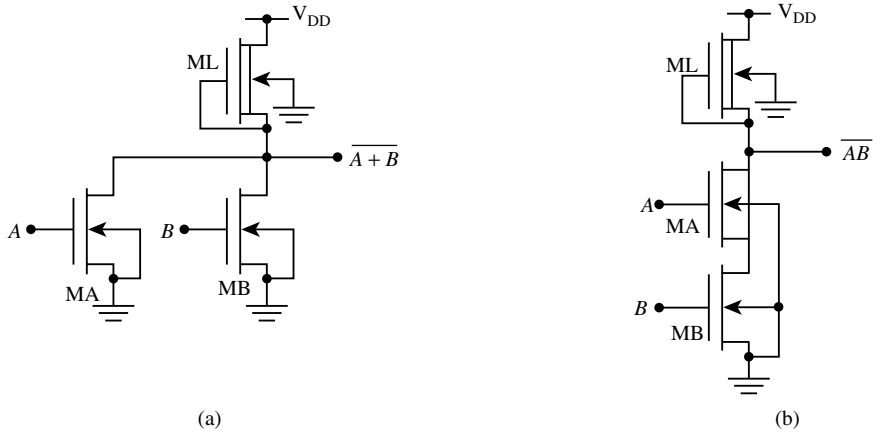

FIGURE 60.9 nMOS NOR and NAND gates. (a) Two-input NOR gate; (b) two-input NAND gate.

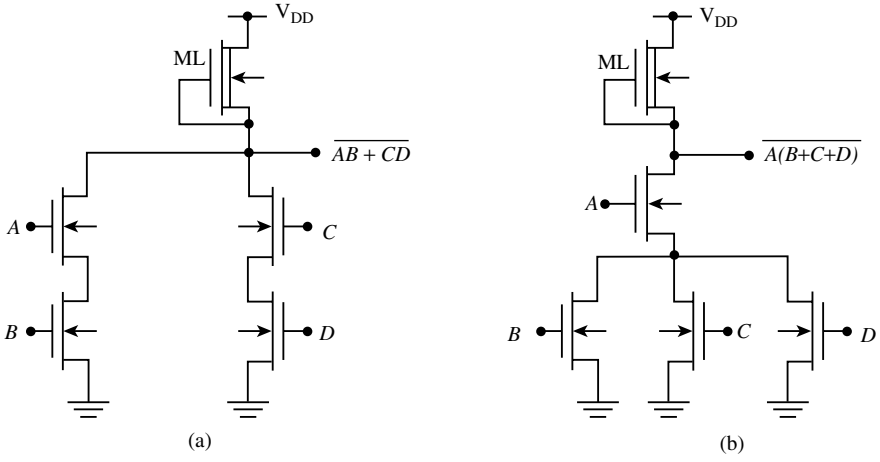

FIGURE 60.10 nMOS AOI logic gates.

FET arrays collectively act like a driver network that must be designed to have a large overall effective β-value. Although parallel-connected MOSFETs are not a problem, the pull-down resistance of series-connected MOSFETs can be large unless the individual aspect ratios are increased. Satisfying this condition requires additional chip area, decreasing the logic density.

CMOS Inverter

A CMOS inverter is shown in Fig. 60.11. This circuit uses a pair of transistors, one nMOS and one pMOS, connected with their gates together. When $V_{\text{in}} < V_{Tn}$, the pFET is active and the nFET is in cutoff. Conversely, when $V_{\text{in}} > (V_{DD} - V_{Tn})$, the nFET is active while the pFET is in cutoff. The two MOSFETs are said to form a complementary pair.

The complementary arrangement of the MOSFETs gives the circuit a full rail-to-rail output range, i.e., $V_{OL} = 0$ V and $V_{OH} = V_{DD}$. The devices are connected in such a way that terminal voltages satisfy

$$\begin{aligned} V_{GSn} + V_{SGp} &= V_{DD} \\ V_{DSn} + V_{SDp} &= V_{DD} \end{aligned} \tag{60.16}$$

© 2003 by CRC Press LLC

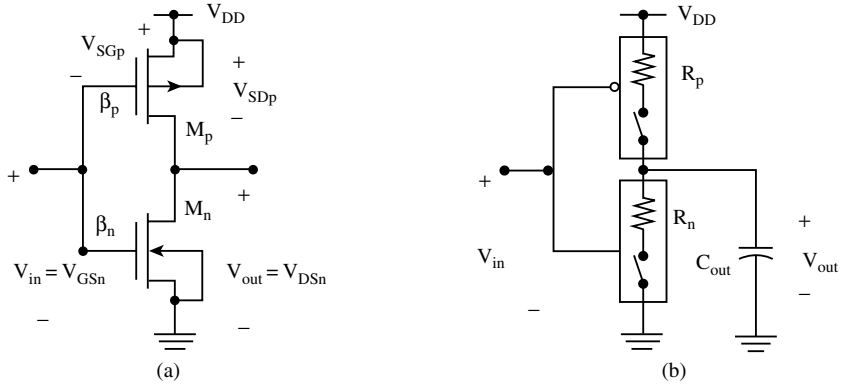

FIGURE 60.11 CMOS inverter. (a) Circuit; (b) switch model.

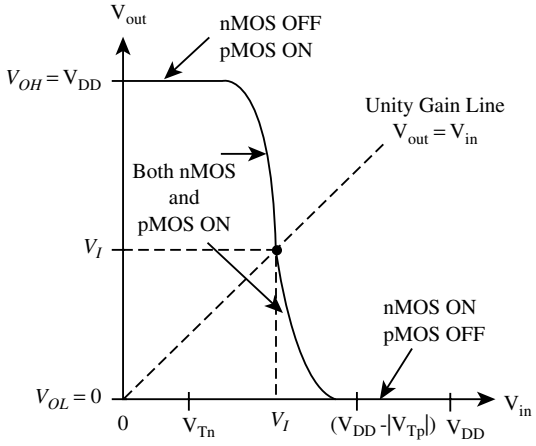

FIGURE 60.12 CMOS VTC.

Note in particular the relationship between the gate-source voltages. Increasing the voltage on one transistor automatically decreases the voltage applied to the other. This provides the VTC with a very sharp transition, as shown in Fig. 60.12. Moreover, the shape of the VTC is almost insensitive to the power supply value V_{DD}, which allows CMOS circuits based on this construction to be used with a range of values. The minimum value of V_{DD} is set by the device the device threshold voltages, and is usually estimated as being about 3 V_T. This is based on the input switching voltage V_{in}, and allows one V_T to switch the nFET, one V_T to switch the pFET, and one V_T for separation. Currently, V_T values equal ~0.5 V, so that the minimum V_{DD} is about 1.5 V. Because V_T is set in the fabrication, the minimum power supply used in low-voltage designs depends upon the process specifications. The maximum value of the power supply voltage is limited by the reverse breakdown voltages of the drain-bulk junctions. This is typically around 14 to 17 V.

Because the structure of the CMOS circuit automatically gives a full-rail output logic swing, the DC design of the gate centers around setting the inverter threshold voltage V_I. At this point, both FETs are saturated, and equating currents gives the expression

$$V_I = \frac{\sqrt{\beta_n/\beta_p}\,V_{Tn} + \left(V_{DD} - \left|V_{Tp}\right|\right)}{1 + \sqrt{\beta_n/\beta_p}} \tag{60.17}$$

© 2003 by CRC Press LLC

This equation shows that V_I can be set by adjusting the ratio β_n/β_p. If $\beta_n = \beta_p$, and $V_{Tn} \approx |V_{Tp}|$, then $V_I \approx (V_{DD}/2)$. Increasing this ratio decrease the inverter switching voltage. If the nFET and pFET are of equal size, then $\beta_n > \beta_p$ (as $k_n' > k_p'$), and $V_1 < (V_{DD}/2)$.

The transient characteristics are obtained by analyzing the charge and discharge current flow paths through the transistors. By using the switch model in Fig. 60.11(b), the primary time constants are

$$\tau_n = R_n C_{\text{out}} = \frac{C_{\text{out}}}{\beta_n\left(V_{DD} - V_{Tn}\right)}$$
$$\tau_p = R_p C_{\text{out}} = \frac{C_{\text{out}}}{\beta_p\left(V_{DD} - |V_{Tp}|\right)} \tag{60.18}$$

Analyzing the transitions with a step input voltage yields

$$t_{HL} = \tau_n\left[\frac{2\left(V_{Tn} - V_0\right)}{\left(V_{DD} - V_{Tn}\right)} + \ln\left(\frac{2\left(V_{DD} - V_{Tn}\right)}{V_0} - 1\right)\right]$$
$$t_{LH} = \tau_p\left[\frac{2\left(|V_{Tp}| - V_0\right)}{\left(V_{DD} - |V_{Tp}|\right)} + \ln\left(\frac{2\left(V_{DD} - |V_{Tp}|\right)}{V_0} - 1\right)\right] \tag{60.19}$$

where $V_0 = 0.1\ V_{DD}$ is the 10% voltage. Noting once again that $k_n' > k_p'$, equal size transistors will give $t_{LH} > t_{HL}$. To obtain symmetrical switching, the pMOSFET must have an aspect ratio of $(\text{W/L})_p = (k_n'/k_p')(\text{W/L})_n$. This illustrates that while the ratio of β-values sets the DC switching voltage V_I, the individual choices for β_n and β_p determine the transient switching times. In general, fast switching requires large transistors, illustrating the speed vs. area trade-off in CMOS design. The propagation delay time exhibits the same dependence.

Another interesting characteristic of the CMOS inverter is the power dissipation. Consider an inverter with stable logic 0 or logic 1 inputs. Because one MOSFET is in cutoff, the DC power supply current I_{DD} is very small, being restricted to leakage levels. The standby DC power dissipation is $P_{DC} = I_{DD}V_{DD} \approx 0$, so that static logic circuits do not dissipate much power under static conditions. Appreciable I_{DD} from the power supply to ground flows only during a transition. Dynamic power dissipation, on the other hand, occurs due to the charging and discharging of the output capacitance C_{out}. The dynamic power dissipation can be estimated by

$$P_{\text{Dynamic}} = C_{\text{out}} V_{DD}^2 f \tag{60.20}$$

where f is the switching frequency of the signal. Qualitatively, this is understood by noting that this is just twice the average stored energy multiplied by the frequency. This illustrates the important result that the power dissipation of a CMOS circuit increases with the switching frequency.

Static CMOS Logic Gates

Static logic gates are based on the inverter. The term "static" means that the output voltages (logic levels) are well defined as long as the inputs are stable. The nFET rules discussed for nMOS logic gates still apply to CMOS. However, static logic gates provide an nFET and a pFET for every input. Proper operation requires that rules be developed for the pMOSFET array as follows:

- pMOSFETs (or groups) in parallel provide the NAND operation
- pMOSFETs (or groups) in series provide the NOR operation

© 2003 by CRC Press LLC

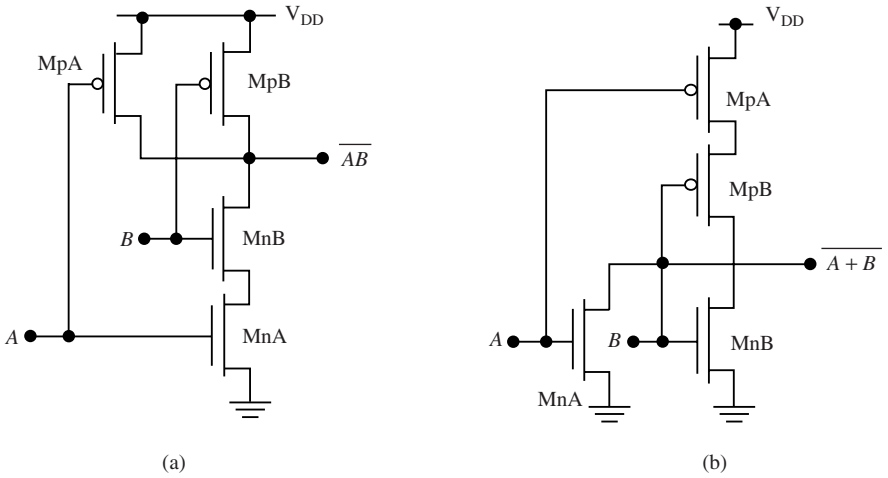

FIGURE 60.13 CMOS (a) NAND and (b) NOR gates.

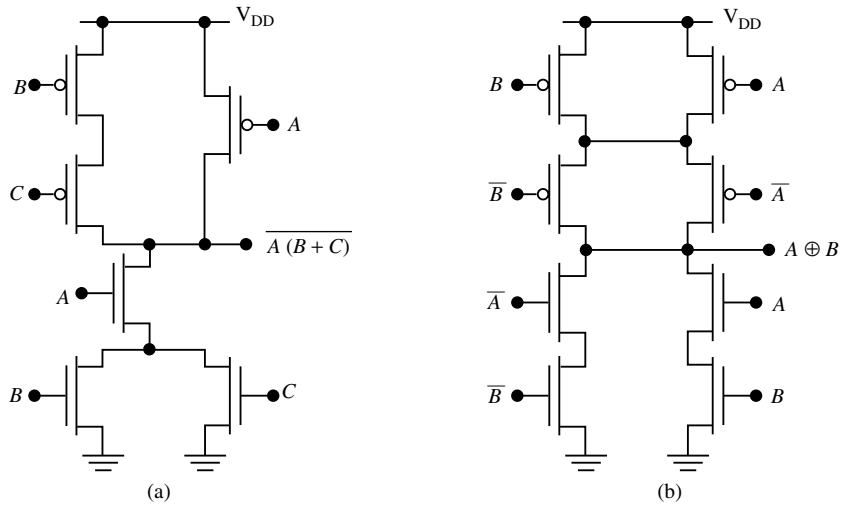

FIGURE 60.14 CMOS AOI logic examples. (a) AOI gate; (b) XOR circuit.

When these rules are compared to the nMOS rules, it is seen that the nFET and pFET arrays are logical duals of one another (i.e., OR goes to AND, and vice versa).

An N-input static CMOS logic gate requires 2N transistors. NAND and NOR gates are shown in Fig. 60.13 using the rules; this type of logic is termed series-parallel, for obvious reasons. Examples of complex logic gates are shown in Fig. 60.14. Note in particular the circuit in Fig. 60.14(b). This implements the XOR function by means of

$$A \oplus B = \overline{AB + \overline{A}\,\overline{B}} = A\overline{B} + \overline{A}B \tag{60.21}$$

Reductions of this type are often performed to work the AOI or OAI equation into a more familiar form.

As seen from these examples, the logic function is determined by the placement of the nFETs and pFETs in their respective arrays. Electrically, the design problem centers around choosing the aspect ratios to achieve acceptable switching times. Because a MOSFET has a parasitic drain-source resistance that varies as $(1/\beta)$, series-connected transistor chains exhibit larger time constants than parallel-connected

© 2003 by CRC Press LLC

arrangements. Recalling that $R_n < R_p$ shows that for equal size devices, series chains of nFETs are preferable to the same number of series-connected pFETs. Consequently, NAND gates are used more frequently than NOR gates, and AOI logic functions with a small number of OR operations are better. It is also possible to expand to transistor arrays that are not of the series-parallel type, such as a delta configuration, but it is difficult to devise general design guidelines for these circuits.

Canonical CMOS static logic design is based on using pairs of nMOS and pMOS transistors. In modern very large scale integration (VLSI) design, the design complexity is limited by the interconnect (as opposed to the number of transistors), so that the need to connect every input to two transistors may result in problems in the chip layout. Pseudo-nMOS circuits provide an alternative to standard CMOS circuits. These logic gates implement logic using nFET arrays; however, the pMOS array is replaced by a single *p*-channel MOSFET that acts as a load device. Figure 60.15 shows an inverter and an AOI circuit implement based on pseudo-nMOS structuring. In both circuits, the load pMOSFET is biased active with $V_{SGp} = V_{DD}$ by grounding the gate. Although the circuits are simplified, two main problems arise with this type of circuit. First, the output low voltage V_{OL} is determined by the driver-to-load ratio $(\beta_n/\beta_p) > 1$, so that large driver nFETs are required. Second, if the input voltage is high, then the circuit dissipates DC power. Despite these drawbacks, pseudo-nMOS circuits may be useful in certain situations.

Transmission gates (TGs) provide another approach to implementing logic functions in CMOS. The properties of transmission gates are discussed in more detail in the next section. However, because they are useful for certain types of logic gates, a short discussion has been included here. A basic TG consists of an nMOSFET and a pMOSFET in parallel, as shown in Fig. 60.16(a); the symbol in (b) represents the

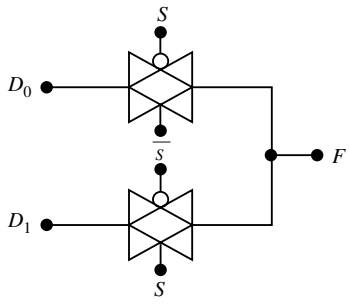

FIGURE 60.17 TG-based 2:1 multiplexer.

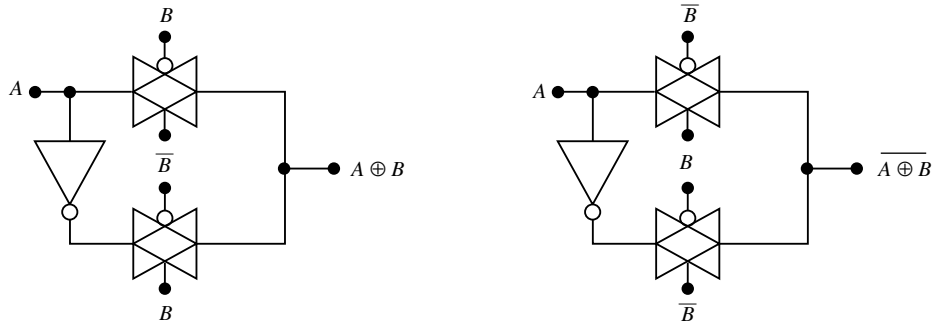

FIGURE 60.18 TG-based (a) XOR and (b) XNOR logic gates.

composite structure. Transmission gates act like voltage-controlled switches: logically, a condition of $C = 0$ gives an open switch, while $C = 1$ gives a closed switch. Transmission gates can pass the full range of voltages (from 0 V to V_{DD}) in either direction; this is not possible with a single device, due to the threshold voltage characteristic discussed earlier in this section.

Figure 60.17 illustrates a simple 2: 1 multiplexer (MUX) with two input lines, D_0 and D_1, and a control bit S. When S = 0, the upper TG is closed, and the output is $F = D_0$. Conversely, $S = 1$ closes the bottom TG, so $F = D_1$. The operation of this circuit is expressed by

$$F = \overline{S}D_0 + SD_1 \tag{60.22}$$

The circuit can be expanded easily to create larger multiplexers. For example, an 8: 1 requires three select bits, and each of the eight lines will be a switching network using three TGs. Several other TG-based logic functions are popular in CMOS design. Figure 60.18 shows the exclusive-OR (XOR) and exclusive-NOR (XNOR) circuits. The primary drawbacks of TG-based logic circuits are that (1) the TG does not have a connection to the power supply, and acts as a parasitic RC element to the stage that drives it, and (2) the chip layout may become large, complicated, or both. In particular, (1) implies that TG circuits may be slower than equivalent functions designed using basic static CMOS techniques.

Dynamic CMOS Logic Gates

Dynamic CMOS logic gates are characterized as having outputs that are valid only for a limited time interval. Although this property inherently makes the circuit design more challenging, dynamic logic circuits can potentially achieve fast switching speeds. In general, dynamic circuits use parasitic capacitors in the MOS circuit to store charge Q. Because $Q = CV$, the presence or absence of charge corresponds to a logic 1 or logic 0 level, respectively, MOSFETs are used as voltage-controlled switches to "steer" the

© 2003 by CRC Press LLC

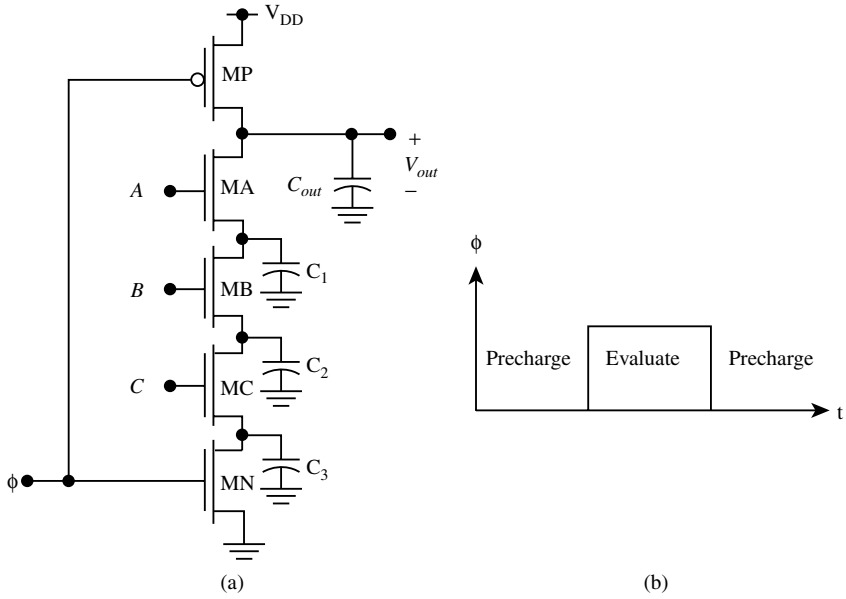

FIGURE 60.19 Dynamic CMOS logic gate. (a) Three-input NAND gate; (b) timing intervals.

charge on and off the logic nodes. Several dynamic logic families have appeared in the literature, each having distinct characteristics. We now merely touch on some characteristics of a basic circuit which illustrates the important points.

Consider the dynamic logic circuit in Fig. 60.19 for a three-input NAND gate. The transistors labeled MP and MN are controlled by the clock $\phi(t)$, and provide synchronization of the data flow. Note the presence of capacitors C_{out}, C_1, C_2, and C_3. These represent parasitic capacitances due to the transistors and interconnect, and are crucial to the operation.

The circuit is controlled by the timing provided by $\phi(t)$. When $\phi = 0$, MP is ON and MN is OFF. During this time, C_{out} is charged to a voltage $V_{\text{out}} = V_{DD}$, which is called a **precharge event**. When ϕ changes to a level $\phi = 1$, MP is driven into cutoff, but MN is biased ON; the operation of the circuit during this time is termed a **conditional discharge event**. If the inputs are set to $(A, B, C) = (1, 1, 1)$, then all three logic transistors, MA, MB, and MC, are ON, and C_{out} can discharge through these transistors and MN to a final voltage of $V_{\text{out}} = 0$ V. If at least one input is a logic 0, then C_{out} does not have a direct discharge path to ground. Ideally, V_{out} would stay at V_{DD}. However, charge leakage occurs across the reverse-biased drain-bulk *pn* junctions in the MOSFETs, eventually leading to a value of V_{out} 0 V. Typically, the output voltage can be held only for a few milliseconds, thus leading to the name "dynamic circuit".

Another problem that arises in dynamic logic circuits is that of **charge sharing**. Consider the three-input NAND gate with inputs of $(A, B, C) = (0, \text{X}, \text{X})$ during the precharge, where X is a do not care condition. The total charge transferred to the circuit from the power supply is

$$Q_T = C_{\text{out}} V_{DD} \tag{60.23}$$

Now suppose that the inputs are switched to $(A, B, C) = (1, 1, 0)$ during the evaluation phase. MOSFETs MA and MB are ON, but MC is OFF, blocking the discharge path. Charge sharing occurs because the charge originally stored on C_{out} is now shared with C_1 and C_2. After the transients have decayed, the three capacitors are in parallel, Ignoring any threshold drop, they will share the same final voltage V_f such that

$$Q_T = \left(C_{\text{out}} + C_1 + C_2\right) V_f \tag{60.24}$$

© 2003 by CRC Press LLC

Equating the two expressions for charge gives

$$V_f = \frac{C_{\text{out}}}{C_{\text{out}} + C_1 + C_2} V_{DD} < V_{DD} \tag{60.25}$$

To ensure that the output voltage remains at a logic 1 high voltage, the capacitors must satisfy the relation

$$C_{\text{out}} \gg C_1 + C_2 \tag{60.26}$$

The capacitance values are proportional to the sizes of the contributing regions, so that the performance is closely tied to the layout of the chip.

60.2 Transmission Gates

Robert C. Chang and Bing J. Sheu

A signal propagates through a transmission gate (TG) in a unique manner. In conventional logic gates, the input signal is applied to the gate terminal of an MOS transistor and the output signal is produced at the drain or the source terminal. In a TG, the input signal propagates between the source and the drain terminals through the transistor channel, while the gate voltage is held at a constant value. The TG is turned off if the voltage applied to the gate terminal is below the threshold voltage. The TG approach can be used in digital data processing to implement special switching functions with high performance as well as a small transistor count [1]. It also can be used in analog signal processing to act as a compact voltage-controlled resistor.

Digital Processing

Single Transistor Version

A TG can be constructed by a single nMOS or pMOS transistor, as shown in Fig. 60.20. For an nMOS TG to pass a signal V_{in} to the output terminal, the selection signal S is set to the logic 1 value, i.e., the gate voltage V_G is set to a high voltage value V_{DD}. If the input signal is also the V_{DD} value, the output voltage V_{out} is determined by [2],

$$V_{\text{out}}(t) = \left(V_{DD} - V_{thn}\right)\left[\frac{t/\tau_{nc}}{1 + \left(t/\tau_{nc}\right)}\right] \tag{60.27}$$

where V_{thn} is the threshold voltage of the nMOS transistor with the body effect and τ_{nc} is the charging time constant which can be expressed as

© 2003 by CRC Press LLC

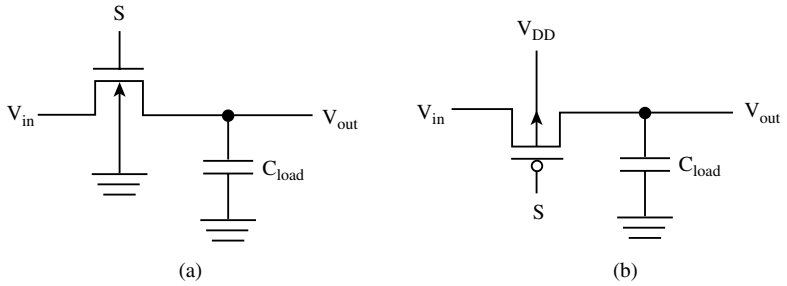

FIGURE 60.20 (a) nMOS TG; (b) pMOS TG.

$$\tau_{nc} = \frac{2C_{\text{out}}}{\mu_n C_{\text{OX}}(\text{W/L})(V_{DD} - V_{thn})} \tag{60.28}$$

Here, μ_n is the carrier mobility, C_{OX} is the per-unit-area capacitance value, and W/L is the transistor aspect ratio. If time t goes to ∞, then V_{out} will approach $V_{DD} - V_{thn}$, which indicates that a threshold voltage loss occurs in the signal from the input node to the output node. This is due to the fact that V_{GS} must be greater than the threshold voltage to turn on the nMOS transistor. Owing to this voltage reduction, an nMOS TG can only transmit a "weak" logic 1 value. However, a logic 0 can be transmitted by an nMOS TG without penalty. In order to analyze this case, we set $V_{\text{in}} = 0$ and $V_{\text{out}}(t = 0) = V_{DD} - V_{thn}$. The output voltage V_{out} is determined by

$$V_{\text{out}}(t) = (V_{DD} - V_{thn})\left[\frac{2e^{-(t/\tau_{nd})}}{1 + e^{-(t/\tau_{nd})}}\right] \tag{60.29}$$

where the discharge time constant can be expressed as

$$\tau_{nd} = \frac{C_{\text{out}}}{\mu_n C_{\text{OX}}(\text{W/L})(V_{DD} - V_{thn})} \tag{60.30}$$

Notice that V_{out} will approach zero as time goes to infinity. Input-output (I-O) characteristics of an nMOS transmission gate are shown in Fig. 60.21.

The schematic diagram of a pMOS TG is shown in Fig. 60.20(b). For a pMOS transmission gate to pass a signal V_{in} to the output terminal, the selection signal S is set to the logic 0 value. To transmit a logic 0 value with the initial V_{out} value being V_{DD}, the expression for V_{out} is given as

$$V_{\text{out}}(t) = |V_{thp}| + \frac{V_{DD} - |V_{thp}|}{1 + (V_{DD} - |V_{thp}|)(t/2\tau_{pd})} \tag{60.31}$$

where τ_{pd} is the discharging time constant for the pMOS TG. As time goes to infinity, V_{out} will approach $|V_{thp}|$, so that the pMOS TG can only transmit a "weak" logic 0 value. On the other hand, the pMOS

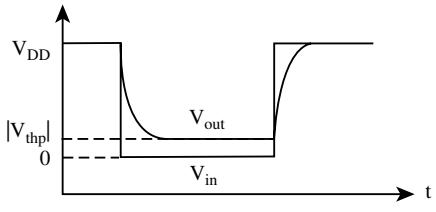

FIGURE 60.21 Characteristics of nMOS TG.

© 2003 by CRC Press LLC

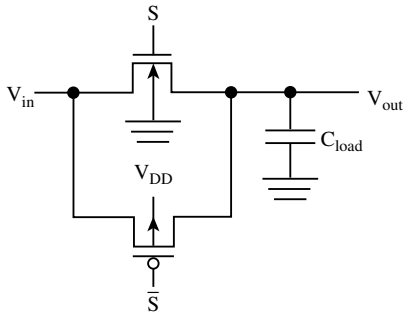

FIGURE 60.22 Characteristics of pMOS TG.

transmission gate can perfectly transmit a logic 1 value. To analyze this case, we set $V_{in} = V_{DD}$ and assume the initial V_{out} Value as $|V_{thp}|$. The expression for V_{out} is given as

$$V_{out}(t) = V_{DD} - \left(V_{DD} - |V_{thp}|\right)\left(\frac{2e^{-(t/\tau_{pc})}}{1+e^{-(t/\tau_{pc})}}\right) \tag{60.32}$$

where τ_{pc} is the charging time constant for the pMOS TG. The output voltage will approach V_{DD} as time goes to ∞. The transfer characteristics of the pMOS transmission gate is shown in Fig. 60.22.

Complementary Transistor Version

Figure 60.23 is the schematic diagram of a complementary transistor version of the TG which can be constructed by combining the characteristics of nMOS and pMOS TGs. The CMOS TG can transmit both the logic 0 and logic 1 values without any degradation. The voltage transmission properties of the single transistor and CMOS TGs are summarized in Table 60.1. The overall behavior of the CMOS TG can be described as follows. When the selection signal S is low, both the nMOS and pMOS transistors are cut off. The output voltage V_{out} will remain at a high impedance state. When the selection signal S is high, both the nMOS and pMOS transistors are turned on and the output voltage will be equal to the input voltage.

Three regions of operation exist for a CMOS TG. In region 1 $V_{in} < |V_{thp}|$, then nMOS transistor is in the triode region and the pMOS transistor is in the cutoff region. Because the pMOS transistor is turned off, the total current, I_{tot}, is supplied by the nMOS transistor and I_{tot} decreases as V_{in} increases. In region $2|V_{thp}| < V_{in} < V_{DD} - V_{thn}$ both the nMOS and pMOS transistors are in the triode region. In this region, the nMOS transistor current decreases and the pMOS transistor current increases as V_{in} increases. Thus, I_{tot} is approximately a constant value. In region 3 $V_{in} > V_{DD} - V_{thn}$ the nMOS transistor is turned off and the pMOS transistor is in the triode region. The plot of the TG on-resistance is shown in Fig. 60.24.

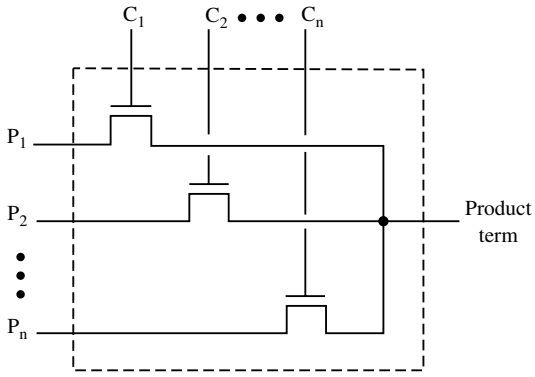

FIGURE 60.25 Model for pass transistor logic.

Pass-Transistor Logic

Pass-transistor logic is a family of logic which is composed of TG. Methods for deriving pass-transistor logic using nMOS TGs have been reported [3]. Figure 60.25 shows the schematic diagram of the pass-transistor logic in which a set of pass signals, $P_i's$, are applied to the sources of the nMOS transistors and another set of control signals, $C_i's$, are applied to the gates of the nMOS transistors.

The desired logic function F can be expressed as $F = C_1 \cdot P_1 + C_2 \cdot P_2 + \ldots + C_n \cdot P_n$. When $C_i's$ are high, $P_i's$ are transmitted to the output node. $P_i's$ can be logic 0, logic 1, true, or complement of the ith input variable X_i, or the high-impedance state Z. Constructing a Karnaugh map can help one to design the pass-transistor circuit. The pass function rather than the desired output values is put to the corresponding locations in the Karnaugh map. Then any variables that may act as a control variable or a pass variable are grouped.

For example, consider the design of a two-input XOR function. The truth table and the modified Karnaugh map of the XOR function are given in Tables 60.2 and 60.3, respectively. By grouping the A column when B is 0, and the $\overline{A}$ column when B is 1, the function can be expressed as

$$F = \overline{B} \cdot A + B \cdot \overline{A} \tag{60.33}$$

where the B is a control variable and A is a pass variable.

		B	B
	1	A	$\overline{A}$
		$\overline{B}$	$\overline{B}$

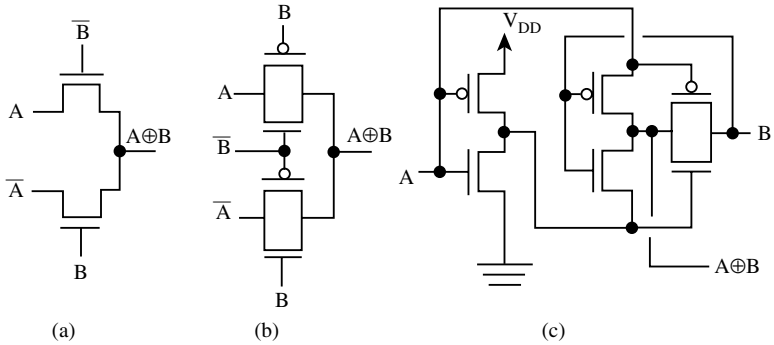

FIGURE 60.26 XOR gates. (a) nMOS version. (b) Complementary version I. (c) Complementary version II.

Figure 60.26(a) and (b) show the schematic diagrams of nMOS and CMOS implementations of the XOR function. When the control variable B is with a logic 0 value, the pass variable A is transmitted to the output. When the control variable B is with a logic 1 value, the pass variable $\overline{A}$ is transmitted to the output. Another implementation of the XOR function is shown in Fig. 60.26 (c).

It is not permitted to have groupings that transmit both true and false values of the input variable to the output simultaneously. The final expression must contain all the cells in the Karnaugh map. Note that the *p*-transistor circuit is the dual of the *n*-transistor circuit. Thus, the *p*-pass function must be constructed when a complementary version is required. In addition, the pass variable with logic 0 value is transmitted by the nMOS network in a complementary implementation while the pass variable with logic 1 value is transmitted by the pMOS network.

The OR function can be constructed by one pMOS transistor and one CMOS TG, as shown in Fig. 60.27. When the input signal A is with the logic 0 value, the CMOS TG is turned on and the input signal B is passed to the output node. On the other hand, if the input signal A is with the logic 1 value, the pMOS TG is turned on and the logic 1 value of input signal A is transmitted to the output node. Because the pMOS TG can propagate a "strong" logic 1 value it is not necessary to use another CMOS TG.

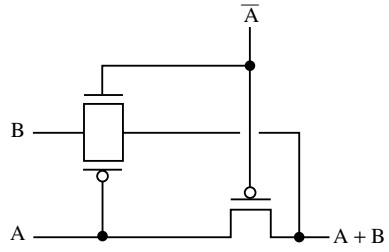

FIGURE 60.27 OR gates.

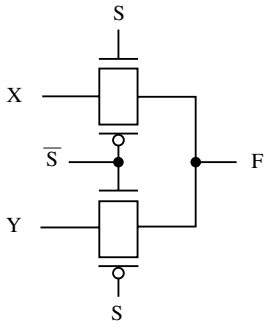

FIGURE 60.28 A two-input multiplexer.

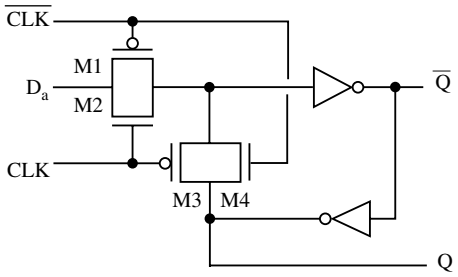

FIGURE 60.29 A CMOS *D* latch.

Transmission gates can be used to construct a multiplexer which selects and transmits one of the inputs to the output. Figure 60.28 is the circuit schematic diagram of a two-input multiplexer, which is composed of CMOS TGs. The output function of the two-input multiplexer is

$$F = X \cdot S + Y \cdot \overline{S} \tag{60.34}$$

If the selection signal S is at a logic 1 value, the input signal X is transmitted to the output. On the other hand, if the selection signal S is at a logic 0 value, the input signal Y is transmitted to the output. Multiplexers are important components in CMOS data manipulation structures and memory elements.

A basic *D* latch can be constructed by two TGs and two invertes, as shown in Fig. 60.29. When the *CLK* signal is at a logic 0 value, pass transistors M1 and M2 are turned off so that the input signal D_a cannot be transmitted to the outputs Q and $\overline{Q}$. In addition, pass transistors M3 and M4 are turned on so that a feedback path around the inverter pair is established and the current state of Q is stored. When the *CLK* signal is at a logic 1 value, M1 and M2 are turned on and M3 and M4 are turned off. Thus, the output signal Q is set to the input signal D_a and $\overline{Q}$ is set to $\overline{D}_a$. Because the output signal Q will follow the change of input signal D_a when the *CLK* signal is high, this circuit is a positive level-sensitive *D* latch. A positive edge-trigger register or so-called *D* flip-flop can be designed by combining one positive level-sensitive *D* latch and one negative level-sensitive *D* latch. By cascading *D* flip-flops, a shift register can be constructed.

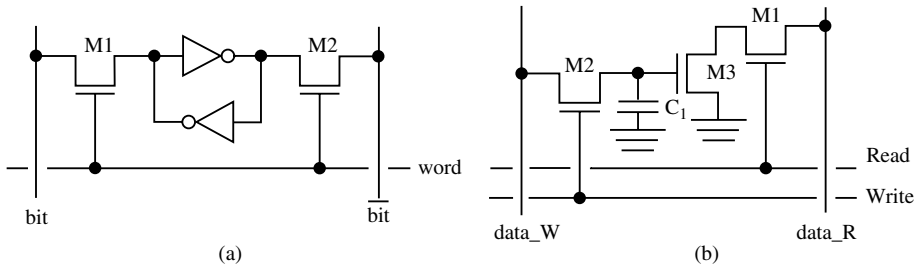

FIGURE 60.30 (a) SRAM cell; (b) DRAM cell.

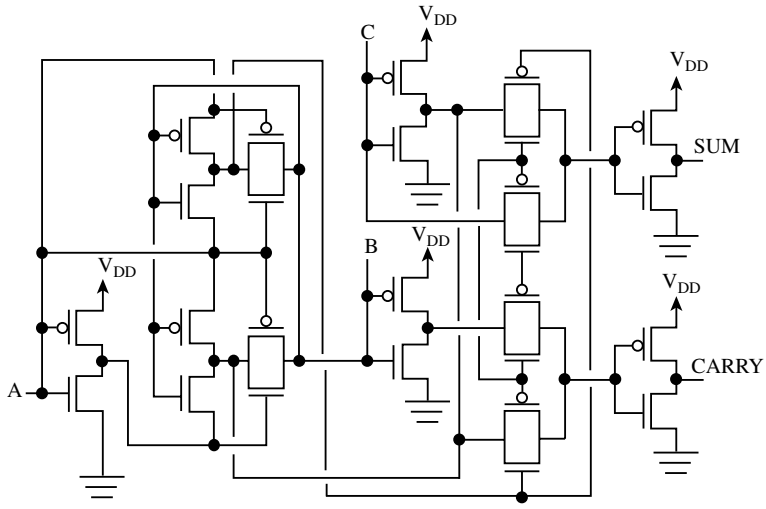

FIGURE 60.31 TG adder.

Transmission gates can be used in the design of memory circuits. A typical random access memory (RAM) architecture consists of one row/word decoder, one column/bit decoder, and memory cells. The memory cells used in RAMs can be categorized into static cells and dynamic cells. Memory data/charges are stored on the latches in static cells, while on the capacitors in dynamic cells. The static random access memories (SRAMs) are not forced to include the refresh circuitry and are faster than the dynamic random access memories (DRAMs). However, the size of SRAM cells is much larger than that of DRAM cells. The most commonly used circuit in the design of SRAM cells is the six-transistor circuit shown in Fig. 60.30. Four transistors are used to form two cross-coupled inverters. The other two transistors, M1 and M2, are TGs to control the read/write operation of the memory cell. If the word line is not selected, the data stored on the latch will not change as long as the leakage current is small. If the word line is selected, the transistors M1 and M2 are turned on. Through the bit and $\overline{bit}$ lines, data can be written into the latch or the stored data can be read out by the sense amplifier. Transmission gates can also be found in the four-transistor DRAM cell circuit, as shown in Fig. 60.30(b). When the *Read* line is selected, pass transistor M1 is turned on and the data stored on the capacitor C_1 are read out. When the *Write* line is selected, pass transistor M2 is turned on and the data from *data_W* line are written into the cell.

Figure 60.31 is the circuit schematic diagram of a TG adder, which consists of four transmission gates, four inverters, and two XOR gates [4]. The *SUM* output, which represents $A \oplus B \oplus C$, is constructed by a multiplexer controlled by A $\oplus$ B and its complement. Notice that when $A \oplus B$ is false, the *CARRY* output equals *A* or *B*. Otherwise, *CARRY* output takes the value of input signal. *C*. Although the TG adder has the same number of transistors as the combinational adder, it has the advantage of having

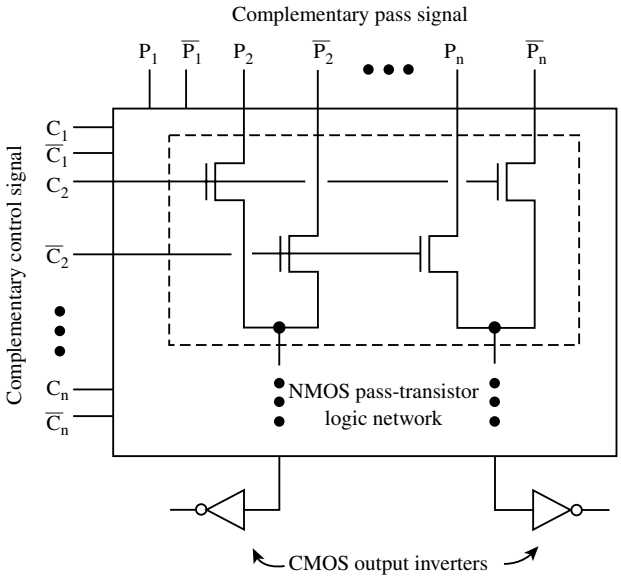

FIGURE 60.32 Schematic structure of the basic CPL circuit.

noninverted *SUM* and *CARRY* output signals and an equal delay time for the *SUM* and *CARRY* output signals.

Another form of differential CMOS logic, complementary pass-transistor logic (CPL), has been developed and utilized on the critical path to achieve very high speed operation [5]. Figure 60.32 is the circuit schematic diagram of the basic CPL structure using an nMOS pass-transistor logic organization. The CPL is constructed by an nMOS pass-transistor logic network, complementary inputs and outputs, and CMOS output inverters. As the nMOS pass transistor will transmit a logic 1 signal with one threshold voltage reduction, the output signals must be amplified by the CMOS inverters which can shift the logic threshold voltage and drive a large capacitive load. One attractive feature of the CPL design is that complementary outputs are generated by the simple four-transistor circuits. Because inverters are not required in CPL circuits, the number of critical-path gate stages can be reduced.

Figure 60.33 shows the schematic diagrams of four basic CPL circuit modules: an AND/NAND module, an OR/NOR module, an XOR/XNOR module, and a wired-AND/NAND module [5,6]. By combining these four circuit modules, arbitrary Boolean functions can be constructed. These modules have an identical circuit schematic and are distinguished by different arrangements of input signals. This property of CPL is quite suitable for master-slice design.

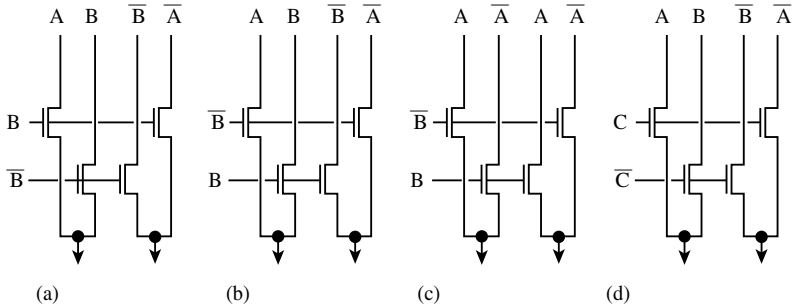

FIGURE 60.33 CPL circuit modules. (a) AND/NAND; (b) OR/NOR; (c) XOR/XNOR; (d) Wire-AND/NAND.

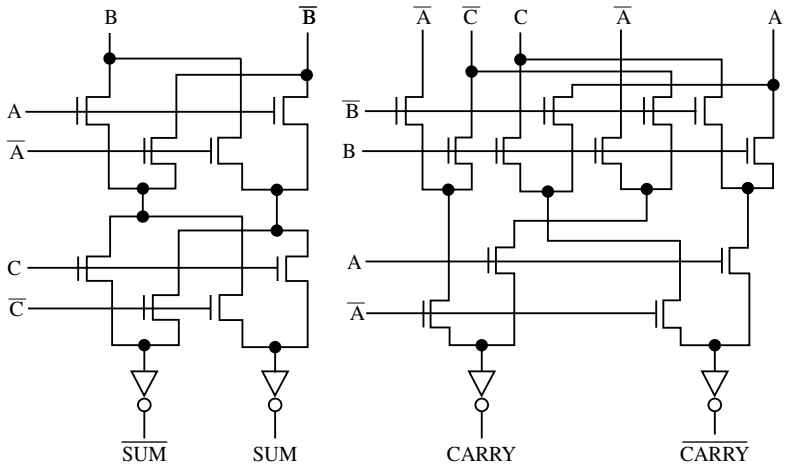

FIGURE 60.34 CPL full adder circuit.

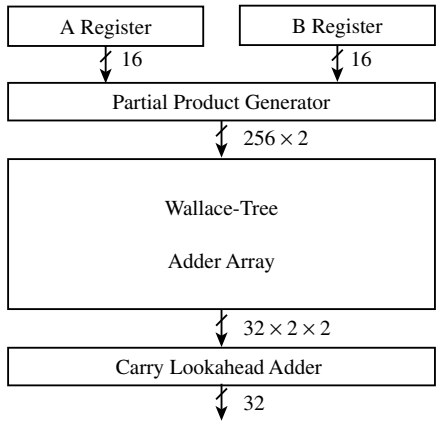

FIGURE 60.35 Block diagram of the 16 × 16 bit multiplier.

The schematic diagram of a CPL full adder is shown in Fig. 60.34. Both the circuitry to produce the *SUM* output signal and the circuitry to produce the *CARRY* output signal are constructed from basic CPL modules. The *SUM* circuitry consists of two XOR/XNOR modules, while the *CARRY* circuitry consists of three wired-AND/NAND modules. The CMOS output inverters are fixed "overhead" because they are required whether the circuit has one, two, or many inputs. Thus, designing with a complex Boolean function in a CPL gate is preferred to minimize the delay time and overall device count.

Figure 60.35 is the block diagram of a 16 × 16 bit multiplier, which is constructed by using a parallel multiplication architecture. A carry-look-ahead (CLA) adder and a Wallace-tree adder array are used to minimize the critical-path gate stages. The number of transistors in the CPL multiplier is less than that in a full CMOS counterpart [7].

Due to the continued device miniaturization and the recent drive of portable systems, VLSI systems have been pushing toward low-voltage, low-power operation. Various techniques from system level to device level were developed to reduce the operating voltage and the power consumption of the VLSI circuits [8, 9]. The low-power design can be addressed at four levels: algorithm, architecture, logic style, and integration. At the logic design level, capacitive loads are to be reduced and the number of charging/discharging operations are to be minimized. A CPL is one of the most attractive logic families that can achieve very low power consumption. The input capacitance in CPL is about half that of the CMOS

© 2003 by CRC Press LLC

configuration because pMOS can be eliminated in logic organization. Therefore, CPL can achieve a higher speed and dissipate less power. Experimental results [5] show that for the same delay time of the CMOS full adder operating at 5 V, the CPL adder requires only a 2-V supply. As the supply voltage decreases, the delay time will increase, but the power-delay product will decrease. Hence, it is desirable to operate at the slowest allowable speed to reduce power dissipation. Experimental results indicate that performance of CPL logic style is better than the conventional CMOS logic style from the viewpoint of power consumption.

Analog Processing

MOS Operational Amplifier Compensation

The frequency stabilization of a basic two-stage CMOS amplifier can be achieved by using a pole-splitting capacitor C_C [10]. The pole p_1 due to the capacitive loading of the first stage is pushed down to a very low frequency, and the pole p_2 due to the capacitance at the output node of the second stage is pushed to a very high frequency. However, a right-half-plane zero is introduced by the feedthrough effect of the compensation capacitor C_C. It will degrade the stability of the op amp and make the second stage behavior like a short-circuited configuration at high frequencies. In order to remove the effects of the zero, a source follower can be inserted in the path from the output back through the compensation capacitor. Another approach is to insert a nulling resistance, R_Z, in series with the compensation capacitor. If R_Z is set to $1/g_{m2}$, where g_{m2} is the transconductance of the second stage, the zero vanishes and the feedthrough effect is cancelled out. A single transistor or complementary version of the TG can be used to implement R_Z. Figure 60.36 is the schematic diagram of a basic two-stage op amp supplemented by a feedback branch (M8, C_C) for compensation [11]. Capacitance C_L is the load capacitance to be driven by the amplifier. The pMOS TG M8 is biased in the triode region and provides the equivalent resistance.

Transmission gates can be used to construct the cascode configuration of an op amp. A fully differential folded-cascode op amp is shown in Fig. 60.37 [11]. The output cascode stage consists of TGs M5 to M10. A high output impedance can be achieved by using the split-load arrangement. The bias voltage V_{bias1} establishes the bias current I of the input stage, and a bias current I_0 in the output transistors M7 to M12. Thus, each transistor of M3 to M6 has a stabilized current $I_0 + I/2$. The source voltages of M5 and M6 are stabilized because they conduct stabilized currents and their gate voltages are fixed at V_{bias2}. This fixes $|v_{DS3}|$ and $|v_{DS4}|$. Let transistors M3 and M4 have the same W/L ratio and bias them in the triode region by choosing a suitable value for V_{bias2}. If the ouput common-mode voltage $v_{0,c}$ drops, the resistance

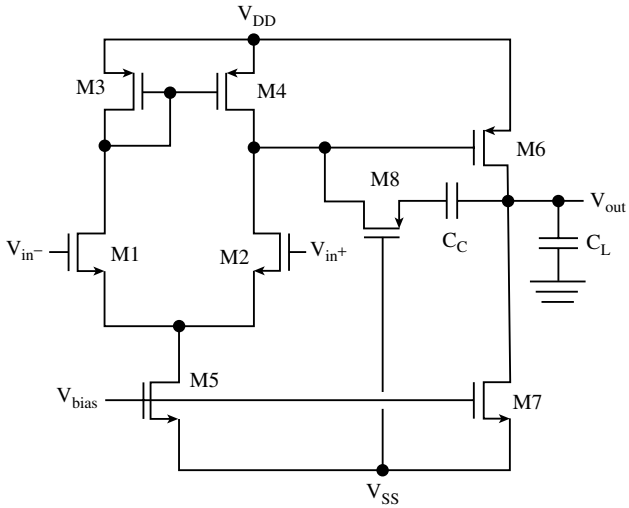

FIGURE 60.36 CMOS op amp.

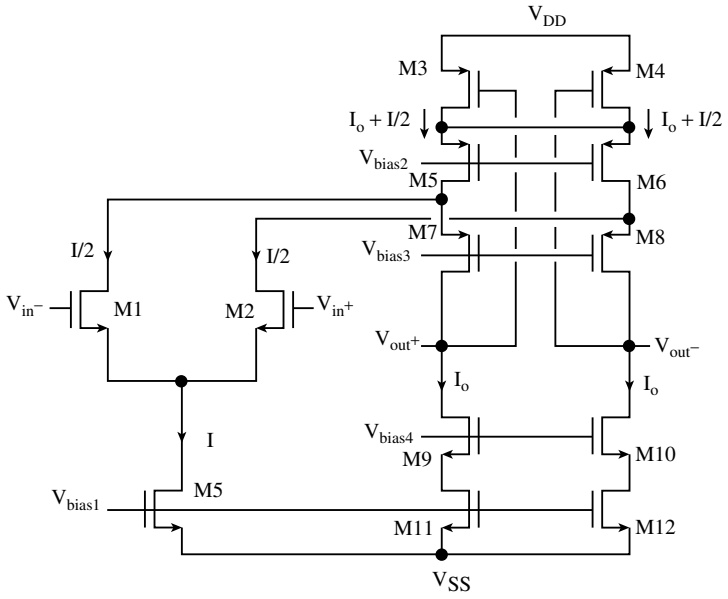

FIGURE 60.37 A fully differential CMOS op amp with stabilized DC output level.

of M3 and M4 reduces, which increases $|v_{GS5}|$ and $|v_{GS6}|$. Because the current in M5 and M6 remains unchanged, $|v_{DS5}|$ and $|v_{DS6}|$ are forced to decrease. Then, the drain voltages of M5 and M6 increase, which increases $|v_{GS7}|$ and $|v_{GS8}|$. Therefore, $|v_{DS7}|$ and $|v_{DS8}|$ reduce which forces v_0^+ and v_0^- to rise. The common-mode voltage $v_{0,c}$ is thus increased. This approach can increase the common-mode rejection ratio (CMRR) of the op amp. The negative feedback scheme tends to keep $v_{0,c}$ at a constant value. It means that the small-signal common-mode output is zero or a very small value. Thus, a high CMRR is achieved.

Transimpedance Compensation

The optical receiver is an important component of the optical fiber communication system. One of the basic modules in a high performance optical receiver is the low-noise preamplifier. Several approaches are available to design the preamplifier. One approach is to use the transimpedance design which can avoid the equalization and limited dynamic range problems by using negative feedback. Transmission gates can be used to provide the feedback resistance for a transimpedance amplifier.

A complete preamplifier circuit schematic is given in Fig. 60.38 [12]. This circuit consists of three gain stages and two TGs. Each gain stage is composed of a pMOS current source achieving a common-source amplification with a folded nMOS load. One TG transistor, M10, functions as a feedback resistor and the other, M11, functions to implement the automatic gain control function. The gate voltage of M10 is derived from another circuit which minimizes the temperature and power supply dependence of the feedback resistance [12]. Transistor M11 is controlled by the automatic gain control voltage [13] and is normally off. If the input current to the preamplifier forces the output voltage out of its linear range, M11 is turned on and begins to shunt current away from the feedback resistor and into the first stage output node.

With recent progress in intelligent information processing, artificial neural networks can be used to perform several complex functions in scientific and engineering applications, including classification, pattern recognition, noise removal, optimization, and adaptive control [14]. Design and implementation of VLSI neural networks have become a very important engineering task. The basic structure of an artificial neural network consists of a matrix of synapse cells interconnecting an array of input neurons with an array of output neurons. The inputs, V_i, are multiplied by weight values, T_i, of the synapses. The results of the multiplication are summed and compared to the threshold value θ_i in the output neurons. Schematic diagrams of a mathematical model of a neuron and its electronic counterpart are shown in

Fig. 60.39. The circuit in Fig. 60.39(b) uses a gain-controllable amplifier in which the voltage gain is controlled by changing the feedback resistance. The feedback resistor R_{FB} can be constructed by the TG structure so that feedback resistance can be adjusted by the gain-control voltage V_{GC} [15].

Continuous-Time Filters

Resistors are important components in the construction of continuous time filters [16]. However, the implementation of resistors by integrator circuit (IC) fabrication technologies was found to be lacking

© 2003 by CRC Press LLC

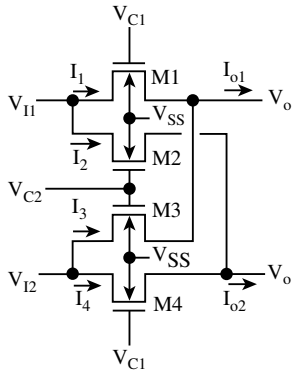

FIGURE 60.40 Double-MOS implementation of a differential AC resistor.

in several areas of performance. The TG can be used to realize active resistance. For example, a double-MOS differential configuration, shown in Fig. 60.40, is used to implement a differential AC resistor [17].

This circuit consists of four nMOS transmission gates. Not only can it linearize the AC resistor, but it can also eliminate the effects of the bulk-source voltage [18]. To determine the AC resistance, assume that all the transistors are matched and are biased in the triode region.

The current I_{01} and I_{02} can be expressed as

$$\begin{aligned} I_{01} &= I_1 + I_3 \\ &= \mu_n C_{OX}(W/L)\left[\left(V_{C1} - V_0 - V_{thn}\right)\left(V_{I1} - V_0\right) - (1/2)\left(V_{I1} - V_0\right)^2\right] \\ &\quad + \mu_n C_{OX}(W/L)\left[\left(V_{C2} - V_0 - V_{thn}\right)\left(V_{I2} - V_0\right) - (1/2)\left(V_{I2} - V_0\right)^2\right] \end{aligned} \tag{60.35}$$

$$\begin{aligned} I_{02} &= I_2 + I_4 \\ &= \mu_n C_{OX}(W/L)\left[\left(V_{C2} - V_0 - V_{thn}\right)\left(V_{I1} - V_0\right) - (1/2)\left(V_{I1} - V_0\right)^2\right] \\ &\quad + \mu_n C_{OX}(W/L)\left[\left(V_{C1} - V_0 - V_{thn}\right)\left(V_{I2} - V_0\right) - (1/2)\left(V_{I2} - V_0\right)^2\right] \end{aligned} \tag{60.36}$$

Equation (60.35) and (60.36) can be combined to determine the differential current

$$I_{01} - I_{02} = \mu_n C_{OX}(W/L)\left[\left(V_{C1} - V_{C2}\right)\left(V_{I1} - V_{I2}\right)\right] \tag{60.37}$$

Thus, r_{ac} is given by

$$r_{ac} = \frac{V_{I1} - V_{I2}}{I_{01} - I_{02}} = \frac{1}{\mu_n C_{OX}(W/L)\left(V_{C1} - V_{C2}\right)} \tag{60.38}$$

Because all transistors are required to be biased in the triode region, (60.38) holds when

$$V_{I1}, V_{I2} \le \min\left[V_{C1} - V_{thn}, V_{C2} - V_{thn}\right] \tag{60.39}$$

The double-MOSFET differential resistor is really a transresistance, thus, it can be applied only to differential-in, differential-out op amps.

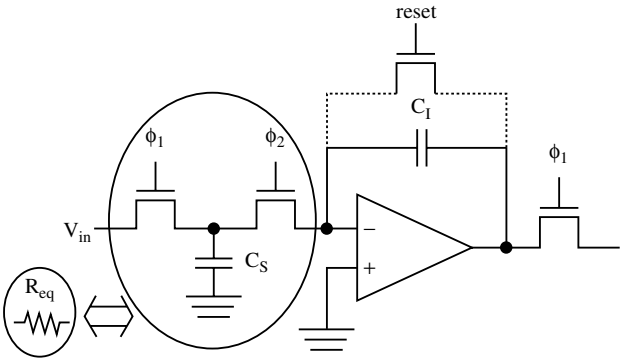

FIGURE 60.41 Direct digital integrator.

Switched-Capacitor Circuits

Switched-capacitor circuits make use of TGs in processing the analog signals [11, 17, 19]. This approach uses switches and capacitors and is in discrete time. If the clock rate is much higher than the signal frequency, an AC resistor can be implemented by combining switches and capacitors. The equivalent resistance is dependent only on the clock rate and the capacitor. The circuit schematic diagram of the direct digital integrator (DDI) is shown in Fig. 60.41. The resistance is realized by two MOS switches and one capacitor. The difference equation can be expressed as

$$v_{0,n+1} = v_{0,n} - \frac{C_s}{C_I} v_{\text{in}} \tag{60.40}$$

After taking the *z*-transform, the new expression becomes

$$z \cdot V_0(z) = V_0(z) - \frac{C_s}{C_I} V_{\text{in}}(z) \tag{60.41}$$

By rearranging the various terms, the transfer function of the DDI integrator can be expressed as

$$\frac{V_0(z)}{V_{\text{in}}(z)} = -\frac{C_s}{C_I} \cdot \frac{z^{-1}}{1 - z^{-1}} \tag{60.42}$$

By setting $z = e^{j\omega T}$, the frequency response can be determined:

$$\frac{V_0}{V_{\text{in}}}(j\omega) = -\frac{C_s}{C_I} \frac{1}{j\omega T} \cdot \frac{\omega T/2}{\sin(\omega T/2)} \cdot e^{-j\omega T/2} \tag{60.43}$$

where T is the period of the clock. In (60.43), the first term corresponds to an ideal integrator, the second term contributes to the magnitude error, and the third term is the phase error. Because the frequency response of the ideal integrator is $-[\, j\omega R_{\text{eq}}\, C_I]^{-1}$, the equivalent resistance value is determined by

$$R_{\text{eq}} = \frac{T}{C_s} \tag{60.44}$$

A ladder network can be constructed by cascading the DDI integrators. In the ladder network all cascaded stages sample the input signal at clock Φ_1 and transform the signal at clock Φ_2, where Φ_1 and Φ_2 are nonoverlapping clock signals. This clocking scheme induces the extra half-cycle phase delay. This phase

© 2003 by CRC Press LLC

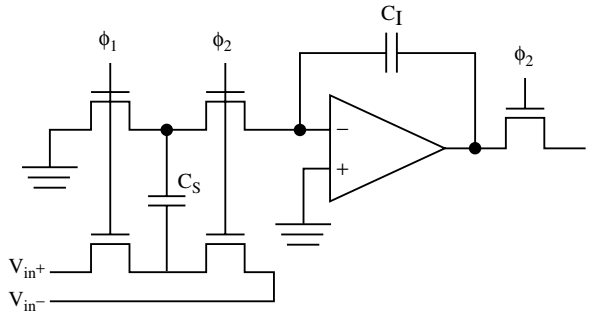

FIGURE 60.42 Bottom-plate differential-input lossless digital integrator.

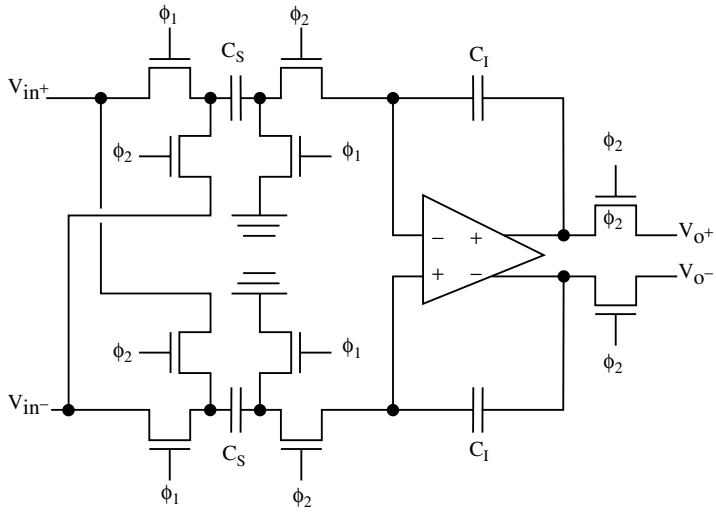

FIGURE 60.43 Differential bilinear integrator.

error can cause extra peaking in frequency response and generate cyclic response. In order to remove the excess phase, other integrators, such as lossless digital integrators (LDI) or bilinear integrators, can be used. In an LDI ladder network, the odd-number stages sample the input signal at clock Φ_1 and transform the signal at clock Φ_2, while the even-number stages sample the input signal at clock Φ_2 and transform the signal at clock Φ_1. Thus, the frequency response of an LDI integrator can be expressed by

$$\frac{V_0}{V_{\text{in}}}(j\omega) = -\frac{C_S}{C_I}\frac{1}{j\omega \text{T}} \cdot \frac{\omega T/2}{\sin(\omega T/2)} \tag{60.45}$$

Figure 60.42 is the circuit schematic diagram of the bottom-plate differential-input LDI. Output of an LDI integrator is more insensitive to parasitic components.

Figure 60.43 is the circuit schematic diagram of a differential bilinear integrator. The transfer function of the bilinear integrator is

$$\frac{V_0^+ - V_0^-}{V_{\text{in}}^+ - V_{\text{in}}^-} = \frac{C_S}{C_I} \cdot \frac{1+z^{-1}}{1-z^{-1}} \tag{60.46}$$

As the output of the bilinear integrator does not change during clock Φ_1, it can be used to feed another identical integrator.

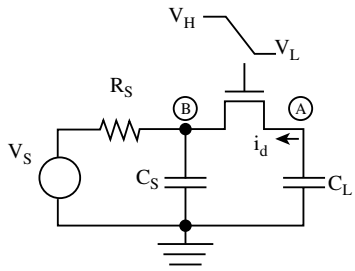

FIGURE 60.44 Circuit for analysis of switch charge injection.

Transmission gates can be used to initialize the switched-capacitor circuits. For example, capacitor C_I in Fig. 60.41 is to perform the integration function and to be reset or discharged before operation. An nMOS TG can be put in parallel with the capacitor C_I. Before normal operation, the TG is turned on and the capacitor C_I is discharged so that the initial capacitor voltage value is reset to zero.

The accuracy of switched-capacitor circuits is disturbed by charge injection when the controlling switch turns off [20]. The turn-off of an MOS switch consists of two phases. The gate voltage is higher than the transistor threshold voltage V_{th} during the first phase. A conduction channel extends from the source to the drain of the transistor. As the gate voltage decreases, mobile carriers exit through both the drain and the source terminals and the channel conduction decreases. During the second phase, the gate voltage is smaller than V_{th} and the conduction channel no longer exists. The coupling between the gate and the data-holding node is only through the gate-to-diffusion overlap capacitance. The following analysis is focused on the switch charge injection due to the first phase of the switch turn-off.

Figure 60.44 is the circuit schematic corresponding to the general case of switch charge injection. Capacitance C_L is the lumped capacitance at the data-holding node. Capacitance C_S could be the lumped capacitance associated with the amplifier output node, while resistance R_S could be the output resistance of an op amp. Let C_G represent the total gate capacitance of the switch, including both the channel capacitance and gate-to-drain/gate-to-source overlap capacitances. Kirchhoff's current law at node A and node B requires

$$C_L \frac{dv_L}{dt} = -i_d + \frac{C_G}{2}\frac{d\left(V_G - v_L\right)}{dt} \tag{60.47}$$

and

$$\frac{v_S}{R_S} + C_S \frac{dv_S}{dt} = i_d + \frac{C_G}{2}\frac{d\left(V_G - v_s\right)}{dt} \tag{60.48}$$

where v_L and v_S are the error voltages at the data-holding node and the signal-source node, respectively. Gate voltage is assumed to decrease linearly with time from the turn-on value V_H:

$$V_G = V_H - \alpha t \tag{60.49}$$

where α is the falling rate. When the transistor is biased in the strong inversion region,

$$i_d = \beta\left(V_{HT} - \alpha \cdot t\right)\left(v_L - v_S\right) \tag{60.50}$$

where

$$\beta = \mu\, C_{OX}\frac{W}{L} \tag{60.51}$$

and

$$V_{HT} = V_H - V_S - V_{thn} \tag{60.52}$$

© 2003 by CRC Press LLC

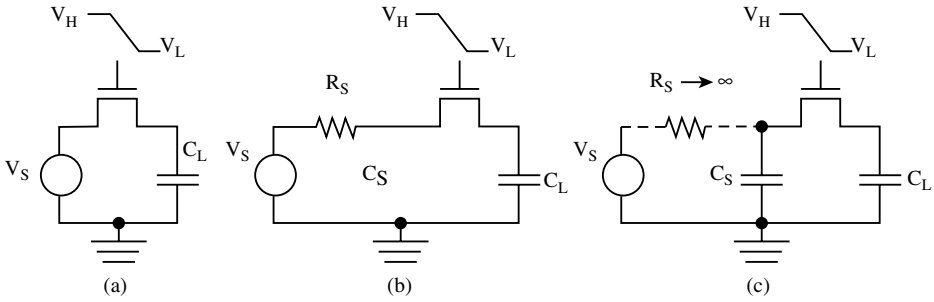

FIGURE 60.45 Special cases of switch charge injection. (a) No source resistance and capacitance. (b) No source capacitance. (c) Infinitely large source resistance.

Here, V_{thn} is the transistor effective threshold voltage, including the body effect. For small-geometry transistors, narrow- and short-channel effects should be considered in determining the V_{thn} value. Under the condition $|dV_G/dt| \gg |dV_L/dt|$ and $|dV_S/dt|$, and (60.47) and (60.48) can be simplified to

$$C_L \frac{dv_L}{dt} = -\beta\left(V_{HT} - \alpha t\right)\left(v_L - v_S\right) - \frac{C_G}{2}\alpha \tag{60.53}$$

and

$$\frac{v_S}{R_S} + C_S \frac{dv_S}{dt} = \beta\left(V_{HT} - \alpha t\right)\left(v_L - v_S\right) + \frac{C_G}{2}\alpha \tag{60.54}$$

No closed-form solution to this set of equations can be found. Numerical integration can be employed to find final results. Analytical solutions to special cases are given next.

Figure 60.45(a) is the circuit schematic diagram of the case, with only a voltage sourced at the signal-source node. Because $C_S \gg C_L, v_s$ can be approximated as zero and the governing equation reduces to

$$C_L \frac{dv_L}{dt} = -\beta\left(V_{HT} - \alpha t\right)v_L - \frac{C_G}{2}\alpha \tag{60.55}$$

When the gate voltage reaches the threshold condition, the error voltage at the data-holding node is

$$v_L = -\sqrt{\frac{\pi\alpha C_L}{2\beta}}\left(\frac{C_G}{2C_L}\right) erf\left(\sqrt{\frac{\beta}{2\alpha C_L}}V_{HT}\right) \tag{60.56}$$

Notice that the value of the error function $erf(\cdot)$ can be found from mathematical tables.

Another special case is when the source capacitance is negligibly small, as is shown in Fig. 60.45(b). The governing equations reduce to

$$C_L \frac{dv_L}{dt} = -\beta\left(V_{HT} - \alpha t\right)\left(v_L - v_s\right) - \frac{C_G}{2}\alpha \tag{60.57}$$

and

$$\frac{v_s}{R_s} = \beta\left(V_{HT} - \alpha t\right)\left(v_L - v_S\right) + \frac{C_G}{2}\alpha \tag{60.58}$$

© 2003 by CRC Press LLC

When the gate voltage reaches the threshold condition, the error voltage at the data-holding node is

$$v_L = -\frac{\alpha C_G}{2C_L}\exp\left(-\frac{V_{HT}}{\alpha C_L R_S}\right)\cdot\int_0^{V_{HT}/\alpha}\left[\beta R_S\left(V_{HT}-\alpha\theta\right)+1\right]^{1/C_L\beta R_s^2\alpha} \cdot\exp\left(\frac{\theta}{C_L R_S}\right)\left(2-\frac{1}{1+\beta R_S\left(V_{HT}-\alpha\theta\right)}\right)d\theta \tag{60.59}$$

If a time constant $R_S C_S$ is much larger than the switch turn-off time, then the channel charge will be shared between C_S and C_L, as shown in Fig. 60.45(c). For the case of a symmetrical transistor and $C_S = C_L$, half of the channel charge will be deposited to each capacitor. Otherwise the following equations can be used to find the results:

$$C_L\frac{dv_L}{dt} = -\beta\left(V_{HT}-\alpha t\right)\left(v_L - v_s\right) - \frac{C_G}{2}\alpha \tag{60.60}$$

and

$$C_S\frac{dv_S}{dt} = \beta\left(V_{HT}-\alpha t\right)\left(v_L - v_s\right) + \frac{C_G}{2}\alpha \tag{60.61}$$

We can multiply (60.61) by the ratio C_L/C_S and then subtract the result from (60.60) to obtain

$$C_L\frac{d\left(v_L - v_S\right)}{dt} = -\beta\left(V_{HT}-\alpha t\right)\left(1+\frac{C_L}{C_S}\right)\left(v_L - v_S\right) - \frac{\alpha C_G}{2}\left(1-\frac{C_L}{C_S}\right) \tag{60.62}$$

When the gate voltage reaches the threshold condition, the amount of voltage difference between the data-holding node and the signal-source node becomes

$$v_L - v_s = -\sqrt{\frac{\pi\alpha C_L}{2\beta\left(1+C_L/C_S\right)}}\left(\frac{C_G\left(1-C_L/C_S\right)}{2C_L}\right) \cdot erf\left(\sqrt{\frac{\beta\left(1+C_L/C_S\right)}{2\alpha C_L}}V_{HT}\right) \tag{60.63}$$

61.1 Programmable Logic Devices

F. Gail Gray

Traditional programmable logic devices (PLDs) and field programmable gate arrays (FPGAs) allow circuit designers to implement logic circuits with fewer chips relative to standard gate level designs based on primitive gates and flip-flops. As a result, layout and unit production costs are generally reduced. In this chapter, we use the term *programmable device* to refer to the class of moderately complex single-chip devices, in which the user in the field can program the function of the device. We include such devices as the programmable logic array (PLA), programmable array logic (PAL), programmable read-only memory (PROM), and the field programmable gate array (FPGA). Since most commercial vendors provide software design aids for mapping designs to their specific chips, initial design costs and time to market are low. Another important advantage of programmable device designs is *flexibility*. Design changes do not require physical changes to the printed circuit board as long as the revised functions still fit onto the same programmable chip. The low cost of design revisions makes programmable chips very

TABLE 61.1 Complexity Ladder of Devices

Device	Complexity of a Single Chip	Range of Realizable Functions	Initial Design and Cost of Design Change	Unit Product Cost (High Volume)	Time to Market
SSI discrete gate chip	Lowest	All functions	High	High	High
MSI chip		Narrow	High	High	High
PLD[a]		Moderate	Low	Moderate	Low
LSI (PROM)[a]		All combinational functions with *n* inputs	Very low	Moderate	Low
FPGA		Wide	Low	Moderate	Low
MPGA		Wide	High	Low	High
Standard cell		Wide	High	Low	High
Custom chip	Highest	All functions	Very high	Very low	Very high

[a] Field programmable.

attractive for prototype design and low volume production. Designers often move up the design ladder once proven designs move into high volume production.

Table 61.1 shows the position of PLDs, PROMs, and FPGAs on the complexity ladder of device types. In the "Range of Realizable Functions" column, we compare the range of realizations for various device types. Discrete gates can implement any function if enough gates are available. MSI chips implement very specialized functions such as shift registers, multiplexers, decoders, etc. The table compares programmable devices (PLDs, FPGAs, and PROMs) relative to the range of functions that can be implemented on a single chip. A PROM chip with *n* address inputs can implement any combinational function of *n* variables. A PLD chip with n inputs can implement only a subset of the combinational functions of *n* variables. Gate arrays can implement a wide range of both combinational and sequential functions. The programmable devices are characterized by low time to market, low design cost, low cost of modifications, and moderate production costs. Non-field programmable devices such as mask programmable gate arrays (MPGAs), standard cell devices, and full custom devices are characterized by high initial design costs and longer time to market, but have lower volume production costs. Custom chips are preferred for large volume production because of the very low unit production costs. However, initial design costs and the cost of design changes is very high for custom chip design. Also, the design of custom chips requires highly trained personnel and a large investment in equipment. The low design cost, low cost of design changes, and low time to market make PLDs and FPGAs good choices for lower volume production and for prototype development.

The primary difference between PLDs and FPGAs arise because of a difference in the ratio of the number of combinational logic gates to the number of flip-flops. PLD devices are better for applications that require complex combinational logic functions that drive a relatively small number of flip flops, such as finite-state machine controllers or purely combinational logic functions. FPGAs are better for devices that require arithmetic operations (adders, multipliers, and arithmetic logic units), or that require a large number of registers and less complex combinational logic functions, such as digital filters.

PLD Device Technologies

Companies produce PLD devices in different technologies to meet varying design and market demands. There are two categories of technologies. *Process technology* refers to the underlying semiconductor structure, which affects device speed, power consumption, device density, and cost. *Programming technology* refers to the physics of chip programming and affects ease of programming and the ability to reprogram or to reconfigure chips.

Process Technologies

The dominant technologies in PLD devices are bipolar and CMOS. Bipolar devices are faster and less expensive to manufacture, but consume more power than CMOS devices. The higher power requirements

© 2003 by CRC Press LLC

of bipolar devices limit the gate density. Typical CMOS devices, therefore, achieve much higher gate densities than bipolar devices. The power consumption of CMOS devices depends on the application because a CMOS device only consumes power when it is switching states. The amount of power consumed increases with the speed of switching. Therefore, the total amount of power consumed depends on the frequency and speed of state changes in the device. Some devices have programmable power standby activation that puts the device in a lower power consumption configuration if no input signal changes for a predefined amount of time. The device then responds to the next input change much slower than normal but switches back to the faster speed configuration and maintains the faster speed as long as input changes continue to occur frequently. When programmed in the *standby power mode,* power consumption is reduced on the average at the expense of response time of the device. When programmed to operate in the *turbo* mode, the device stays in the faster configuration at all times. The result is higher power consumption, but faster response time. The mode of operation is selected by the user to match the requirements of an application.

To take advantage of the higher densities of CMOS devices and still be compatible with bipolar devices, many CMOS PLAs have special driver circuits at the input and output pins to allow pin compatibility with popular bipolar devices such as the commonly used TTL devices.

ECL is a very high-speed technology used in some PLD devices. Although ECL has the highest speed of the popular technologies, the power consumption is very high which severely limits the gate density.

Security is another issue that is related to process technology. Many PLDs have a programmable option that prevents reading the program. Since the software provided by most manufacturers allows the user to read the program in the chip in order to verify correct programming, it is extremely easy to copy designs. To prevent illegal copying of patented designs, one simply blows the *security fuse*, which permanently prevents anyone from reading the program by normal means. However, the program in most bipolar circuits can easily be read by removing the case and examining the programmed fuses under a microscope. CMOS PLDs are much more secure because it is virtually impossible to determine the program by examining the circuit.

Programming Technologies

The programming technologies used in PLDs are virtually the same as the programming technologies available for ROMs. Programming technologies are divided into two broad categories: mask programmable devices and field programmable devices.

In *mask programmable* technologies, identical base chips are produced in mass. The final metallization step is simply omitted. A mask programmable PLD chip is programmed by performing a final metal deposition step that selects the programming options. Clearly, this step must be performed at the manufacturer's plant. The user makes entries on order forms that specify how the chip is to be programmed and sends it to the manufacturer. The manufacturer must then prepare one or more production masks prior to making the chip. Mask programmable devices incur a high setup cost to make the first device, but unit production costs are typically less than half of that for field programmable technologies. The usual practice is to use field programmable devices for prototype work and implement only proven designs in mask programmable technologies when a large production volume is required. Many PLD devices are available in both mask programmable and field programmable versions, which make the conversion easy and reliable.

The user can program field programmable technologies directly. Specialized equipment is needed. Modern programming devices can actually program both ROM and PLD devices. The programmer is typically controlled by a small computer (PC) and uses files prepared in standard format (JEDEC) by software provided by the manufacturer or written by software vendors. Such software can include elegant features such as a programming language (ABEL, VHDL, Verilog, etc.), truth table input, equation input, or state machine input. Selection of a chip vendor should include careful evaluation of the support software for programming the chip.

Field programmable PLD technologies can be classified into three broad categories: fusible link PLDs, ultraviolet erasable PLDs (EPLDs), and electrically erasable PLDs (EEPLDs). Field programmable ROMS

© 2003 by CRC Press LLC

come in analogous forms: fusible link ROMs (PROMs), ultraviolet erasable ROMS (EPROMs), and electrically erasable ROMS (EEPROMs).

Fusible link PLDs typically utilize bipolar process technology. The programmer blows selected fuses in the device. Because higher than normal voltages and currents are required to blow the fuses, programming fusible link PLDs can be quite stressful for the device. Overheating is a common problem. However, this technology is quite well developed and the design of programming devices is sufficiently mature so that reliable results can be expected as long as directions are carefully followed. Fusible link technologies provide the convenience of on-site programming, which reduces the time required to develop designs and the time required to make design changes. The trade-off involves at least a twofold increase in per unit cost and a significant reduction in device density relative to mask programmable devices because the fuses take up considerable chip space. A fusible link PLD can be programmed only once because the blown fuses cannot be restored.

Ultraviolet erasable PLDs (*EPLDs*) have a window on the top of the chip. Programming the chip involves storing charges at internal points in the circuit that control switch settings. Shining ultraviolet light through the window on the chip can dissipate the charges. Therefore, EPLDs provide the convenience of reprogramming as a design evolves. On the downside, EPLDs cost at least three times as much per chip as mask programmable PLDs and operate at much slower speeds. Since EPLDs typically utilize CMOS technology, they are slower than fusible link PLDs but require less power. Therefore, EPLDs are often used in development work with the final design being implemented in either fusible link technology (for faster speed) or mask programmable technology (for faster speed and lower density). In spite of the fact that EPLDs cost more than fusible link PLDs, the reprogramming feature eventually results in a lower cost for development than using fusible link PLDs. This technology requires an additional piece of hardware to erase the chips.

Electrically erasable PLDs (*EEPLDs*) provide the convenience of reprogramming without the need to erase the previous program because the chip is programmed by setting the states of flip-flops inside the device. It is, therefore, not necessary to purchase an erasing device. The reprogramming also requires less time to accomplish. Of course, EEPLD chips cost more and have a lower gate density than EPLD chips.

PLD Notation

PLDs typically have many logic gates with a large number of inputs. Also, there are often many gates that have the same set of inputs. For example, the PAL22V10 has 132 AND gates, each with the same 44 gate inputs. Obviously, the diagram for such a complex circuit using standard AND gate symbols would be extremely complex and difficult to read.

Figure 61.1 is the conventional diagram for an 8-input AND gate. Clearly, a similar diagram for a 44-input AND gate would be very cumbersome. Figure 61.2 is the same 8-input AND gate in PLD

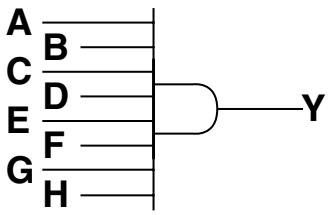

FIGURE 61.1 Conventional diagram for an 8-input AND gate.

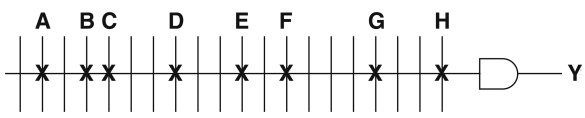

FIGURE 61.2 PLD notation for an 8-input AND gate.

© 2003 by CRC Press LLC

notation. The 8 parallel wires that actually occur as inputs to the AND gate are represented by a single horizontal line in PLD notation. The actual inputs to the AND gate are drawn perpendicular to the single line. There are usually more signal lines than just the 8 needed for this gate. An X is placed at the intersection of the single line with each of the perpendicular lines that provide actual inputs to the AND gate. Keep in mind that the single horizontal line actually represents 8 parallel wires that are not physically connected to each other.

By comparing the internal structures of PLAs, PALs, and PROMs, we will describe the capabilities and limitations of each type of PLD. Since the PAL is currently the most popular PLD device, we will describe design methodology for both combinational and sequential PAL devices. By emphasizing the difference between designing with PALs and designing with standard logic gates, we provide practical insights about PLD design.

Programmable Logic Array (PLA)

Figure 61.3 shows that the basic PLA consists of a programmable AND array followed by a programmable OR array. Vertical lines in the AND array represent the input variables (A, B, C, D). Since each input drives many AND gates, an internal buffer provides high current drive signals in both true and complemented format for each input variable. Initially, there is a connection from each input variable and its complement to each AND gate. In this example circuit, each AND gate initially has 8 inputs (A, $\overline{A}$, B, $\overline{B}$, C, $\overline{C}$, D, $\overline{D}$). Each AND gate input line contains a fuse or electronic switch. We program the chip by blowing the fuses in lines that we do not need, or by programming the electronic switches. After programming, we remove the Xs from the lines that are disconnected. For example, in the programmed chip of Fig. 61.4, the upper AND gate implements product term ($\overline{A} \cdot \overline{C} \cdot \overline{D}$).

In the OR array of Fig. 61.3, there is an initial connection from each AND gate output to every input on each OR gate. Again, the single vertical line connected on the input side of each OR gate represents all six wires. Each of the input lines to the OR gates also contains a fuse or programmable switch. Figure 61.4 shows that, after programming, output X connects to product terms $\overline{A} \cdot \overline{C} \cdot \overline{D}$, $B \cdot D$, and $C \cdot \overline{D}$.

The number of product lines on a chip limits the range of functions that fit onto the chip. The PLA chip in Fig. 61.3 can implement any three functions (X, Y, Z) of the same four variables (A, B, C, D) as long as the total number of required product terms is less than or equal to six. However, there are 100 different

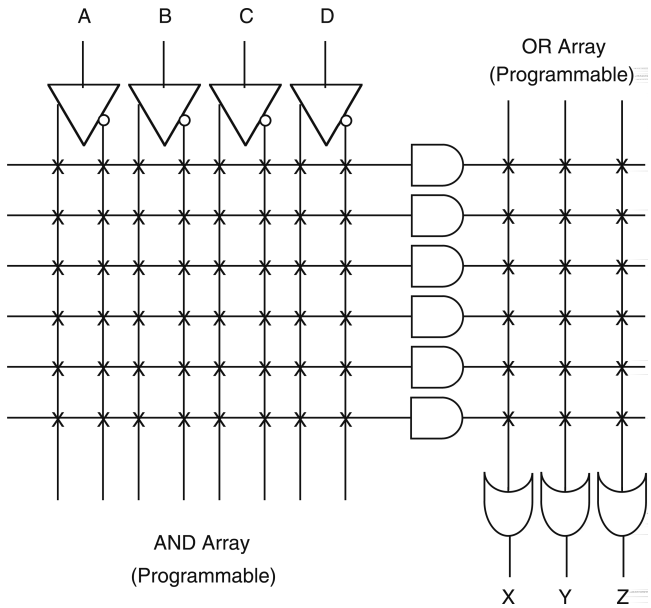

FIGURE 61.3 Basic architecture for a PLA.

$$X = \overline{A} \cdot \overline{C} \cdot \overline{D} + B \cdot D + C \cdot \overline{D}$$
$$Y = \overline{A} \cdot \overline{C} \cdot \overline{D} + A \cdot D + B \cdot C$$
$$Z = \overline{A} \cdot \overline{C} \cdot \overline{D} + B \cdot D + A \cdot \overline{D}$$

FIGURE 61.4 An example of a programmed PLA.

product terms involving 4 variables. So, practical chips have many more product lines than this contrived example.

In order to fit functions onto the chip, designers must be able to simplify multiple output functions using gate sharing whenever possible. Finding a minimal gate implementation of multiple output functions with gate sharing is a very complex task. The goal is to minimize the total number of gates used. The size of gates does not matter. For example, whether an AND gate has four inputs or two inputs is not important. All that changes is the number of fuses that are blown. This differs dramatically from the minimization goals when discrete gates are used. For discrete gate minimization, a four-input gate costs more than a two-input gate. Therefore, the classical minimization programs need to be modified to reflect the different goals for PLA development.

Three parameters determine the capacity of a PLA chip. Let n be the number of inputs, p the number of product term lines, and m the number of outputs. Then the PLA chip can implement any m functions of the same n variables that require a total of p or fewer product terms. The device complexity is proportional to $(m + n)p$.

Programmable Read Only Memory (PROM)

The programmable read only memory is the most general of the combinational logic PLD devices described in this section. However, from a structural viewpoint, the PROM is a special case of the PLA in which the AND array is fixed and the OR array is programmable. Figure 61.5 is a conceptual diagram of a PROM. The filled circles in the AND array represent permanent connections. The Xs in the OR array indicate that it is programmable. The number of product lines in a PROM is 2^n; whereas the number of product lines in a typical PLA is much smaller. A PROM has a product line for each combination of input variables. Since any logic function of n variables can be expressed in a canonical sum of minterms

© 2003 by CRC Press LLC

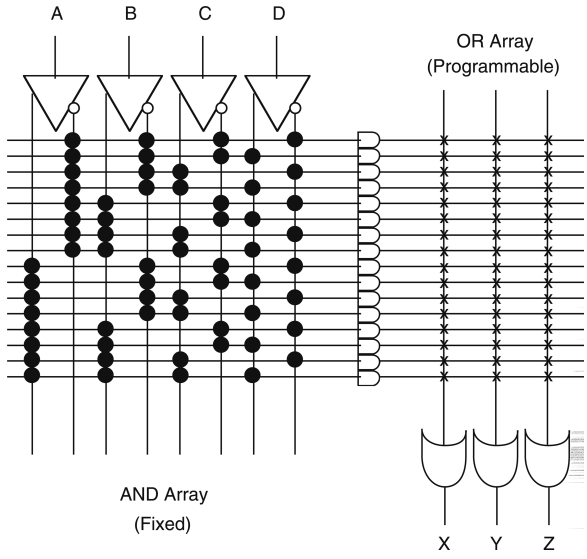

FIGURE 61.5 Conceptual diagram of a PROM.

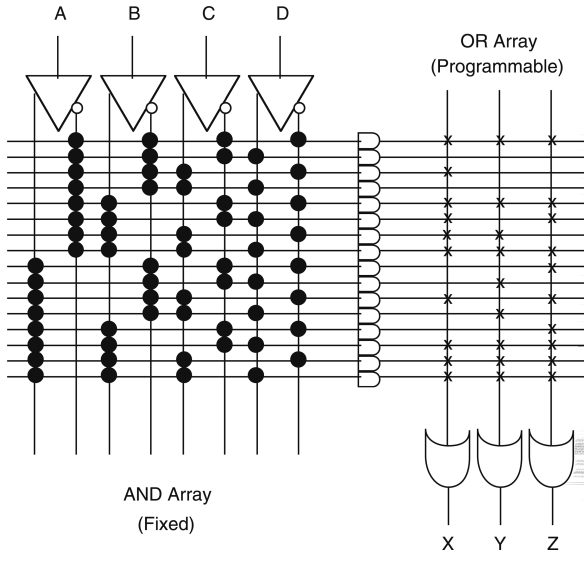

FIGURE 61.6 An example of a programmed PROM.

form in which each product term is a product of exactly *n* literals, the PROM can implement any function of its *n* input variables.

To demonstrate the generality of the PROM, Fig. 61.6 shows how the PROM of Fig. 61.5 must be programmed so as to implement the same set of logic functions that are programmed into the PLA of Fig. 61.4. The PROM program follows directly from the truth table for a logic function. The truth table for the logic functions X, Y, and Z appears in Table 61.2. The correspondence between the truth table and the program in the PROM of Fig. 61.6 is straightforward. A logic 1 in the truth table corresponds to an X in the figure and a logic 0 in the table corresponds to the absence of an X.

A PROM with *n* address lines (serving as *n* input variable lines) and *m* data lines (serving as *m* output variable lines) can implement any *m* functions of the same *n* variables. Unlike a PLA, a PROM has no

© 2003 by CRC Press LLC

TABLE 61.2 Truth Table for the Logic Functions Implemented in the PROM

ABCD	XYZ	ABCD	XYZ
0000	111	1000	001
0001	000	1001	010
0010	100	1010	101
0011	000	1011	010
0100	111	1100	001
0101	101	1101	111
0110	110	1110	111
0111	111	1111	111

restrictions due to a limited number of product lines. The PROM contains an n input, 2^n output decoder that generates 2^n internal address lines that serve as product lines. Since the decoder grows exponentially in size with n, the cost of a PROM also increases rapidly with n. The justification for a PLA is to reduce the cost of the PROM decoder by providing fewer product terms since many practical functions require significantly fewer than 2^n product terms. As a result, some n variable functions will not fit onto a PLA chip with n input variables, whereas any n variable function will fit onto a PROM with n address lines.

Programmable Array Logic (PAL)

Programmable array logic (PAL) is the most popular form of PLD today. Lower price, higher gate densities, and ease of programming all tend to make PAL more popular than PLA. On the negative side, the range of functions that can fit onto a chip with the same number of inputs, outputs, and product lines is less for a PAL than for a PLA.

Figure 61.7 is the basic architecture of a PAL. The PAL architecture is a special case of the PLA architecture in which the OR array is fixed. The filled circles in the OR array indicate permanent connections. Only the AND array is programmable. Compare this PAL architecture with the PLA architecture in Fig. 61.3. Since the OR array is not programmable, it is immediately evident that fewer functions will fit onto the PAL. In the PLA, the product terms can be divided among the three outputs in any way desired and product terms that are used in more than one output can share the same product line. In the PAL, each output is limited to a fixed number of product terms. In Fig. 61.7, all outputs are limited

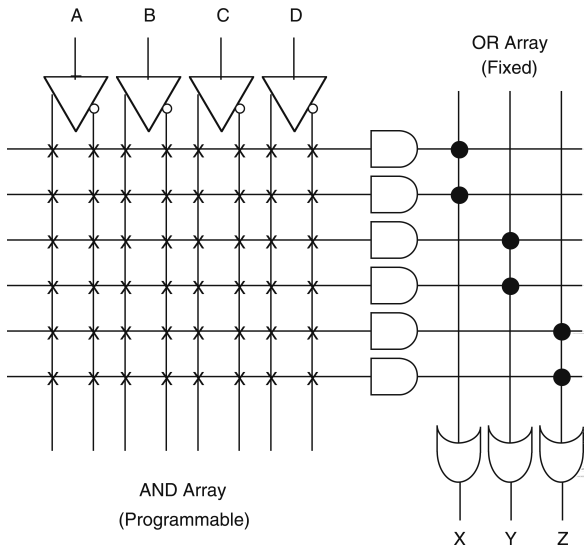

FIGURE 61.7 Basic architecture of a PAL.

$X = \overline{A} \cdot \overline{C} \cdot \overline{D} + B \cdot D$

$Y = \overline{A} \cdot \overline{C} \cdot \overline{D} + D$

$Z = \overline{A} + B \cdot D$

FIGURE 61.8 An example of a programmed PAL.

to two product terms. In addition, if two output functions both require the same product term in a PAL, two different product lines must be used.

Consider the three functions implemented on the PLA in Fig. 61.4. Since the three functions require a total of nine product terms, they will not fit onto the PAL of Fig. 61.7. However, any function that would fit onto this PAL would obviously fit onto the PLA since the OR array in the PLA can be programmed to be identical to the OR array of the PAL. Figure 61.8 is an example of three functions that fit onto this PAL. Note that we must use two different product lines to provide the same product term $(\overline{A} \cdot \overline{C} \cdot \overline{D})$ to outputs X and Y.

In order to describe the range of applications for a PAL, we must know the number of inputs, n, the number of outputs, m, and the number of product lines that are permanently connected to each output OR gate. The PAL of Fig. 61.7 has four inputs, $n = 4$, three outputs, $m = 3$, and has two product lines connected to each OR gate. This PAL is described as a 2-2-2 PAL with four input variables. Many PALs have the same number of product terms permanently connected to each output. In this case, the three parameters n, m, and p completely describe the size of the PAL. For PALs, the parameter p usually represents the number of product terms per output instead of the total number of product terms, as was the case for PLAs.

The minimization algorithm for multiple output PALs is significantly less complex than the minimization algorithm for a PLA because gate sharing is eliminated as a possibility by the fact that the OR array is not programmable. This means that each output function can be minimized independently. Minimizing a single output function is much less complex than minimizing a set of output functions where gate sharing must be considered.

Overall, the higher density, less complex minimization algorithms, and lower cost of PALs tend to offset the additional functional capabilities of PLAs.

Classification of Combinational Logic PLD Devices

The programmability of the AND and OR array provide a convenient means to classify combinational logic PLD types. The classification of Table 61.3 illustrates comparative features of combinational logic PLD devices. Even though PLAs have the most general structure (i.e., both the AND and OR arrays are

© 2003 by CRC Press LLC

TABLE 61.3 Classification of Combinational PLD Devices

AND Array	OR Array	Device	Typical Number of Product Terms per Output Gate
Fixed	Mask programmable	ROM	2^n
Fixed	Field programmable	PROM, EPROM, EEPROM	2^n
Field programmable	Fixed	PAL	16
Field programmable	Field programmable	PLA	50–150

programmable), the number of functions that fit onto the chips is limited by the number of product terms per output. ROMs and PROMs have fixed AND arrays, but all possible product terms are provided. Therefore, PROMs and ROMs are the most general devices from a functional viewpoint. Applications are only limited by the size and cost of available devices. PALs are the most restricted devices from both the structural and functional viewpoints. Nevertheless, the lower cost relative to PROMS and PLAs, higher gate densities relative to PLAs, and wider variety of available chip types have contributed to a rapid rise in popularity of PAL devices. For this reason, we will concentrate on PAL devices in the rest of this section.

Designing with Combinational Logic PAL Devices

Determining if a function will fit onto a PAL device is a complex procedure. To demonstrate the difficulty, we will examine the types of functions that can fit onto a PAL16L8 chip. Figure 61.9 shows that the PAL16L8 chip has 8 output pins and 16 pairs of vertical input lines to the AND array. The "L" in the chip name indicates that the 8 outputs are all active low combinational logic outputs. The most important information not provided by the device name is the number of product terms per output, which is 7 for this device. An additional product term provides an output enable for each output pin, so there are 8 product lines per output pin (a total of 64 product lines). There are 10 primary input pins (pin numbers 1–9 and 11). In terms of our definitions, it would seem that $n = 10$, $m = 8$, and $p = 7$. As we will demonstrate, this simplistic analysis significantly understates the capacity of this chip.

A simplistic analysis would say that the PAL16L8 chip could implement any 8 functions of the 10 input variables as long as each function requires no more than 7 product terms. As far as it goes, this statement is correct. However, it significantly understates the capacity of the chip because it does not take into account the fact that 6 of the output pins are internally connected as inputs to the AND array (pins 13–18). This is the source of the additional 6 inputs to the AND array. These internal feedback connections significantly expand the capacity of the chip.

Consider the following logic function.

$$X = A\overline{B}C + B\overline{C}D + \overline{A}E + D\overline{E}F + \overline{A}C + \overline{D} + \overline{F}GH + F\overline{G}I + BE\overline{H} + \overline{C}H + \overline{I}J + \overline{B}E\overline{J} + \overline{D}H$$

It appears that this logic function will not fit onto the PAL16L8 chip because it requires 13 product terms and each output has only 7 product lines. However, if not all chip outputs are needed for the application, we can use one of the feedback lines to fit this function onto the chip.

We first partition the function X as follows:

$$X = A\overline{B}C + B\overline{C}D + \overline{A}E + D\overline{E}F + \overline{A}C + \overline{D} + Y$$

$$Y = \overline{F}GH + F\overline{G}I + BE\overline{H} + \overline{C}H + \overline{I}J + \overline{B}E\overline{J} + \overline{D}H$$

Since Y has only 7 product terms, we will map function Y to the macro-cell connected to pin 18 and use the feedback line from pin 18 to connect Y to a pair of vertical lines in the AND array. Function Y is now available to all other cells as an input variable. Since function X also has 7 product terms, we will map X to the macro-cell connected to pin 17. One of the product terms in X is the single variable Y. Figure 61.10 shows the final implementation. To obtain the needed product terms for output X, we used two macro-cells in the array. As a result, pin 18 is no longer available as an output.

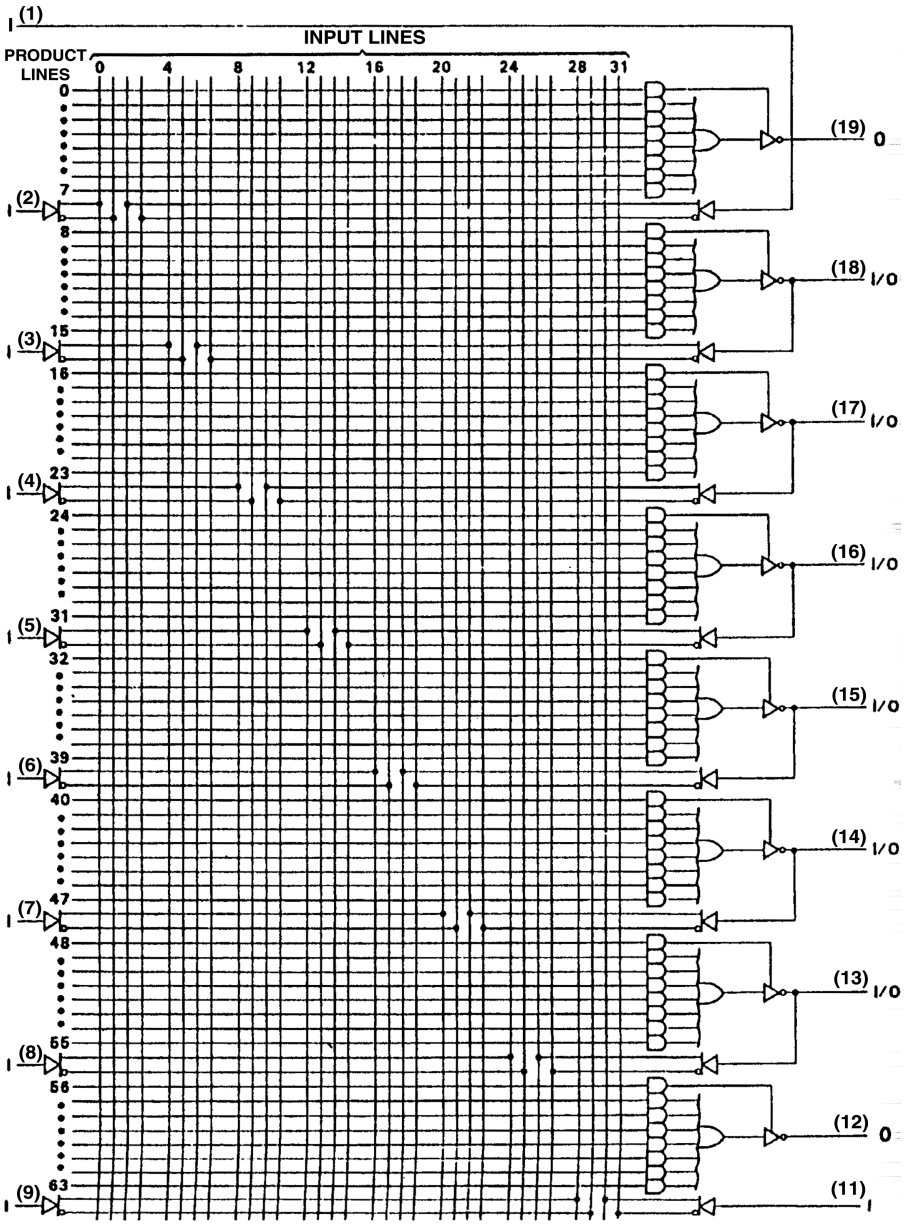

FIGURE 61.9 Logic diagram of PAL 16L8 chip. (Courtesy of Texas Instruments.)

Two practical matters need to be considered. First, some signals must now pass through the AND array twice as they proceed from an input to an output due to the feedback path. Therefore, the delay of the chip is now twice what it was when the feedback path was not utilized. Second, the buffer inverts the outputs; therefore, we actually obtain $\overline{X}$ on pin 17. If X is specified to be *active low,* then the output on pin 17 is exactly what we need. If the output X is specified to be active high, then an inverter is required. Since PALs are available with both active low and active high outputs, a designer should select an appropriate PAL to eliminate the need for inverters.

Another feature that adds to the flexibility of the chip is that pins 13–18 can be used either as inputs or as outputs. For example, the enable for the output buffer at pin 15 can be permanently disabled. Since

© 2003 by CRC Press LLC

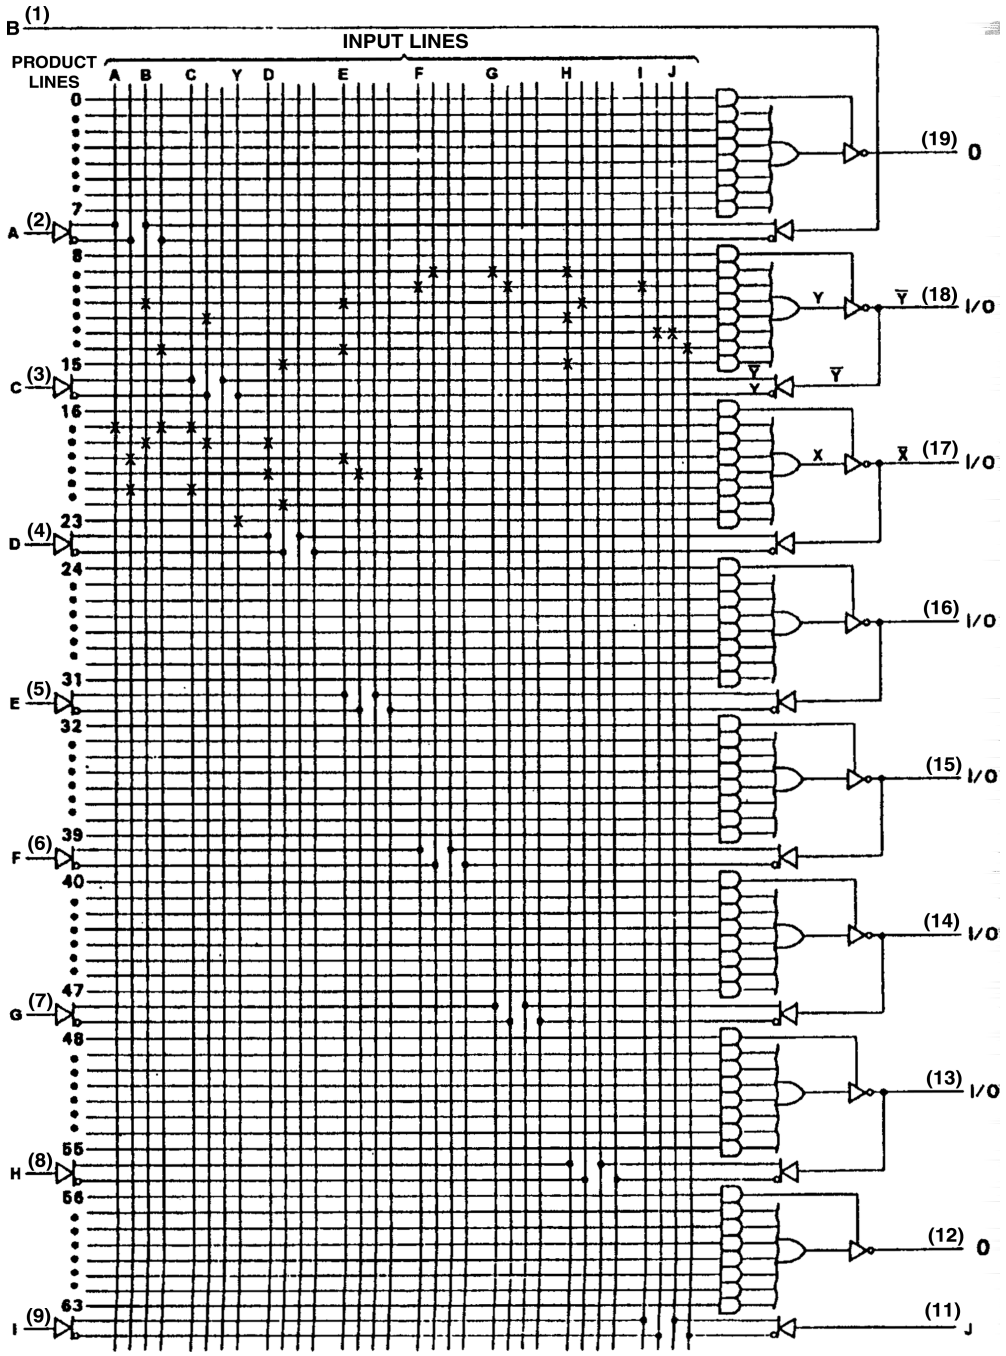

FIGURE 61.10 Implementation of function with 13 product terms on PAL16L8 chip.

pin 15 is connected directly into the AND array, it is no different from any other input, say pin 2. Of course, by permanently disabling the buffer at pin 15, the OR array connected to the buffer is also disconnected. In order to use pin 15 as an input, we must give up the use of the macro-cell connected to pin 15. However, dual use pins and feedback lines dramatically extend the range of applications for the chip. For example, suppose we need only one output and select pin 19 for that use. Then, pins 13–18

© 2003 by CRC Press LLC

are available either as inputs or as feedback lines. We can therefore fit a wide range of functions onto the chip with varying numbers of inputs and product terms.

Assuming that we need only the one output on pin 19, then we could have up to 16 inputs (pins 1-9, 11, 13-18). We could, of course, use only the 7 product lines in the macro-cell connected to pin 19 to implement our function. We, therefore, conclude that the PAL16L8 chip can implement any single function of 16 variables that requires no more than 7 product terms.

If we need more product terms but not as many input variables, then we can connect pin 11 to pin 12. This connects the output on pin 12 back into the AND array the same as any other input variable. The output on pin 19 can pick up the 7 product terms on pin 12 as an input. This takes up one of the product lines for pin 19, but 6 product lines remain. Therefore, the single output on pin 19 can now have up to 13 product terms. However, pin 11 is no longer available as an input. Therefore, we must conclude that the PAL16L8 can implement any single function of 15 variables that requires no more than 13 product terms.

If we want to maximize the number of product terms for a single output at pin 19, then we can use pins 13–18 and pin 11 as feedback lines. Each feedback line contributes 7 product terms. The AND array for pin 19 can pick up all 49 product terms by using one product line to pick up each feedback variable. All product lines are now busy. The OR gate at pin 19 then sums all 49 product terms. The only pins that are now available for inputs are 1–9. We therefore conclude that the PAL16L8 can implement any single function of 9 variables that requires 49 or fewer product terms.

Clearly, there are many combinations of implementations with a variety of values for the number of inputs, the number of outputs, and the number of product terms per output. Table 61.4 shows the full range of possible implementations. For example, from the tables we note that the PAL16L8 can implement any 3 functions of 10 variables in which the product terms are distributed among the three outputs in any of the following ways: 7-7-37, 7-13-31, 7-19-25, 13-13-25, or 13-19-19. The notation 7-7-37 means that two of the outputs require at most 7 product terms and that the third output requires at most 37 product terms. To accomplish these results, 5 of the output pins must be devoted to feedback lines.

Any implementation that uses a feedback line will have a time delay equal to twice that of a single macro-cell. In the "Delay" column of Table 61.4, symbol T_A represents the delay that a signal experiences while passing through the AND–OR array one time. In implementations that do not use feedback lines, signals experience a maximum delay of T_A. For implementations that use one or more feedback lines, the delay is 2 T_A because some input signals propagate through the AND–OR array twice before reaching an output pin. However, none of the implementations in the table require more than twice the normal time delay for a single macro-cell.

Although the tables cover broad generalizations for classes of functions that will fit onto the PAL16L8 chip, there are certain special types of more complex functions that will fit. For example, suppose that input variables A, B, C, D, E, F, G, H, and I occupy pins 1–9. Further suppose that we implemented functions S, T, V, W, X, Y, and Z using the macro-cells connected to pins 12, 13, 14, 15, 16, 17, and 18, respectively. Further suppose that we connect pin 12 to pin 11 so that all of these functions are connected to a pair of vertical input lines in the AND array. Thus, all of these functions are now available to the single output P at pin 19. This approach allows many very complex logic functions to fit onto the chip.

Example 61.1. Let each of the functions S, T, V, W, X, Y, and Z be a sum of products expression involving the 9 input variables with at most 7 product terms. For example, S might be

$$S = A\overline{B}CD\overline{E}F\overline{G}HI + \overline{A}B\overline{C}DE\overline{F}GH\overline{I} + \overline{B}CD\overline{E}F\overline{G}HI + \overline{F}G\overline{H}I + \overline{A}H\overline{I} + \overline{D}EF\overline{G}HI + ABCDEFGHI$$

Variables T, V, W, X, Y, and Z could be of similar complexity.

Then, output P might be

$$P = A\overline{B}CD\overline{E}FG\overline{H}IS\overline{T}VW\overline{X}Y\overline{Z} + B\overline{C}DEFG\overline{S}T\overline{V}WXY\overline{Z} + \cdots$$

where P has at most 7 such product terms.

The delay of this implementation is still twice the delay of one basic macro-cell.

Example 61.2. This example illustrates embedded factors. Each equation has at most 7 product terms involving the listed variables.

$$S = f(A - I) = \overline{A}BC\overline{D}E\overline{F}GH\overline{I} + A\overline{B}\,\overline{C}DEF\overline{G}HI + \cdots$$

$$T = f(S, A - I) = AB\overline{C}D\overline{E}FG\overline{H}IS + \overline{A}BCD\overline{E}\,\overline{F}GHI\overline{S} + \cdots$$

$$V = f(S, T, A - I) = \overline{C}DE\overline{F}GHI\overline{S}\,\overline{T} + BC\overline{D}HIS\overline{T} + \cdots$$

$$W = f(S, T, V, A - I) = \overline{A}BCD\overline{E}F\overline{G}HI\overline{S}T\overline{V} + \overline{D}E\overline{F}HIS\overline{T}V + \cdots$$

$$X = f(S, T, V, W, A - I) = \overline{A}\,\overline{B}CDE\overline{F}G\overline{H}I\overline{S}TV\overline{W} + \overline{E}T\overline{V}W + \cdots$$

$$Y = f(S, T, V, W, X, A - I) = ABC\overline{D}EFG\overline{H}IS\overline{T}VW\overline{X} + \overline{D}H\overline{I}S\overline{T}V\overline{W}X + \cdots$$

$$Z = f(S, V, T, W, X, Y, A - I) = A\overline{B}CD\overline{E}FGHI\overline{S}T\overline{V}WX\overline{Y} + \overline{F}H\overline{I}WXY + \cdots$$

$$P = f(S, V, T, W, X, Y, Z, A - I) = A\overline{B}CD\overline{E}FG\overline{H}IS\overline{T}VW\overline{X}Y\overline{Z} + B\overline{C}DEF\overline{G}\,\overline{S}T\overline{V}WXY\overline{Z} + \cdots$$

© 2003 by CRC Press LLC

The delay of this implementation is 8 times the delay of a single macro-cell because an input signal change might have to propagate serially through all of the macro-cells on its way to the output at pin 19.

These examples demonstrate that very complex functions can fit onto the chip. Determining the optimum way to factor the equations is a very complex issue. Chip manufacturers and third party vendors provide software packages that aid in the fitting process.

Designing with Sequential PAL Devices

The concept of registered outputs extends the range of PAL devices to include sequential circuits. Figure 61.11 is the logic diagram for the PAL16R4 chip. Again, this chip has 16 pairs of inputs to the AND array. The R4 part of the designation means that the chip has four outputs connected directly to D type flip-flops, i.e., the outputs are *registered*. Let us add another parameter, k, to designate the number of flip-flops on the chip. An examination of Fig. 61.11 indicates that the PAL16R4 also has four combinational outputs with feedback connections to the AND array. These pins are I/O pins because they can also be used as inputs if the OR output to the pins is permanently disabled. All outputs are active low. The chip has eight input pins. Using our parameter system, the PAL16R4 apparently has $n = 8$, $m = 4$, $k = 4$, $p = 7$ for combinational pin outputs and p = 8 for registered pin outputs. However, as for the PAL16L8, these numbers significantly understate the capabilities of this chip.

Since the four registered outputs are also connected back into the AND array, this chip can implement a sequential circuit with the registered outputs serving as state variables. Therefore, this chip can implement any 8-input, 4-output, sequential circuit that needs no more than 4 state variables (16 states) and no more than 7 product terms for each output or 8 product terms for each state variable. Separate pins provide an enable for the state variables (pin 11) and a clock for the flip-flops (pin 1). Thus, the state variables are also available at output pins.

By an analysis similar to that used in the previous section, we can utilize the feedback lines to significantly expand the types of circuits that will fit onto the PAL16R4 chip. Table 61.5 shows the range of basic possibilities.

For example, the table indicates that the PAL16R4 chip can implement any single output, 8-input, sequential circuit that requires no more than four state variables (16 states) and in which the available product terms may be divided among the outputs and state variables in seven different distributions. The notation (7)-(8-8-8-26) means that the single output can have up to 7 product terms, that one state variable can have up to 26 product terms, and that the other three state variables can have up to 8 product terms each.

Designing with PALs Having Programmable Macro-Cell Outputs

The PAL16R4 chip has limited application potential because the outputs from pins 14-17 *must* be registered. Most new chips allow a user to decide whether to have registered or combinational outputs at each pin and also allow the user to select either active high or active low outputs.

The PAL22V10 chip (see architecture in Fig. 61.12), demonstrates this additional flexibility. Each of 10 macro-cells contains a normal PAL AND array and an I/O architecture control block. Each PAL AND array provides a differing number of product terms permanently connected as inputs to an OR gate and an additional product term that enables an output buffer. The number of product terms per output is printed near the OR gate symbol (8, 10, 12, 14, 16, 16, 14, 12, 10, 8). Figure 61.13 shows that this chip is similar in form to the PAL chips described earlier in this chapter. There are 22 vertical pairs of input lines to the AND array. Of these pairs, 11 are connected directly to input pins labeled $I_1 - I_{11}$ (pins 2-11, 13). Ten pairs are feedback lines from the architecture control blocks of the 10 macro-cells. Each macro-cell is associated with a bi-directional pin (pins 14-23) that can be used either as an input pin, an output pin, or a bi-directional bus pin. If used as a bi-directional bus pin, the designer must control the output enable using a product term from the AND array. The 22nd pair, labeled CLK/I_0, is connected to pin 1. If the chip is being used to implement a purely combinational circuit, pin 1 can be used as an additional input variable. If a sequential circuit is being implemented, pin 1 must be used as the clock signal for the flip-flops.

© 2003 by CRC Press LLC

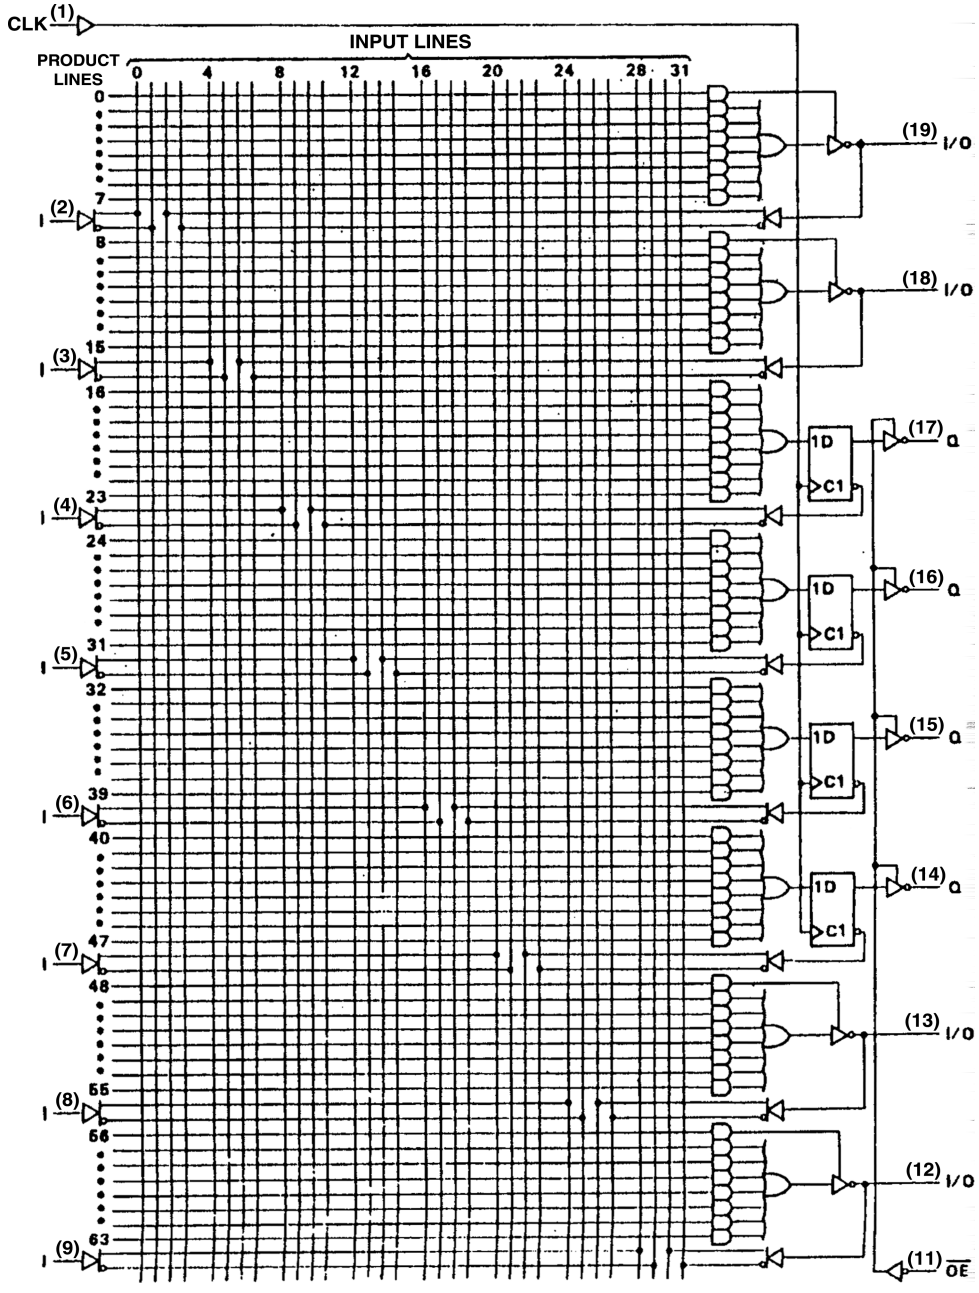

FIGURE 61.11 Logic diagram of PAL16R4 chip.

The architecture control block in each macro-cell provides designer control over the signal that is connected to the bi-directional pin and feedback line associated with that macro-cell. Figure 61.14 shows that the architecture control block contains a D flip-flop, an inverter, two multiplexers with programmable select lines, and an output buffer with an enable. The Output MUX selects either the direct output of the combinational AND array (either active high or active low) or the data value stored in the D flip-flop (either active high or active low). If the output enable is active, the buffer steers the signal selected by the Output MUX to the pin. An inactive enable causes the buffer to enter the high impedance state,

TABLE 61.5 Range of Basic Implementations of PAL16R4 Chip

m	*n*	*k*	Number of Product Terms per (Combinational Output)–(State Variable)	Delay
1	11	4	(7)-(8-8-8-8)	T_A
1	10	4	(7)-(8-8-8-14), (13)-(8-8-8-8)	$2T_A$
1	9	4	(7)-(8-8-8-20), (7)-(8-8-14-14), (13)-(8-8-8-14), (19)-(8-8-8-8)	$2T_A$
1	8	4	(7)-(8-8-8-26), (7)-(8-8-14-20), (7)-(8-14-14-14), (13)-(8-8-8-20), (13)-(8-8-14-14), (19)-(8-8-8-14),(25)-(8-8-8-8)	$2T_A$
2	10	4	(7-7)-(8-8-8-8)	T_A
2	9	4	(7-7)-(8-8-8-14), (7-13)-(8-8-8-8)	$2T_A$
2	8	4	(7-7)-(8-8-8-20), (7-7)-(8-8-14-14), (7-13)-(8-8-8-14), (7-19)-(8-8-8-8), (13-13)-(8-8-8-8)	$2T_A$
3	9	4	(7-7-7)-(8-8-8-8)	T_A
3	8	4	(7-7-7)-(8-8-8-14), (7-7-13)-(8-8-8-8)	$2T_A$
4	8	4	(7-7-7-7)-(8-8-8-8)	T_A

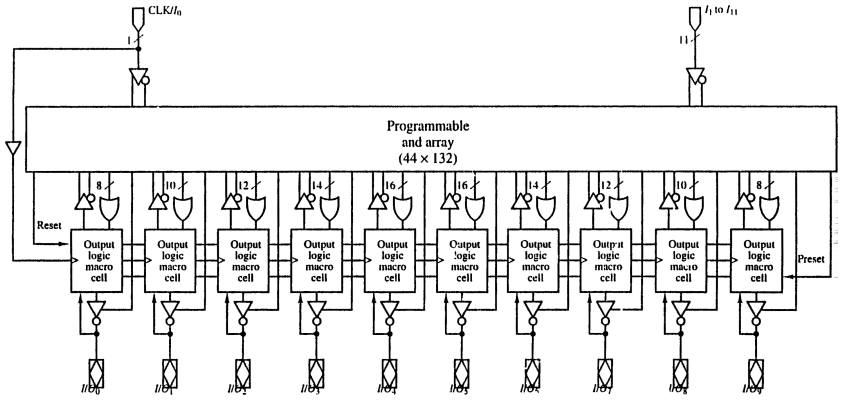

FIGURE 61.12 Architecture of the PAL22V10 chip. (Courtesy of Advanced Micro Devices, Inc.)

which effectively disconnects the buffer from the pin. The pin can then be an input or can be connected to an external bus.

The feedback signal selected by the Feedback MUX is either the pin signal or the data value stored in the flip-flop (low active). Therefore, the feedback line can be used to expand the number of product terms, to provide a state variable for a sequential circuit, to provide an additional input for the chip, or to implement a bi-directional pin.

Figures 61.13 and 61.14 show that the common clock input to all flip flops comes directly from pin 1, that a single product term (SP) provides a common synchronous preset for all flip flops and that another single product line (AR) provides a common asynchronous reset for all flip flops. The asynchronous reset occurs when the product line is active independent of clock state. The synchronous preset occurs only on the active edge of the clock when the preset product line is active.

The two programmable multiplexers in the architecture control block significantly increase the flexibility of the chip compared to either the PAL16L8 or the PAL16R4. Table 61.6 shows several combinations of switch settings along with typical applications for each setting.

The PAL22V10 is much more versatile than either the PAL16L8 or the PAL16R4. Since pins 14-23 can be used as inputs, combinational outputs, or registered outputs, the following inequalities describe the possibilities.

If the chip is used to implement a combinational logic function, the constraints are:

$$n \le 22, \quad m \le 10$$

$$(n + m) \le 22$$

© 2003 by CRC Press LLC

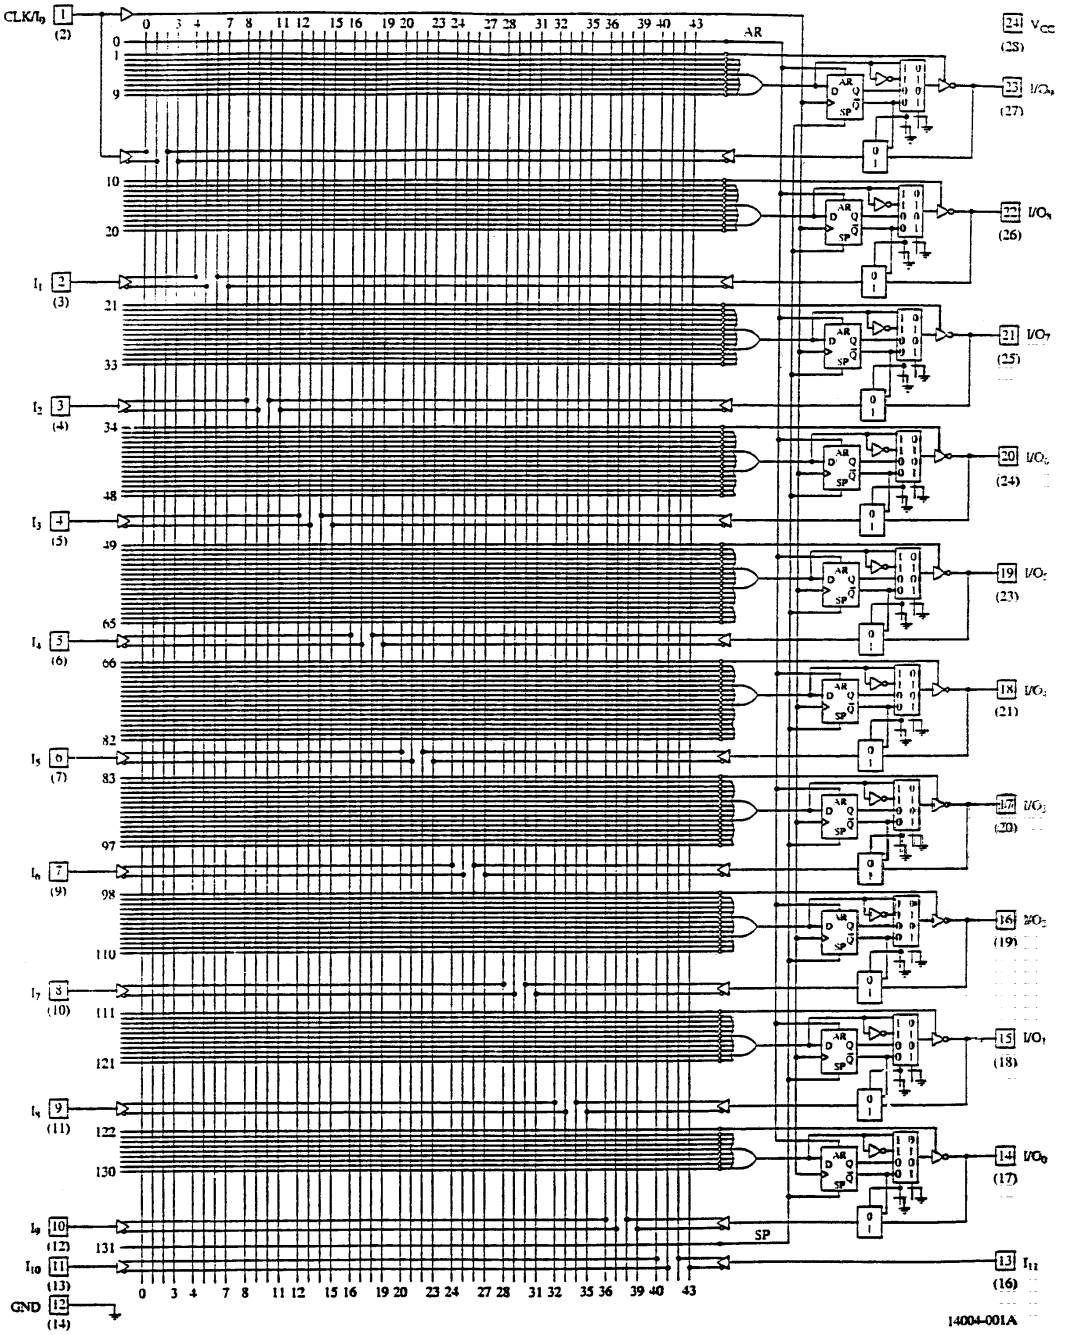

FIGURE 61.13 Complete circuit diagram for the PAL22V10 chip. (Courtesy of Advanced Micro Devices, Inc.)

For sequential circuits, the constraints are:

$$n \le 21, \quad m \le 10, \quad k \le 10$$

$$(m+k) \le 10, \quad (n+m+k) \le 21$$

because the clock signal for the flip-flops uses one of the input pins (pin 1).

TABLE 61.6 Applications for Combinations of Switch Settings for the PAL22V10 Chip

Name	Output Connection	Feedback Connection	Application
INP	None	Pin	Use pin as input only
COCF	Combinational	Combinational	Combinational output and/or combinational feedback
COIF	Combinational	Pin (input)	Bi-directional pin implementing a combinational output
RORF	Register	Register	Typical state machine controller
ROIF	Register	Pin (input)	Bi-directional pin with registered output. Bus applications

Table 61.7 shows representative sizes for circuits that will fit onto the PAL22V10 chip.

FPGA Technologies

Due to the relatively high complexity of FPGAs, almost all FPGAs use CMOS process technology because of its high density and low power characteristics. Currently, there are two popular FPGA programming technologies, static RAM (SRAM) and anti-fuse.

The anti-fuse device gets its name from the fact that its electrical properties are the dual of the electrical properties of a fuse. The anti-fuse is a pair of conducting plates separated by a di-electric insulator, similar to a small capacitor. By contrast, the fuse is a pair of terminals separated by a thin conducting wire. A fuse is programmed by passing a high current through the thin wire causing the wire to heat up and melt, producing an open circuit where a short circuit previously existed. Fusible link technology is used in many PLA and EPROM devices. By contrast, the anti-fuse is programmed by applying a high voltage across the di-electric insulator that permanently breaks down the di-electric insulator, producing a short-circuit where an open-circuit previously existed. Both fusible-link and anti-fuse devices are non-volatile which makes them particularly well-suited for use in extreme environments, such as space and other high radiation environments. Anti-fuse technology also provides higher speed operation than other technologies.

SRAM chips are volatile (i.e., they lose their program when power is removed) and have lower density and slower speed than anti-fuse chips. On the positive side, SRAM chips are lower cost, re-programmable

2	8	11	(16-16)-(8-8-10-10-12-12-14-14)	T_A

and, therefore, dynamically reconfigurable. In the current marketplace, SRAM chips have captured most of the popular commercial market.

FPGA Architectures

Figure 61.15 shows a high-level layout of an FPGA chip. Each chip contains a two-dimensional array of identical configurable logic blocks (CLBs). The FPGA in Fig. 61.15 has 64 CLBs arranged in an 8×8 array. The user can program the CLBs to implement specific combinational or sequential logic functions. A programmable interconnect structure is permanently placed in the space between CLBs. The user

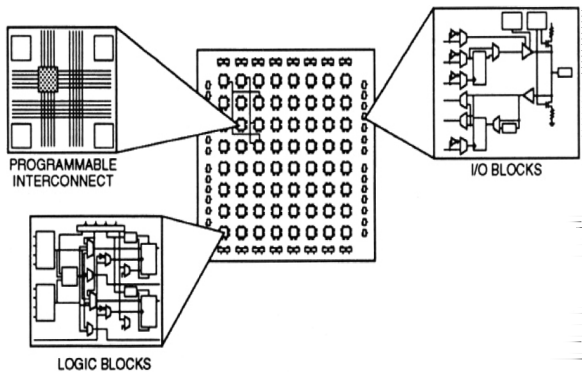

FIGURE 61.15 FPGA architecture. (Courtesy of Xilinx.)

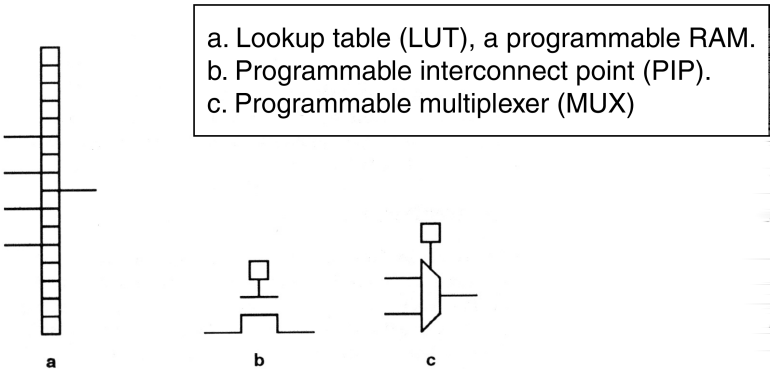

FIGURE 61.16 Programmable FPGA elements. (Courtesy of Xilinx.)

programs switches that make desired connections between his programmed CLBs either by setting SRAM bits or by permanently closing the anti-fuses. Programmable I/O blocks are located around the perimeter of the chip that allows the user to connect signals to pins on the chip.

For convenience, in this paragraph we describe FPGA elements using SRAM terminology. Anti-fuse devices have similar components. FPGAs have three basic programmable elements, illustrated in Fig. 61.16. The lookup table (LUT) is a programmable RAM. The LUT shown in Fig. 61.16a is a 16×1 RAM. It has four address inputs and one data output. It is programmed by storing either a logic 1 or a logic 0 in each RAM location. The value at a specific location is read out (looked up) by applying the address at the RAM inputs. A programmable interconnect point (PIP) is simply a CMOS pass transistor with a programmable SRAM bit controlling the gate signal. If a connection between the two transistor terminals for the PIP in Fig. 61.16b is desired, a logic 1 is stored in the SRAM control bit. If no connection is desired, a logic 0 is stored in the SRAM control bit. SRAM bits also control the address lines of programmable multiplexers (MUX). The MUX in Fig. 61.16c has two input lines and therefore can be controlled by one SRAM bit. Programming the SRAM control bit to be logic 0 connects the upper MUX input to the MUX output. Programming the SRAM control bit to be logic 1 connects the lower MUX input to the MUX output.

To illustrate the principles, consider the minimal CLB shown in Fig. 61.17. This CLB has three input signals (A, B, and C) and one output signal (X). The CLB has one 8×1 LUT and one D flip-flop with a reset input (R). It has three 2×1 programmable MUXs with SRAM control bits labeled M1, M2, and M3, respectively. The MUX controlled by M3 connects either the LUT output (F) or the bit stored in the flip-flop (Q) to the CLB output (X). If M3 = 0, the D flip-flop is bypassed and the CLB will implement the combinational logic function stored in the LUT. If M3 = 1, the CLB will implement a sequential function. The MUX controlled by SRAM bit M2 selects either the LUT output (F) or the input signal (C) as the reset signal for the flip-flop. The MUX controlled by SRAM bit M1 selects either input signal C or the bit stored in the flip-flop (Q) as the third address input (E) to the LUT. Inputs A and B are permanently connected to two of the LUT address lines.

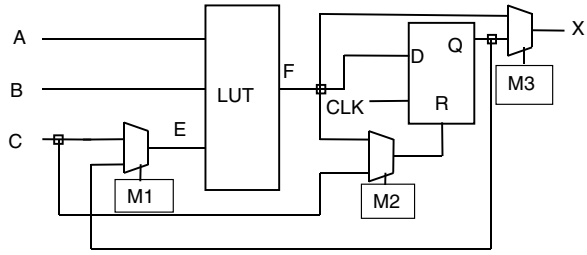

FIGURE 61.17 A minimal CLB.

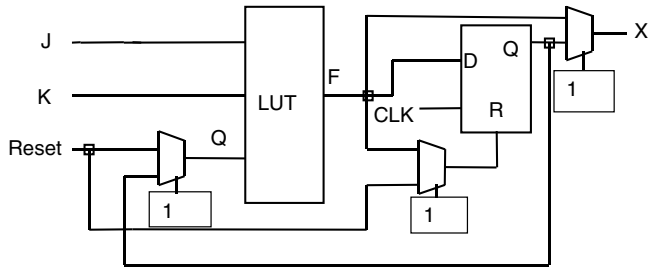

FIGURE 61.18 Minimal CLB programmed to be a JK flip-flop.

TABLE 61.8 Contents of LUT for Programmed CLB

J	K	Q	F
0	0	0	0
0	0	1	1
0	1	0	0
0	1	1	0
1	0	0	1
1	0	1	1
1	1	0	1
1	1	1	0

To illustrate how the minimal CLB in Fig. 61.17 could be programmed, we will show how to program it to implement a JK flip-flop. M3 will be 1 to select the flip-flop output as the CLB output. M2 will be 1 to select input C as the flip-flop reset signal. M1 will be 1 to select the flip-flop output (Q) as the E input to the LUT. Input A will be designated as the J input and input B will be designated as the K input for the flip-flop. Figure 61.18 shows the programmed CLB with all signal names related to their use in the JK flip-flop. Table 61.8 shows how the LUT must be programmed to implement the function of a JK flip-flop.

Figure 61.19 shows an actual CLB in the XC4010XL chip, a small FPGA chip manufactured by Xilinx. This CLB uses the same small set of elements that we used in the minimal CLB. This CLB contains 2 D-flip-flops, 3 LUTs, and 16 programmable MUXs.

If the user had to directly program each CLB and each PIP in the interconnect structure, the task would be formidable. However, most chip manufacturers provide software packages that allow the user to specify the device function using a variety of high-level abstractions. In the next section, we will discuss this process in more detail.

Design Process

From the previous discussion, it is clear that fitting designs to PLD chips is a complex process. PLD manufacturers and third-party vendors market software packages that help engineers map designs onto chips. Selecting a package appropriate for a particular design environment is a critical decision that will significantly affect the productivity of the design group.

There are basically three types of development system packages: user designed packages, vendor designed packages, and universal packages. Since these programs are very complex and require many years of effort to develop, most design groups will lack the time and resources to develop their own. Many vendors provide design aids that are specific to a particular product line. There is a great danger in becoming dependent upon one vendor's products because new products in this field appear frequently. Clearly, a universal design package that supports a wide variety of product lines is most desirable. A variety of development systems with different features, capabilities, and price is available.

Figure 61.20 shows a flow diagram for the process typically used to design PLAs and FPGAs. *Design entry* refers to the use of an editor to create a source file that specifies the *functional behavior* of the device. High-level simulation verifies correct functional behavior of the device. *Logic synthesis* refers to the process of implementing the design using the primitive elements present on a specific chip, such as gates, flip-flops, registers, etc. Most development systems support *prelayout simulation* at this level to verify that the design still functions correctly. *System partitioning* and *mapping* refers to the process of grouping blocks of primitive elements into sets that map directly into major chip structures, such as CLBs in FPGAs or AND-OR arrays in PLDs. *Place and route* refers to mapping the structures into specific locations on the chip and making connections between them. The software package then performs a timing analysis on the final design to verify that design timing specifications are met. Finally, the chip is *configured* by generating an output file that can be read by the chip programmer.

Design Entry

It is essential for a universal development system to have a variety of design entry modes. Many vendors market the more complex design entry modes as optional features. This section describes some of the more common design entry modes and their value to PLD and FPGA designers.

Boolean equations are an important method of design entry. A PLD design system must support Boolean equation entry because the AND-OR arrays on PLD chips directly implement Boolean equations. Almost all PLD designers will use Boolean equation entry extensively. Boolean equation entry is also useful for FPGA designs.

Truth table entry allows specification of a combinational logic function by defining the output for each of the 2^n input combinations. This form is particularly valuable if *don't care* entries exist. Truth table entry is most commonly used for functions with a small number of input variables that are not easily described by Boolean equations. Code converters, decoders, and lookup tables are examples. A good design tool will support truth table entry.

Symbolic state machine entry is crucial for PLD and FPGA designers because both PLDs and FPGAs are often used to implement state machine controllers. Current tools have features described as state

© 2003 by CRC Press LLC

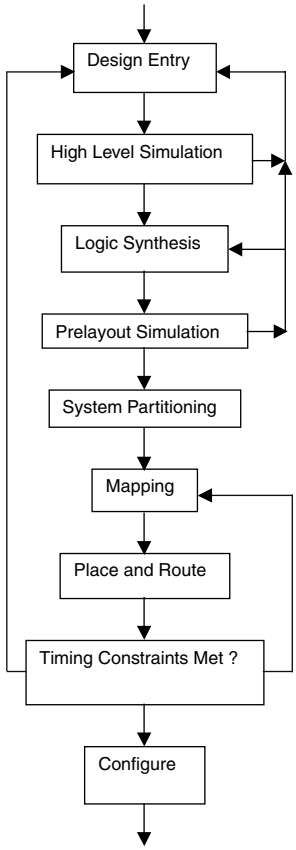

FIGURE 61.20 Design process.

machine entry that vary dramatically in form and usefulness. Before selecting a tool, the specifics of the state machine entry format should be carefully investigated. The most useful formats allow symbolic representation of states and specification of state transitions using some form of conditional statement such as *if_then_else*, or *case*. Relational operators are also useful in this context. The tool should perform automated state assignment and should fit the state variable equations to the target chip.

State diagrams using graphics are useful, but not essential. This feature is mainly a convenience, provided that symbolic state machine entry is available.

Schematic entry is a widely accepted way to describe logic systems. To be useful, it must be combined with a powerful partitioning and mapping tool that can fit the circuit onto chips. Schematic entry is useful to convert existing gate level designs into PLD or FPGA implementations.

Hardware description language (*HDL*) entry is potentially the most useful of all methods. Popular HDL languages are VHDL, Verilog, and System C. Using these languages, a designer can specify an executable specification of his device. Mature simulators exist for all of these languages that allow functional verification of the high level HDL design.

Logic Synthesis

Logic synthesis is the process of transforming a given description of a device produced by one of the design entry methods described in the previous section into an equivalent netlist using primitive components. For example, the process of transforming a symbolic state machine description or an HDL description into a netlist is an example of logic synthesis. The power of the synthesis algorithms in a development system is perhaps the most important feature of the system.

HDL synthesis tools are beginning to be mature enough for use in both PLD and FPGA designs. Very good synthesis tools exist for subsets of the popular HDL languages. Full synthesis tools for all language

© 2003 by CRC Press LLC

constructs are still in the research phase. In the next section, we will illustrate how to synthesize FPGA designs using the VHDL language.

Logic minimization is obviously an essential process in a PLD development system because the number of product terms per output gate on PAL chips is limited. Recall that the goal of logic minimization for PLD designs is to reduce the number of product terms, not the size of the product terms. Classical logic minimization algorithms use cost functions that reward reduction of the number of gate inputs. This is important for TTL gate implementations, for example, because an 8-input gate costs about four times as much as a 4-input gate. In PLD designs, the number of gate inputs does not matter. Each product term consumes one product line in the chip. A one-literal product term, such as X, costs exactly the same as a ten-literal product term, such as $A\overline{B}CD\overline{E}F\overline{G}HIJ$. Therefore, traditional logic minimization programs, such as Espresso, need to be modified for PLD development. If product terms can be shared among different outputs, then multiple output minimization is necessary. However, for most PAL devices, the product terms cannot be shared; therefore, single output minimization algorithms are sufficient. Single output minimization algorithms are much less complex and take much less time to execute than multiple output minimization algorithms. Therefore, systems that do single output minimization result in higher productivity. Therefore, be careful of systems that advertise well-known traditional logic minimization algorithms to market their products, especially if multiple output minimization is stressed.

Equation factoring, which is sometimes called *multiple level minimization*, is essential in order to fit large functions onto PLD chips using multiple cells combined with feedback lines inside the chips. This feature is missing from most vendor PLD development systems. However, in order to provide effective automated PLD synthesis, this operation is absolutely necessary. In most current PLD development systems, the designer must interact with the synthesis program to implement multiple level minimization. Such interaction requires extensive skill from the user of the software package.

Simulation of Designs

All good development systems include some form of simulation capability. The simulators vary widely in scope, user interface, and general usefulness.

Behavioral simulation allows high-level design descriptions to be simulated independent of implementation. Behavioral simulators verify the input-output behavior of the device. Correct behavioral simulation verifies the correctness of the algorithms prior to mapping the design to specific hardware components.

Device simulators verify the function of the design after mapping the design to a specific chip but before actually programming the chip. This is the most common type of simulator in current PLD development systems. A device simulator will construct a software model of the target PLD architecture, map the design to that architecture, and then simulate the behavior of the specific PLD. The better simulators will provide timing information as well as functional information.

Mapping Designs to Chips

System partitioning, mapping, place and route, and configure functions are usually performed by vendor-specific development software. These software packages usually accept a netlist as input and produce an output file that can be read by the programming tool.

VHDL Synthesis Style for FPGAs

Since HDL synthesis is one of the most popular ways to design FPGAs, we will show representative synthesis techniques for VHDL, one of the common HDL languages. The user may use these examples as templates to write code that will synthesize successfully.

Registers and Flip-Flops

Figure 61.21 shows a VHDL template for a register, AREG, with synchronous reset signal (RESET) and data input, A. In VHDL, entities are called processes. This code defines a process named Synchronous-RegProcess. The list of signal names in the parentheses following the word *process* is called the *sensitivity*

© 2003 by CRC Press LLC

```
SynchronousRegProcess: process (CLK)
 begin
  -- No other statements here
  if (CLK'event and CLK='1') then
   if RESET ='0' then
    AREG <= '0';
   else
    AREG <= A;
   end if;
  end if;
  -- No other statements here
 end process;
```

FIGURE 61.21 VHDL code for register with synchronous reset.

list for the process. The sensitivity list for a register process must contain the clock signal for the process. The notation, CLK'event, is a Boolean expression that is TRUE when signal CLK changes value. This change may either be a rising edge or a falling edge. Combining CLK'event with CLK='1' specifies a rising edge triggered clock. The notation *AREG<=A* specifies that the current value of input signal A is assigned to register AREG on the rising edge of signal CLK. Similarly, the notation, AREG<='0', implies that signal AREG is reset to 0 on the rising edge of CLK when RESET='0'. Current synthesis semantics dictate the following constraints on the VHDL code.

1. The "if" statement that identifies the clock signal must be the only top level statement in the process. No other statements may come before or after this "if" statement, as indicated by comments in the VHDL code.
2. The condition that identifies the clock signal for the register, (CLK'event and CLK='1'), must contain no other conditions. For example, we could not implement the synchronous reset by writing (if CLK'event and CLK='1' and RESET = '0' then…).
3. Only one clock edge may occur in each process. That is, it is unacceptable to have both CLK1'event ad CLK2'event in the same process.

Figure 61.22 shows how a synthesis tool will synthesize this VHDL code into a clocked register. Note that the RESET signal is low-active (a logic 0 causes a reset).

Figure 61.23 shows a VHDL template for a register, AREG, with an asynchronous reset. The same restrictions that were listed for the synchronous register also apply here. Notice that the primary differences

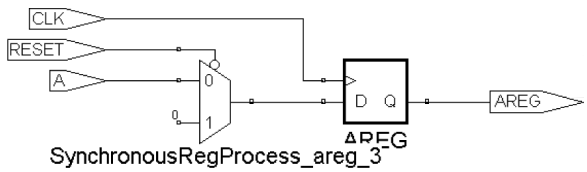

FIGURE 61.22 Synthesis of VHDL code in Fig. 61.21.

```
Asynchronous_Reset: process (CLK, RESET)
 begin
  if RESET='0' then
   AREG <= '0';
  elsif (CLK'event and CLK='1') then
   AREG <= A;
  end if;
 end process;
```

TABLE 61.9 Ones Counter Truth Table

A(2)	A(1)	A(0)	C(1)	C(0)
0	0	0	0	0
0	0	1	0	1
0	1	0	0	1
0	1	1	1	0
1	0	0	0	1
1	0	1	1	0
1	1	0	1	0
1	1	1	1	1

are that, in the asynchronous register, signal RESET must be in the sensitivity list and the RESET test occurs before the test for the clock edge, whereas the test for RESET in the synchronous register occurs after the test for the clock edge. Figure 61.24 shows how a synthesis tool synthesizes the VHDL code in Fig. 61.23 into a register with an asynchronous reset signal.

Combinational Logic

Consider the ones counter truth table of Table 61.9. The input is a 3-bit vector, A, and the output is a 2-bit vector, C. The output reflects the number of ones in the input vector. For example, if A = 111, then C = 11 indicating that A has 3 ones.

There are many ways to represent combinational logic using VHDL. The most direct way is to use a *case* statement, as shown in Fig. 61.25. This type of code is directly related to the truth table format. It simply specifies the output for each combination of the inputs. Figure 61.26 shows how a synthesis tool synthesizes the code in Fig. 61.25. Note that it takes the unusual approach of using a multiplexer as part of the circuit. The reason for this is that the target FPGA chip has many multiplexers in its CLBs. (See Fig. 61.19.)

Latches

Figure 61.28 shows that the VHDL code in Fig. 61.27 synthesizes as a latch with output signal name Q. Note that the process sensitivity list must include both the latch input data signal name, DATA, and the latch enable signal name, ENABLE. Also, the code for a latch may *not* contain an expression referring to

```
process(A)
begin
   case A is
      when "000" => C<= "00";
      when "001"|"010"|"100" => C<= "01";
      when "011"|"101"|"110" => C<= "10";
      when "111" => C<= "11";
      when others => null;
   end case;
end process;
```

```
CLP: process (ENABLE, DATA)
   begin
      if ENABLE='1' then
         Q<=DATA;
      else
         Q<='0';
      end if;
   end process;
```

FIGURE 61.29 VHDL code for combinational logic.

an edge, such as ENABLE'event. The reason that the synthesis tool produces a latch is that a new value is *not* assigned to signal Q during every call to the process. A new value is only assigned when ENABLE = '1'. Otherwise, the signal Q must not change, i.e., it must retain its old value when ENABLE = '0'. This action requires a latch.

Figure 61.30 shows that the VHDL code in Fig. 61.29 synthesizes as combinational logic and does not produce a latch. In this VHDL code, signal Q is assigned a new value every time the process is called. Therefore, the synthesized circuit is combinational logic instead of a latch.

FIGURE 61.31 VHDL template for a state machine.

Synthesis of State Machines

Figure 61.31 shows a VHDL template for a state machine. First, the code includes a declaration of a data type called STATE_TYPE. This data type is simply a list of the names of the states. The names should be chosen to reflect the purpose of the state, such as INITIAL, IDLE, TRANSMIT, RECEIVE, etc. Next,

© 2003 by CRC Press LLC

a signal, STATE, is declared to be of type STATE_TYPE. Signal STATE keeps track of the current state of the state machine. The architecture consists of two processes. Process STATE_PROCESS updates the current state on each positive transition of clock signal CLK. Process OUTPUT_PROCESS updates the state machine outputs whenever there is a change in state. As written, these processes implement a Moore state machine. To design a Mealy state machine, simply add the machine input signals to the OUTPUT_PROCESS sensitivity list. The state machine has a low-active asynchronous RESET signal that initializes the state machine to state S0. A *case* statement performs data transfer statements and computes the next state based on the current state. For other approaches to using high-level languages to design digital systems, see [8].

61.2 Clocking Schemes

Wayne D. Grover

Introduction

Advances in VLSI processing technology, particularly CMOS, have resulted in submicron processes with roughly fourfold increases in circuit densities and two- to threefold increases in speed over the preceding 1.2 μm process. Consequently, CMOS applications at speeds near 1 GHz are now feasible. New design challenges must be mastered to realize systems at these speeds. In particular, clocking-related issues of skew, delay, power dissipation, and switching noise are potentially design-limiting factors. For example, at a bus speed of 200 MHz, 1 ns of skew represents 20% of the clock period. Yet to get the most advantage from available process speed we would like to keep skew under 10% of the clock period, thus setting a target of 500 ps of skew for dies that may be as large as 2 cm on a side.

In large synchronous designs, the clock net is also typically the largest contributor to on-chip power dissipation and electrical noise generation, particularly "ground bounce", which reduces noise margin. Ground bounce is a rise in ground potential due to surges of current returning through a nonzero (typically inductive) ground path impedance. A typical CMOS flip flop consumes 12 μW/MHz. At 200 MHz a system with 2 K flip flops will consume 4.8 W for clocking alone. At the board and shelf level, clock distribution networks also can be a source of electromagnetic emissions, and may require considerable delay tuning for optimization of the clock distribution network.

In the past, multiphase clocking schemes and dynamic logic structures helped minimize transistor count, but this is now less important than achieving low skew, enhancing routability, controlling clock-related switching noise, and providing effective CAD tools for clock net synthesis and documentation.

© 2003 by CRC Press LLC

For these reasons, a shift has occurred toward single-phase clocking and fully static logic in all but the largest custom designs today. In addition, phase-feedback control schemes using phase-locked loops (PLLs) are becoming common, as are algorithmic clock-tree synthesis methods.

This section focuses on the issues and alternatives for on-chip and multichip clocking, with the primary emphasis on CMOS technology. We first review the fundamental nature and sources of skew and the requirements for the clocking of storage elements. We then outline and compare a number of "open-loop" clock distribution approaches, such as the single-buffer, clock trunk, clock ring, H-tree, and balanced clock tree approaches. Phase-locked looped synchronization methods and PLL-based clock generation are then outlined. In closing, we look at future technologies and developments for high-speed clocking. The concepts and methods of this section apply to many circuit technologies on- and off-chip. However, we emphasize CMOS because CMOS processes (including bi-CMOS) presently represent the vast majority of digital VLSI designs and are expected to continue to do so.

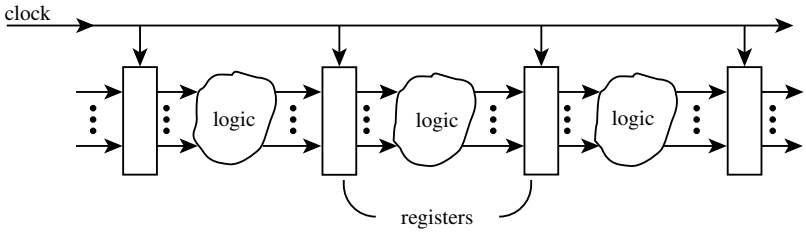
Asynchronous, self-timed, and wavefront array systems are outside the scope of this chapter. These approaches aim to minimize the need for low-skew synchronous clocking. However, truly asynchronous modules tend to require a large overhead in logic for interaction with each other, so that speed, size, and power often suffer relative to synchronous design. Nonetheless, self-timing can be an effective approach for random-access memory and read-only memory (RAM and ROM) cells, to which considerable optimization effort can be invested for reuse in many designs. Self-timed methods should be considered the alternative to fully synchronous design in large, highly modularized systems, particularly where well-defined autonomous modules have relatively infrequent interactions. The main issues in self-timed systems are the possibly high delay required to avoid metastability problems between self-timed modules, and the circuit costs of the synchronization protocol for intermodule communication.

Clocking Principles

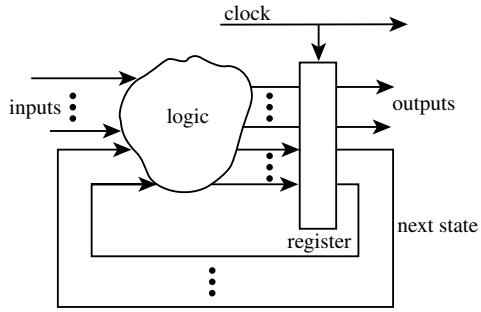
Most of us accept the clocked nature of digital systems without question, but what, fundamentally, is the reason for clocking? Any digital system can be viewed either as a pipeline or as a finite state machine (FSM) architecture, as outlined in Fig. 61.32. In the pipelined architecture clocked sections are cascaded, each section comprising an asynchronous combinational logic block followed by a latch or storage element that samples and holds the logic state at the clock instant. In the FSM, the only difference is that the next state input and the system outputs are determined by the asynchronous logic block, and the sampled next state value (S) are fed back into the combinational logic. The FSM can therefore be conceptually unfolded and also represented in a pipeline fashion. The fundamental reason for clocking digital systems is seen in this pipelined abstraction of a digital system: it is to bring together and retain coordination among asynchronously evolved intermediate results. With physical delays that are temperature, process, and input dependent in combinational logic, we need to create *agreed-upon time instants* at which all analog voltages in a system are valid when interpreted as boolean logic states. Clocking deals with delay uncertainty in logic circuit paths by holding up the fast signals and waiting for the slower signals so that both are valid before they are again combined or interact with each other. Without this coordination purely asynchronous logic would develop severe propagation path differences, and be slow in repetitive operations. Ultimately, a valid state would evolve, but all inputs would have to be stable for the entire time required for this evolution. On the other hand, when the overall combinational logic function is appropriately partitioned between clocked storage latches, system speed can approach the limit given by the delay of a single gate because each logic sub-block is reused in each clock period.

From this, we obtain several insights: (1) only the storage elements of a digital system need become loads on the clock net (assuming state logic gates); (2) the system cannot be clocked faster than the rate set by the slowest combinational signal path delay between clocked storage elements; (3) any uncertainty in clock timing (skew) is indistinguishable from uncertainty in the settling time of the intervening combinational logic; and (4) for a logic family to work, its storage elements must: (i) at no time be transparent (i.e., simultaneously connect input to output), (ii) have a setup time less than $(T - t_{clk-Q})$ where T is the clock period and t_{clk-Q} is the clock-to-Q output delay of the same type of flop, and (iii) have

© 2003 by CRC Press LLC



(a) pipelined architecture



(b) finite-state machine atchitecture

FIGURE 61.32 Architecture of digital systems.

a hold time less than their clock-to-output delay. The last points may be better appreciated by considering that the combinational logic block may be null, i.e., a zero-delay wire, such as in a shift-register.

An implication of [4(i)] is that two-phase nonoverlapping clocks, or an equivalent sequencing process, is fundamental for the storage elements of a digital system. This may sound unusual to readers who have already designed entire systems with SSI and MSI parts, or in gate-array design systems, without having seen anything but single-phase edge-triggered flip flops, latches, counters, etc. However, at least two clock phases (or clock-enabling phases) are internally required in any clocked storage device. An analogy is of a ship descending in elevation through a lock [27]. During the first clock phase sluice gates "charge" the lock up to the incoming water level and open the input gate to bring a ship in. Throughout this phase, it is essential that the output gate is closed, or water will race destructively right though the lock. Only when the ship is entirely in the lock and the input gate is closed (isolating the input) can the output sluice gates be opened to equalize the water level to that on the outgoing side, allowing the ship to leave (producing a new output). Similarly, in a flip flop or latch the currently stored value, which appears at the output, must be isolated from the input while the input evolves to its next value.

Skew and Delay

Clock *skew* is defined must generally as the difference in time between the actual and the desired instant of active clock edge at a given clocked storage element. In the majority of designs in which the desired instant of clocking is the same at all storage elements, skew is the maximum difference in clock waveform timing at different latches. Clock skew is of concern because it ultimately leads to the violation of setup or hold times within latches, or to clock race problems in multiphase clocking. Furthermore, from a design viewpoint, uncertainty in clock timings must be treated as equivalent to actual clock skew. Skew or timing uncertainty are therefore equivalent to an increase in critical path logic delay. In either case, the clock period must be extended to ensure valid logic levels and proper setup/hold requirements relative to the clock time.

To illustrate the equivalence of skew (either actual of design timing uncertainty) to a loss of system speed, consider a 200-MHz process used in a design which as 25 % skew, (i.e., actual clock edge dispersion

© 2003 by CRC Press LLC

or, equivalently, uncertainty in clock timing is 1.25 ns). If a competitor uses the same process at 200 MHz and achieves 5 % skew (0.25 ns), then the latter design has 20 % more of each 5 ns clock cycle for settling combinational logic paths. Alternatively, for the same logic functions, the low-skew system could be clocked at 250 MHz with the same timing margins as the high-skew system. Skew, therefore represents a loss of performance relative to basic process capabilities developed at the great expense. However, skew reduction costs relatively little, and is in the logic designer's control, not the process developer's and yet it is directly equivalent to a basic enhancement in process speed.

Skew is usually of primary concern on-chip or within any module that is designed on the presumption of a uniform clock phase throughout the module. Clock *delay*, on the other hand, is the difference between the nominal clock edge time at an internal flip flop and the system clock, or timing reference, external to the chip. While skew is typically managed internal to the die, delay is of concern at the system level to ensure external setup and hold time requirements. Skew and delay may be independent in any given clock distribution scheme. For example, an on-chip clocking tree that yields essentially zero skew may, nonetheless, impart a high clock delay, which will be of importance at the system level. The "early clock" technique and some PLL methods (presented later) can be used to address on-chip clock delay problems.

Isochronic or Equipotential Regions

The clock distribution problem arises at all scales of system design, from on-chip clock distribution in VLSI and WSI to the synchronization of circuit packs tens of meters apart. These application are unified as a generic problem: synchronous clocking of "electrically large" systems, i.e., systems in which propagation time across the system is significant relative to the clock period. In such systems:

$$D/v > k/f_{app} \tag{61.1}$$

where D is the characteristic scale or distance of the system, v is the propagation velocity, f_{app} is the application clock frequency, and k is the skew requirement as a fraction of the clock period. For all locations around a clock entry point at which (61.1) is false, we can consider events to be essentially simultaneous (or, equivalently, the region is a single electrical node), and the clock can be distributed within such regions without delay equalization. The region over which clock can be distributed without any significant skew is also known as an equipotential [27] region, or an isochronic region [1]. In this section, we are concerned only with cases in which (61.1) is true, but it is implicit that the clocked end nodes may be either clocked loads directly or a buffer that feeds a local isochronic region.

The diameter (and shape) of an isochronic region on-chips depends on the wire type employed for interconnection. To control skew on chip, we need to consider delay differences due both to wire lengths and to the lumped capacitive efforts of the driven loads. Where the RC time constant of the wiring interconnect τ_w is much less than the RC combination of the driving source resistance and the lumped capacitance of N clocked loads on the net ($\tau_{net} = R_s\, C_{gate}\, N = N\tau_g$), we can consider all points on a net to be isochronic, meaning that the net acts like one electrical node characterized by the total lumped capacitance of gates on the net. Wires on a chip are often modeled as distributed R_0C_0 sections, where R_0 and C_0 are the resistance and capacitance per unit length, respectively (see Fig. 61.33). In such cases, the propagation delay for a wire of length l follows the diffusion equation [31]

$$\tau_w = R_o C_o l^2/2 \tag{61.2}$$

Therefore, if we consider a net of length l with N standard loads, we can consider the net to be isochronic if $\tau_w \ll N\tau_g$. From (61.2), this implies:

$$l \ll \sqrt{\frac{2NR_sC_{\text{gate}}}{R_0C_0}} \tag{61.3}$$

© 2003 by CRC Press LLC

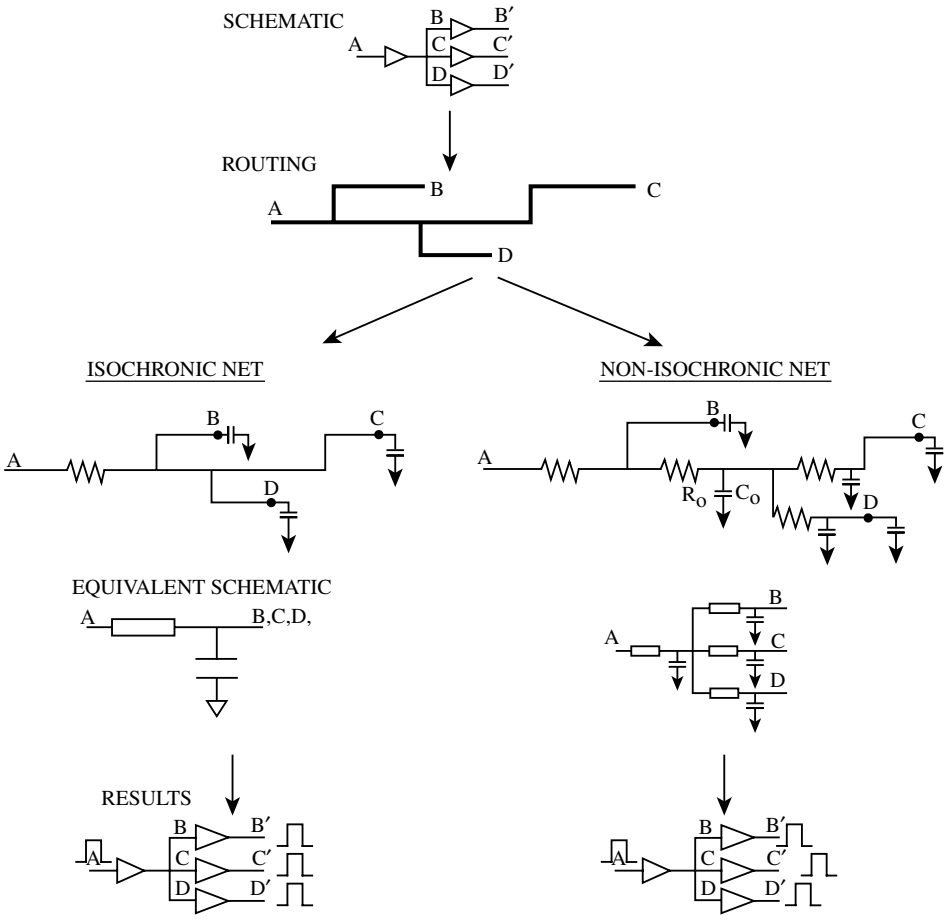


FIGURE 61.33 Isochronic and nonisochronic passive wiring nets.

This relationship provides a guideline for the maximum length over which wire delays may be neglected relative to gate-charging delays. Based on typical values for a 1-μm process, $\tau_g < 500$ ps, isochronic regions for lightly loaded lines (N = 1) are up to 10,000 λ for lines in third layer metal, 5000 and 8000 λ for first and second layer metal, respectively, and 200 λ for polysilicon wires, where λ is the minimum feature size of the process [31]. This illustrates the importance of distributing clock within metal layers to the greatest extent possible. Even a few short polysilicon links may introduce sufficient series resistance to drastically reduce the isochronic region for the given clock line. This also illustrates that if clock is distributed in metal layers, and is always buffered before exceeding the isochronic distance, it will be primarily differences in lumped capacitive loads and not wire length that determine clock signal delays, and hence relative clock skews.

Nature of Skew On-Chip

The concept of isochronic regions helps us understand the nature of clock skews in VLSI and helps explain why on-chip skews may be greater than those between off-chip points that are physically many more times distant. A key realization is that signals do not propagate at the "speed of light". If they did, absolute delays across even the largest chips (2 cm edges) would be subnanosecond and the isochronic diameter would easily encompass an entire die at clock speeds up to 200 MHz. Rather, on-chip propagation delay depends much more on the time needed for output drivers to charge the total lumped capacitance associated with all the gate inputs of the driven net. In other words, fanout and driver current abilities have more to do with delay than path lengths. This is especially true when clock distribution is

© 2003 by CRC Press LLC

exclusively via metal layers, as is the norm in a modern design. On the other hand, off-chip, we route signals via impedance-controlled coaxial or microstrip lines, or via optical fiber, and these media typically do exhibit propagation velocities of 0.6 to 0.8 c. Therefore, off-chip, differences in physical propagation distances are the dominant source of skew, while on-chip, it is imbalances in driver loads that are the most common source of skew.

In on-chip cases in which wire diffusion delays and lumped capacitive effects are both significant, a difference in line length can also result in skew due to a different total wiring capacitance. In addition, equal length lines that go through different metallization layers or through polysilicon links will have different delays due to different levels of capacitive coupling to V_{ss} and different series resistances, especially in the case of polysilicon links. Accordingly, an important principal to simplify clock net design is to aim for buffering levels and fanouts that yield isochronic conditions for the passive wiring nets between buffered points on the clock net. This simplifies skew control in clock net design because attention then only need be paid to balancing loads on each buffer and to matching the number of buffers in each clock path. The alternative, in which passive wiring nets are not isochronic, requires detailed delay modeling of each wire path, taking into account the actual routing, the R_0C_0 of the wire type, the temperature, and the exact position of each lumped load on the wiring path. The important concept, however, is that by the choice of metal layers, line widths, and/or loadings, one can establish formally defined isochronic conditions on some or all portions of a complete clock net, which, in its entirety, is far too large to be isochronic. When fully isochronic subregions (such as a wide clock trunk) can be established, or even when a defined region is not isochronic but has delay that is simply and reliably predicted from position (such as on a clock ring), the remaining clock net layout and skew control problem is simplified, design risk is lowered, and pre-and postlayout simulations are more consistent because final routing of clock paths from these reference regions is shortened and overall uncertainty reduced. We shall see and use this principle in analyzing the popular clock distribution schemes that follow.

The skew that intrinsically arises from differences in RC time constants of either lines or gate loads is aggravated by threshold variations in buffers and clocked loads due to minute differences in electronic parameters and lithographic variation in line widths and lengths at different devices. Time-constant and threshold effects interact to give a worst-case skew, which is the difference between the time at which the voltage response of line with the slowest time constant, τ_{max}, crosses the threshold of the logic element with the *highest* threshold, V_{Tmax}, until switching of the device with the lowest threshold driven by the line with fastest RC time constant. Taking the difference of the earliest and latest switching times we have [32]:

$$\delta = \tau_{\min} \ln\left(1 - \frac{V_{T\,\min}}{V_{DD}}\right) - \tau_{\max} \ln\left(1 - \frac{V_{T\,\min}}{V_{DD}}\right) \tag{61.4}$$

Equation (61.4) implies that a clock system design in which buffered electrical segments of the clock net have 10% variation in τ about τ_{nom}, and 10% variation of V_T about $V_{DD}/2$, will have an estimated skew of at least 17% of τ_{nom}.

Single-Phase Clocking

Clocks ultimately always drive a storage register or latch of some type. The form of clock signal(s) required in a system therefore depends on the type of latch or flip flop element used and on properties of the combinational logic circuits used. True single-phase clocking is the most complex clocking principles with which to design systems, and has traditionally not been used, although recent work has assessed some truly single phase logic families [2]. The reason for caution with single-phase clocking is that invalid states may be passed to the output in two ways, as shown in Fig. 61.34(a) if the combinational logic (CL) delay is *less than* T_h (i.e., too fast) or (b) the CL delay is *greater than* $T_C - t_{charge}$ (i.e., too slow). In other words, a two-sided (min and max) constraint on logic path delay exists for single phase clocking [27]. This means that although attractive to minimize total interconnect, buffer counts, and interphase skew

© 2003 by CRC Press LLC

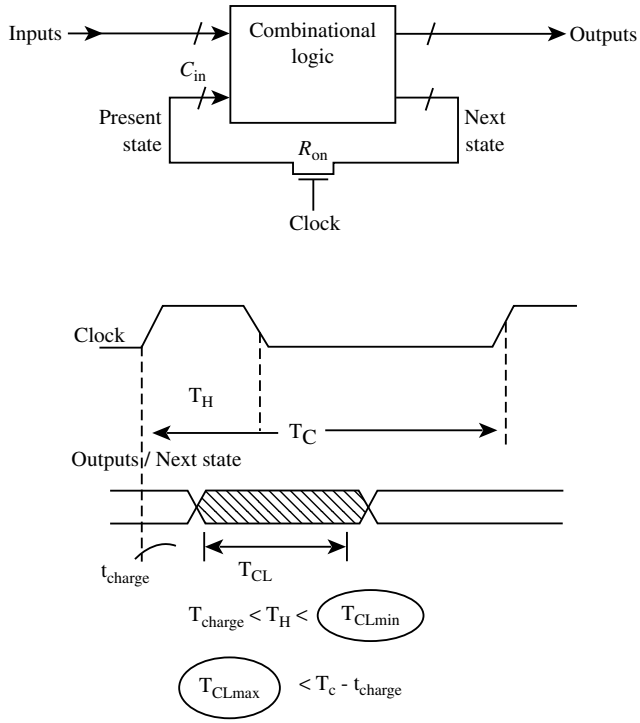

FIGURE 61.34 In single-phase clocking the combinational logic, path must be neither too slow nor too fast.

is avoided, truly single-phase clocking involves a greater design risk and timing analysis complexity. Because of this, the most common overall clocking scheme is single-phase clock *distribution* with local *generation* of a two-phase clock.

Two-Phase Clocking

With two nonoverlapping clock phases, we can eliminate one of the risks of single-phase clocking, that of a logic path being *too fast.* On the first phase the input is made transparent and allowed to affect the CL, charging the inputs through R_{on} C_{in} in time t_{charge}. During this time, the CL outputs are isolated from the input latch. On the second phase, the new CL output values are stored by the second phase latch while the input latch is opaque, isolating inputs from the new values until the next phase one clock time. A nonoverlapping period between phases ensures that at no time does direct transparency occur from input to output. With two-phase nonoverlapping clocks, as shown in Fig. 61.35(a), we need to ensure only that the maximum delay in the CL is less than $T_C - t_{charge} - T_3 - t_{preset}$. It is essential that the nonoverlapping interval, T_2, be greater than zero, but T_3 can be arbitrarily short. When present, however, T_3 acts as an extra timing margin against skew.

It is obviously desirable to make T_2 as small as possible, but we can do so only when distributing two-phase clock directly if the interphase skew is less than T_2. In the worst case, the interphase skew may be twice the skew of each of the two clock phase nets individually. Skew, therefore, necessitates at least a 1:1 derating in speed for two-phase clocking in addition to the basic loss of clock cycle time for logic settling, to ensure correct operation of storage devices. If skews in the two clock phase nets are uncorrelated, however, the extra penalty could be as high as 2: 1. Every nanosecond of skew in the clock net for each phase then not only reduces the basic critical path logic timing margin by 1 ns, but also adds 2 ns to the T_2 requirement.

Therefore, in high-performance systems we have quite an incentive to distribute a single clock phase throughout the design and accept the extra logic required to generate two-phase clocks locally at each device (or small group of similar devices) that requires them.

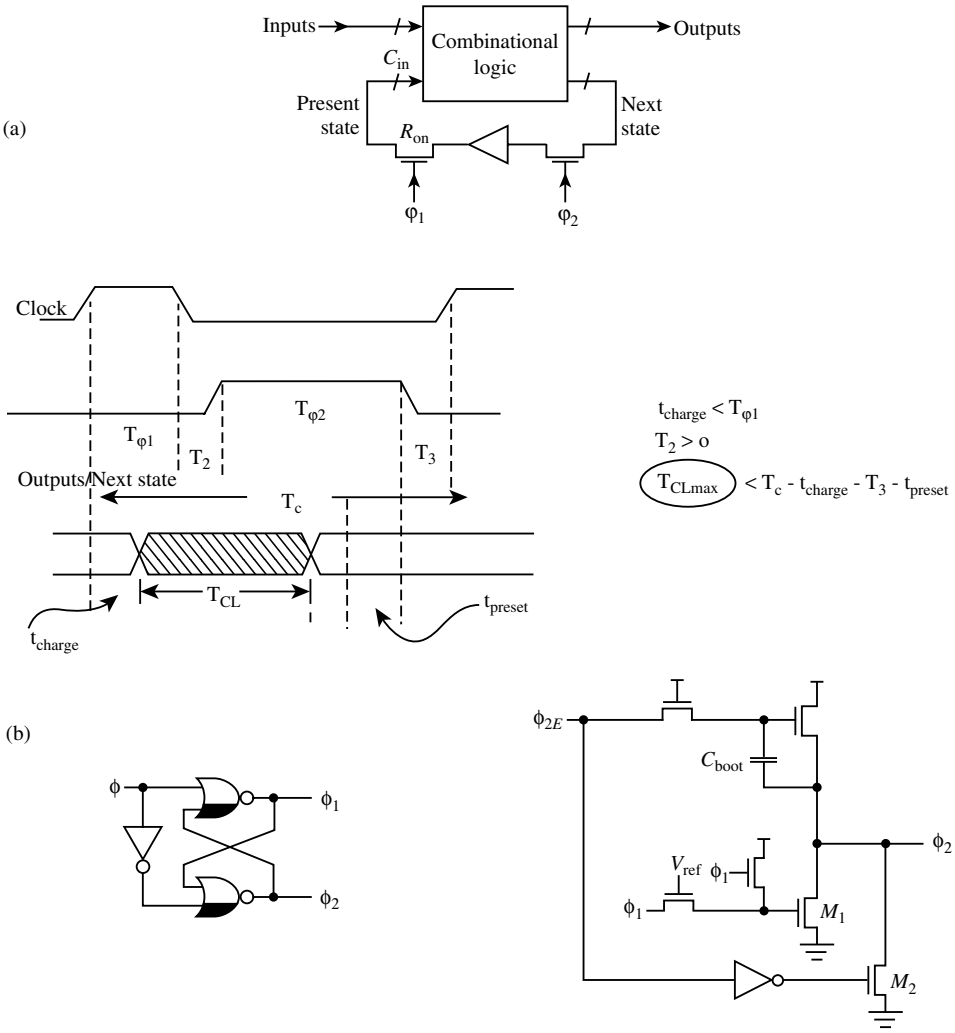

FIGURE 61.35 (a) With nonoverlapping two-phase clocks, no lower limit exists on the combinational logic delay. (b) Generator for two-phase nonoverlapping clock and buffer circuit to ensure nonoverlap period. *Source:* (b) [Glasser and Dobberpuhl, 1985], p. 349.

Two-Phase Clock Generator Circuit

The canonical form of circuit to generate the local two-phase nonoverlapping clocks from a single phase clock is shown in Fig. 61.35(b). The feedback of φ2 into NOR 1 ensures that φ2 must be low before φ1 can go high after the single-phase φ_{in} input has gone low, and vice versa. A special clock buffer circuit is shown in Fig. 61.35(b), which helps ensure that a period of nonoverlap exists in the presence of the threshold variations in the driven loads [12]. It does this by using transistor M1 to clamp the φ2 output low until far into the fall of φ1. φ2 is held low until φ1 has fallen below $(V_{ref} - V_{thresh})$ to finally cut off M1. V_{ref} might be set at 2 V in a 5-V process, thereby ensuring that φ1 is well below the logic threshold of all clocked loads before φ2 begins to rise, while at the same time minimizing but guaranteeing the existence of a nonoverlap period, which is lost processing time.

Multiple-Phase Overlapping Clocks

Generating and/or distributing nonoverlapping clocks with a minimal T_2 can be quite difficult in large systems. An alternative is to define three or more primary functional logic steps and use a similar number

© 2003 by CRC Press LLC

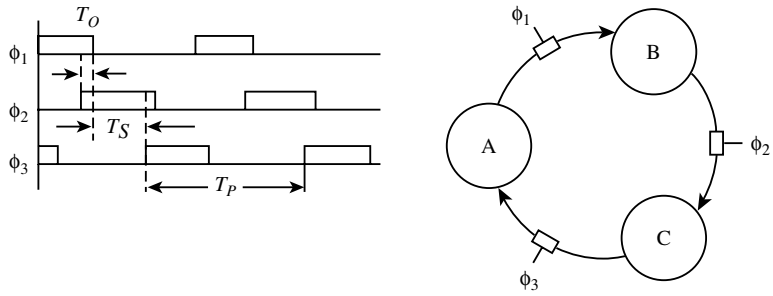

FIGURE 61.36 Principle of multiphase clocking. Outputs are isolated from inputs by other stages of nonactive logic even though any two active clock waveforms may overlap. *Source:* [Glasser and Dobberpuhl], 1985, p. 352.

of overlapping clock phases. In this case, the multiple stages of clocking removes the need for the guaranteed nonoverlap period in two-phase clocking. Let us consider three-phase overlapping clocking. The principles generalize to any higher number of phases.

In three-phase clocking, the middle phase can be thought of as providing the nonoverlap time, which ensures time isolation between input and output activation for the module enabled on each clock phase. In fact, each phase plays a similar isolating role with respect to operations performed on its adjacent phases. Figure 61.36 illustrates the concept. The number of phases and the role for each phase typically reflects some natural cycle or step sequence of the basic system being designed; for example: bus input, add to accumulator, bus output.

In WSI systems, in which uncertainty in clock delays, circuit speeds, and interconnect impedances may be high [10], overlapping clock logic can give high tolerance to clock skew, and is compatible with self-timing in selected subcircuits. Three-phase overlapping clocking has a distinct advantage: no hazard exists unless all three clock phases overlap in time. In the presence of severe clock skew, this can be a major advantage. Although called overlapping clocks, the circuits still function if successive phases do not actually overlap, although speed is sacrificed if overlap is lost.

Overlapping Clock Phase Generator

Figure 61.37 illustrates a circuit for generating three-phase overlapping clocks. Phase overlap is ensured because it is the onset of each phase that kills its predecessor. A Johnston counter comprised of three static *D*-flip flops generates the phase-enabling signals which sequence the actual generator stage, which is comprised of the three cross-coupled NOR gates. A deliberately limited positive-going drive ability of the enable input ensures that the Johnston counter exercises underlying rate and sequence control, while the output waveforms are determined by the interactions between the actual clock phase signals. While the enable inputs to each NOR are logically sufficient to drive the output high when the other input is low, they are arranged not to be able to drive the NOR output low on their own when the enable signal returns high. The output of phase i therefore stays high after its own enable signal has disappeared (gone high) until the phase $i + 1$ output is also high in response to the low-going phase $i + 1$ enable. Figure 61.37 shows this logic and a NORing clock buffer circuit in which the phase $i + 1$ signal is necessary to assist in returning the phase i output to zero.

Clocking Latches

A latch is a storage element which is *level* sensitive to the clock waveform. The latch output conforms to the input that is present while the clock waveform is at its active level for that latch, and then continues to hold that value when the clock level falls below the active level. Latches have setup and hold time requirements analogous to those in the flip flops that follow. Circuit designs for high and low active latches are given in [31]. By combining latches of opposite active polarity, with logic between the stages, there can be two logic operations per clock period. In this type of operation, however, skew adds to the needed clock period as usual, but in addition any imbalance in the clock *duty cycle* requires a further

© 2003 by CRC Press LLC

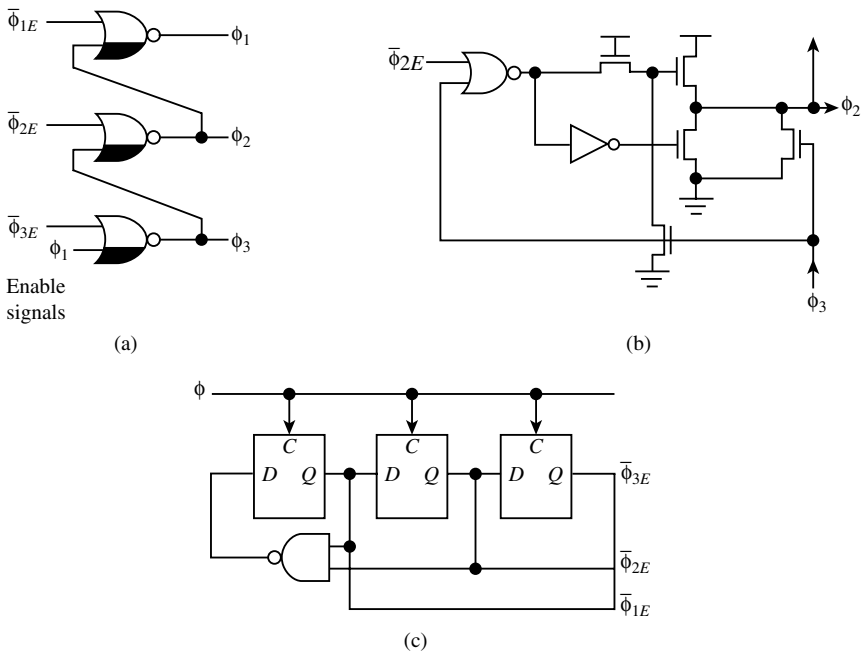

FIGURE 61.37 Three-phase clock generator logic and buffer design to ensure overlap. *Source:* [Glasser and Dobberpuhl], 1985, (a) p. 348, (b), (c) p. 354.

margin because the minimum duty cycle half-width must remain greater than the worst-case logic delay. The clock edges also must be kept sharp enough that transparency never occurs between two successive latches working on opposite clock phases simultaneously, or that some minimum logic delay always exists between latches that exceeds the possible overlap time. The DEC ALPHA microprocessor was an example of a two-phase latch machine in which both phases drive latches that are active in the respective phases permitting logic evaluation twice per cycle. This is one case in which to control the very high transistor count, two-phase clock is distributed globally rather than generated at each module. The entire clock net on each phase is driven from a single large buffer placed at the center of the die where a PLL is also fabricated to advance the on-chip clocking phase relative to external bus timing, thereby compensating for buffer delay.

Two principles for maintaining 50 % clock duty cycle in a latch machine are (1) whenever generating or phase-locking to a system clock, do so at twice the rate needed, then (frequency) divide by two. This results in 50/50 clock waveform, regardless of the original clock source waveform. (2) When repeatedly buffering clock in a chain, or when distributing clock through a hierarchy of clock buffers, use inverting clock buffers at each stage. Inverting the clock at every buffering stage inherently counteracts the effects of different rise and fall times in buffers. Otherwise, these can accumulate to extend or shorten the ON period of the clock waveform. For example, if a noninverting buffer has greater fall time than rise time, a clock path transiting several of these buffers will develop a broadened ON period. This effect is self-compensating in a chain of inverting buffers.

Clocking Flip Flops

Flip flops are more complex storage circuits than latches, but have no dependency on clock duty cycle because they are sensitive only during an active edge of the clock waveform. A rising edge *D*-flip flop (for instance) updates its output to match its *D* input on the rising edge of the clock waveform. The *Q* output retains the updated value thereafter, regardless of further changes in the input or clock waveform (with the exception of another rising clock transition). A latch is a more fundamental circuit element than the *D*-flip flop in that edge-triggered behavior is attained only by implementing two latches and

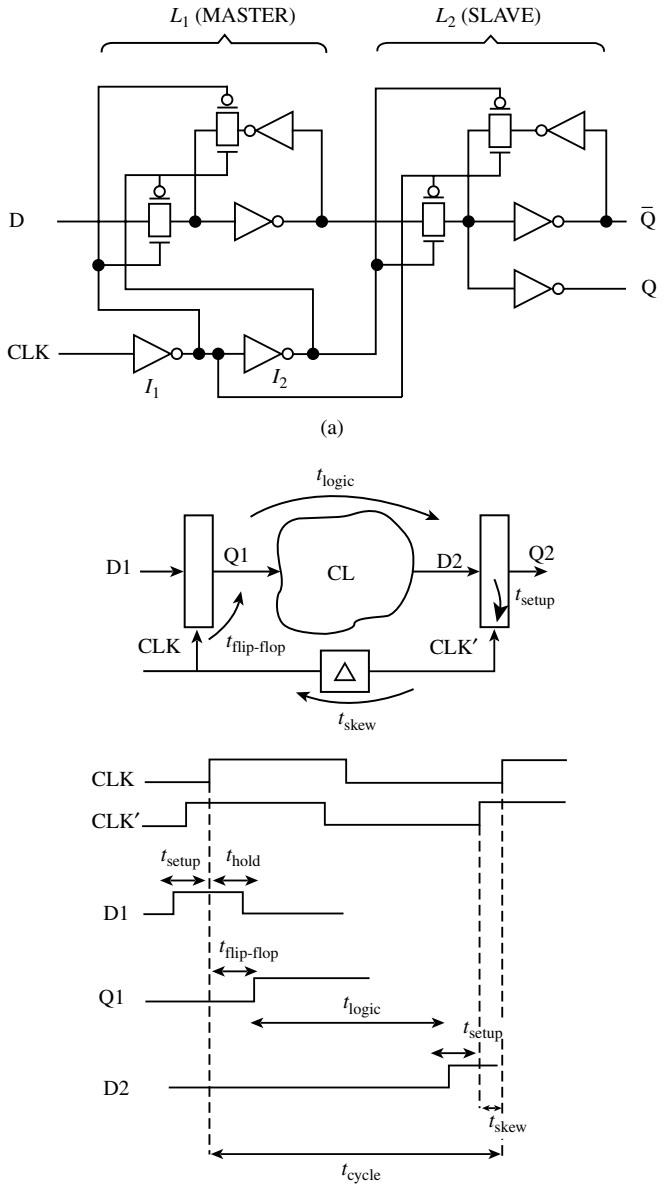

FIGURE 61.38 (a) Two-phase latch structure of a typical CMOS positive edge-triggered *D* flip flop. (b) Setup, hold, and delay times for a *D*-flip showing how skew is equivalent to a shorter clock period and threatens setup time margin. *Source*: [Bakoglu 1990], p. 345.

generating a pair of two-phase nonoverlapping clock pulses internally, in response to the active clock transition at the edge-triggered input.

For instance, Fig. 61.38 shows a typical *D*-flip flop in which inverters *I*1 and *I*2 generate the internal two-phase clock signals for level-sensitive latches *L*1 and *L*2. In specialized applications, it may be advantageous to design a custom module within which multiphase clocks are distributed directly, without incurring greatly increased skew problems. For example, an error-correcting codec ASIC prototype for 45 Mb/s digital communications includes a 2613 stage tapped delay line comprised of seven-gate single-phase

© 2003 by CRC Press LLC

D-flip flop modules. The use of single-phase clock flip flops in this context is relatively expensive, but appropriate for fast validation of the system design. For cost- and power-reduced production in volume, a more detailed latch-based design using directly distributed two-phase nonoverlapping clocks may be worthwhile. In general, while it is most common to conduct system design based on the single-phase clocking model, two-phase or multiphase clocking may be advantageous within specialized substructures.

Although edge triggered, a minimum clock pulse width is still typically required to deliver enough switching energy on the clock line. For correct operation (specifically, to avoid uncertain outputs due to metastability) of an edge-triggered flip flop, data must be stable at the input(s) for a minimum setup time before the clock edge, and the data must remain stable at the input for the hold time, after the clock edge. The time until the *D*-flip flop output is valid after the clock edge occurs is the clock-to-*Q* delay. For hazard-free transfer of data from one stage to another with D-flip flops, without assuming a minimum logic delay constraint between stages, the clock-to-*Q* delay must exceed the hold time. Typical values for a range of D-flip flop types in a 1.5-μm CMOS process are t_{setup} = 0.8 to 1.5 ns, t_{hold} = 0.2 to 0.4 ns, and $t_{clk\text{-}Q}$ = 1.3 to 3.5 ns for *Q* output fanouts of 1 to 16, respectively. With the extra input logic delays in a JK flip flop, many JK flip flop cell implementations exhibit t_{hold} = 0.0 ns. By comparing magnitudes of typical setup and hold time requirements, it is apparent that skew is more likely to cause a setup time violation on critical delay logic paths than it is to result in a hold time violation.

Role of Clocks in Dynamic Logic

Clock signals are also used to implement a variety of logic gate functions in a dynamic circuit style, i.e., based on short-term charge storage, not static logic. This typically involves precharging on one phase and logic evaluation steered by the inputs on the second phase. The "Domino" logic approach combines a dynamic NMOS gate with a static CMOS buffer [8]. In "NORA" (no-race), logic dynamic logic blocks are combined with clocked CMOS latch stages. A variety of other dynamic logic circuits, using up to four clock signals to structure the precharge and to evaluate timing, are covered by [12] and [31]. In all of these gate level circuit implementations, the clocking-related issues are ultimately manifestations of the basic principles already seen for two-phase clocking; i.e., of never simultaneously enabling a direct path from input (or precharge source) to output. These logic styles were developed to reduce transistor counts. However, modern designers will most often be faced with a greater challenge in managing system-level problems of skew in a single clock phase distributed to static register than the challenge of reducing transistor count.

Synchronizers and Metastability

Many systems need to sample external inputs which may be timed independently of the synchronous system clock, such as switch-based control inputs, keyboard states, or external process states in a real-time controller. The external state needs to be synchronized with the system time base for processing. Metastability leading to synchronizer failure is a fundamental possibility that can never be entirely eliminated.

Figure 61.39 is a basic synchronizer circuit. Our concern is that it is possible for the synchronizer output to take an arbitrarily long time to settle to one or the other valid logic states if the input signal voltage is sampled in the intermediate voltage range, i.e., $V_{iL} < V_{in}(t) < V_{iH}$. In this range, it is possible to find the input voltage at a value that leaves the cross-coupled latches internal to a flip flop in an intermediate state, with insufficient positive feedback to snap the output to either high or low valid states. System noise or quantum fluctuation will ultimately perturb such a precarious balance point and the output runs to one direction or the other, but it can take an arbitrarily long time for the synchronizer to reach a valid output state. As shown in Fig. 61.39(b), some flip flop outputs may also tend to rise at least halfway toward the positive output level before deciding the input was really a zero. This glitch may trigger edge-sensitive circuits following the synchronizer.

Fortunately, the probability of an indeterminate latch output falls exponentially with the time *T* after sampling the possibility indeterminate input:

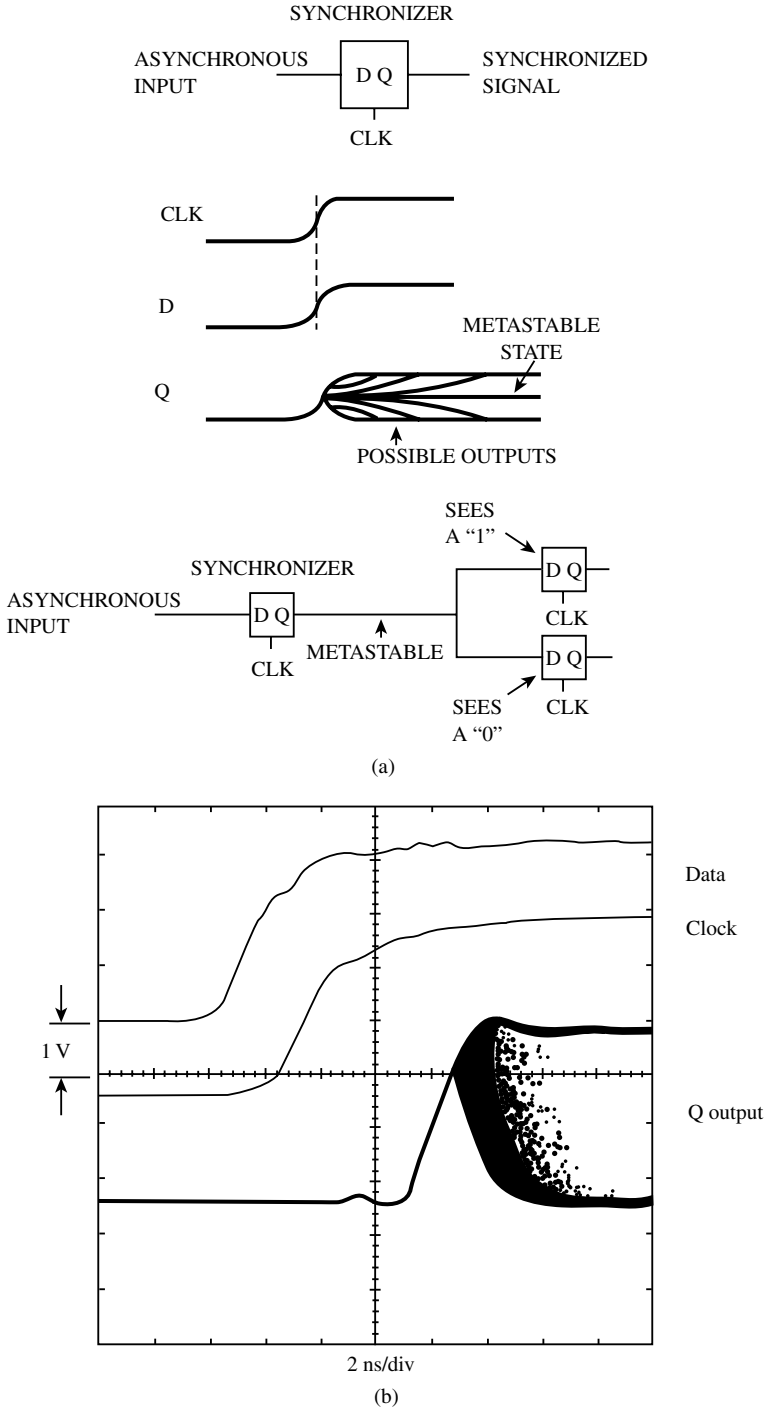

FIGURE 61.39 (a) Metastability in a synchronizer circuit. *Source:* [Bakoglu 1990], p. 357. (b) Experimental illustration of metastability in 74F/74 (TTL) *D*-flip flop showing output rise before indeterminate final response (10-s point accumulation). *Source*: [Johnson and Graham, 1993]. p. 130.

© 2003 by CRC Press LLC

$$P(t > T) = f_{clk} f_{in} \Delta e^{-T/\tau_{sw}} \tag{61.5}$$

where f_{clk} is the synchronous sampling frequency, f_{in} in the frequency of external transitions to be synchronized, Δ is the time taken for the input voltage in transition to cross from V_{iL} to V_{iH} (or vice versa), and τ_{sw} is the time constant characterizing the bandwidth of the latch device.

Having recognized the strict possibility of a metastable logic state resulting from synchronizer input, the designer can address the issue in several practical ways:

1. Use a high gain fast comparator to minimize Δ by minimizing the voltage range V_{iL} to V_{iH}.
2. Ensure or specify fast transition in external sensors or other devices to be sampled, if design control extends to them.
3. If there is no real-time penalty from an additional clock period of input response delay, the synchronizing latch should be followed by one or two more identical synchronizer latch stages, thereby increasing T in (61.5) to reduce the chance of a metastable state being presented to internal circuitry to an acceptably low probability.

The effect of input metastability on the system also should be analyzed for its impact. If it is extremely crucial to avoid a metastability hazard, then phase-locking the external system to the system clock may be considered, or if the system and external timebases are free running but well characterized (for example, in terms of a static frequency offset or known phase modulation), then the anticipated times of synchronization hazard may be calculated and avoided or otherwise resolved.

As a practical matter, the way in which design software handles metastability should be considered. Potentially metastable conditions should be flagged as a warning to the user, but not necessarily treated as a violation prohibited by the design environment. Some applications, particularly in VLSI for telecommunications, need design support for plesiochronous (near-synchronous), phase-modulated, or jittered signal environments. This implies test vector support to represent clocks interacting through logic at slightly different long-term or instantaneous free-running frequencies with design and simulation rules that permit the metastable conditions inherent as such clocks walk relative to one another. Circuit simulations must be allowed to continue with a random value resulting from the simulated "synchronizer failure" to be useful in such applications.

Controlled Introduction of Skew

Skew is not necessarily all bad. In fact, from the viewpoint of the system power supply, and power- and grounded-related noise current surges, it is undesirable to have all logic transitions occurring exactly simultaneously. In a CMOS IC with 20 K register stages at 0.1 pF load each and a 1-ns clock rise time, 10 A of peak current can be drawn by the clock net. This can present a serious $L\,dI/dt$ problem through power and ground pins and can even lead to electromigration problems for the metallic clock lines. Chip clocking strategies should take this into account early in the design by seeking ways to deliberately stagger or slightly disperse the timing of some modules with respect to others. Also, the system clock waveform may not necessarily need the fastest possible rise time. Consistent with avoiding slow-clock problems, and controlling threshold-related skew in buffers, the clock edge should not be made faster than this as an end in itself. Excessively fast clock edges clock edges only aggravate power and ground noise problems as well as ringing and potentially causing electromagnetic radiation problems in the chip-to-chip interconnect. These principles motivate the widely used 10 K ECL logic family, which is based on the much-faster 100 K series with explicit measures to *slow down* the rise and fall times of the basic 100 K logic gates.

When considering random skew, it may or may not be beneficial to pursue skew reduction below a certain level in the design. In the case of a microprocessor or a design in which the fastest possible IC speed is always useful skew reduction does mean a performance improvement. In some other applications, however, the clock speed is set by the application. For instance, a VLSI circuit for a telecommunications multiplexer may be required to operate at a standard line rate of 45 MHz. In this case there may be no

© 2003 by CRC Press LLC

premium for a design that can perform the same functions at a higher speed. A working design with skew of 5 to 7 ns (out of a 22-ns clock period) may then be *more* desirable than a functionally equivalent design with 0.5 ns skew because dI/dT effects are eased by distributing the total switching current over time in the former. This principle may be important in practice as automated clock synthesis tools become more widely used and effective at achieving low skew, possibly creating unnecessary system level noise and EMI emission problems. Future clock-related CAD tools should possibly aim to disperse clock timing at various loads while satisfying a target worst-case skew, rather than absolutely minimizing skew.

Strictly speaking, skew can also be beneficial when allowed to build up in a controlled way in certain regular logic structures. For instance, by propagating clock in the opposite direction to data in a shift register, one enhances the effective setup time of the data transfer from register to register. In general, however, it is not feasible or advisable to try to design every clock path with a desired (non-simultaneous) clocking time at each register, taking into account the individual logic paths of signals leading each clocked latch input. Especially when designing larger systems mediated by CAD tools for placement, routing, and delay estimation, the most practical and low-risk approach is to consider any deviations from a common nominal clock time as undesired skew. Indeed, for any one latch, timing margin may be enhanced by the actual skew that arises, but with thousands of logic paths, it is impossible to analyze the relative data and clock timing for each latch. Only one instance in which the skew works against the assumed timing margin is enough to fail a design. Therefore, the "customized skew" approach is recommended only for small and very high speed specialized circuit design.

Clock Signal Manipulation

As a matter of design discipline, some commercial ASIC and cell-based layout systems may prohibit a designer from directly gating or manipulating a clock signal. Any needed clock qualification is done through defined enable or reset inputs on register structures. As in software development, in which structured design disciplines have been developed, gating the clock may be riskier than its apparent efficiency warrants. In addition, clock gating within random logic designs can interfere with test pattern generation. The risk also exists of creating clock glitches or even logical lockups when clocked logic functions decode conditions that gap its own clock. On the other hand, in high performance and in large system-level designs, clock gating for power down and *clock tuning* may be unavoidable.

Wagner [30] discusses clock pulse-width manipulation, defining four canonical subcircuits that can be used to "chop", "shrink", or "stretch" the clock waveform for either delay tuning or duty cycle maintenance. The effect of these circuits on the positive pulse portion of a clock waveform is shown in Fig. 61.40, where AND gates have delay d_a, OR gates have delay d_0, inverters have delay d_i and the delay elements have delay D. Aside from a single gate delay, the chopper and stretchers leave the rising edge unaltered and tune the trailing edge. These can be used to maintain a balanced clock duty cycle or to tune the nonoverlap period in two-phase clocking. The shrinker delays the rising edge of the clock as might be helpful to specifically delay clocking a latch or a flip flop that is known to follow a particularly long logic path delay. This is not generally a preferred design approach, especially when manufacturing repeatability and temperature dependence of delay elements are considered.

By *clock gating*, we mean selectively removing or masking active phases or edges from the clock signal at one or more latches. One valid reason to gate the clock in CMOS is to reduce power consumption. Many circuit designs possess large modules or subsystems which it makes sense to stop cycling in certain application states. Gating the clock off is therefore the simplest form of power management, because CMOS has negligible power dissipation in a static state. However, even for this simple use of clock gating, the main issue is avoiding glitches when gating the clock.

Before gating any clock, the designer should see if gating can be avoided with an alternate design style. For example, if it is desired to hold the data on one register for a number of cycles while other registers on the same clock proceed, a preferred approach is to use a 2:1 mux at the register input. Rather than gate the clock, the mux is steered to select the register's own output for those cycles in which gating would have occurred. Ultimately, if it is appropriate to gate out one or more clock pulses, a recommended way of doing so in rising edge active logic is to OR out the undesired clock edges, decoding the clock

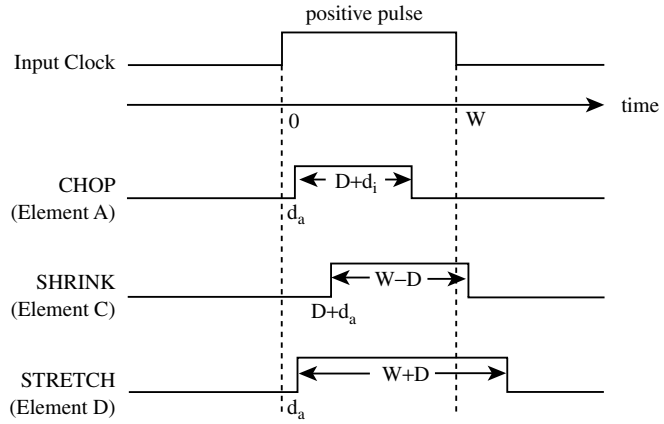
(a) elements



(b) effect on a positive pulse

FIGURE 61.40 Standard circuits for chopping, stretching, and shrinking a clock waveform to adjust duty cycle or timing margins. (*Source*: Adapted from [30], p. 15.)

gapping conditions on the same clock polarity as the one being qualified (see Fig. 61.41). A natural tendency seems to be to AND out the gapped clock edge and/or to decode the gapping condition on $\overline{CLK}$, but these approaches are more apt to generate clock line glitch than the OR-based approach. In the AND approach the gating line returns high at the same time as the falling edge after the last-gapped active edge. In the case of minimum delay through the gapping logic the risk is that both AND inputs are momentarily above threshold.

Minimizing Delay Relative to an External Clock

In a large system skew can build up between clock and data at the system level, even if the clock is skew-free everywhere within the ICs because data paths through ICs can build up delay relative to the system clock. For instance, if an ECL or TTL system clock line is distributed to a large CMOS IC, then the system clock must be level shifted and a large clock buffer may be required in each IC to drive its internal clock net. The delay through the on-chip clock interface and buffer can mean that even if the chip timing is internally skew-free, the on-chip clock is significantly delayed relative to the external system timing. Short of using the phase-lock methods described later, a simple technique to minimize this form of system-level skew is either to retime chip outputs with a separate copy of the system clock that has not gone

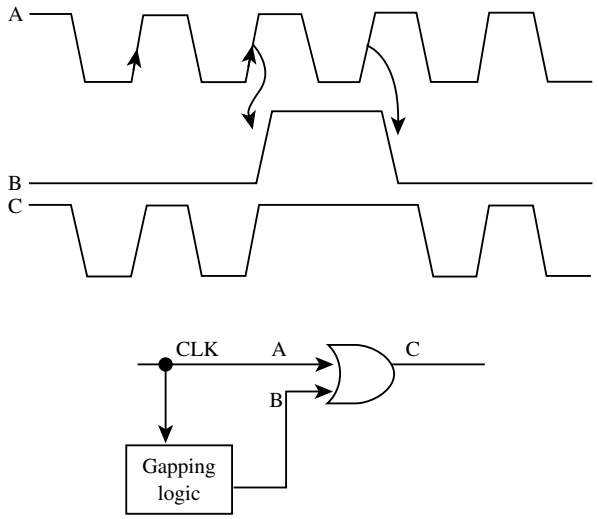

FIGURE 61.41 OR-ing out a clock edge when clock gating is essential.

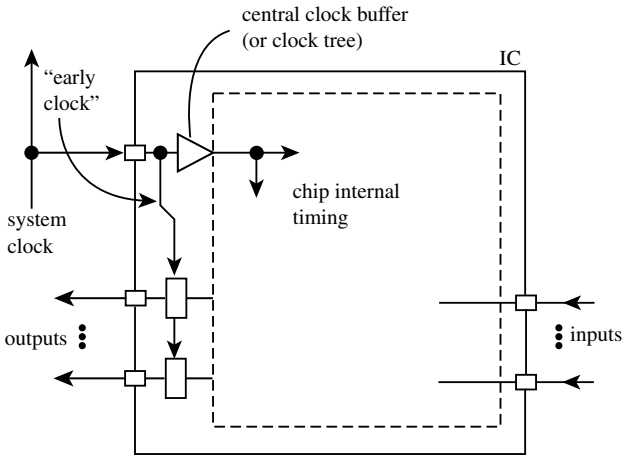

FIGURE 61.42 The "early clock" technique for reducing chip delay relative to external system timing.

through the internal clock buffer, or, if electrically compatible, to use the external system clock to directly retime the output signals from each IC (Fig. 61.42). This is called the *early clock* concept. Note that this assumes an adequate timing margin exists in the final stage of internal logic to permit the relatively early sampling of logic states.

Clock Distribution Schemes

Single-Driver Configurations

Often a single on-chip clock buffer is the simplest and best approach to clock distribution. A single adequately sized clock buffer is typically located at the perimeter to drive the entire clock net of the chip, as shown in Fig. 61.43. This approach can also perform well in large systems if the clock is distributed in a low R_0C_0 routing layer, such as third-layer metal. The main advantage regarding skew is that no matter how the single-clock driver delays or otherwise responds to the external clock input, the output waveform is electrically common to all loads. No intervening buffers and no separate passive net segments

© 2003 by CRC Press LLC

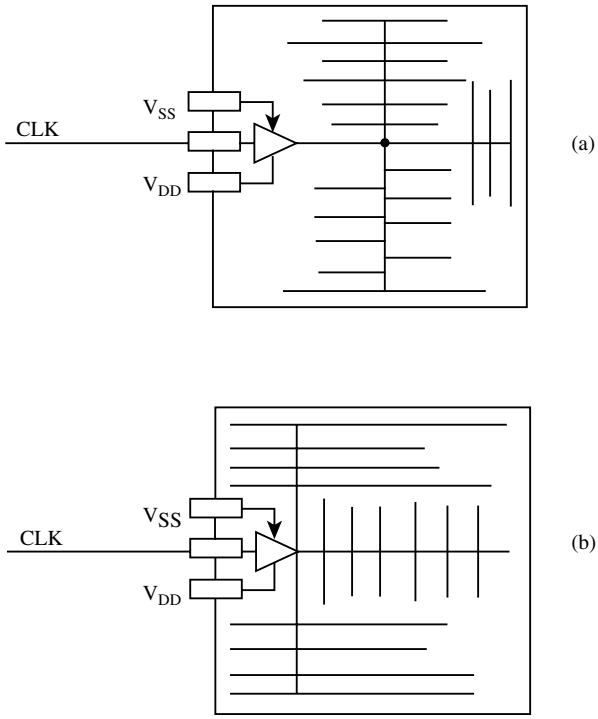

FIGURE 61.43 Single clock buffer placed in the I–O perimeter with dedicated power, ground pins (a) branching from a medial point on die (current density on line to medial point may be high), (b) branching immediately (skew may be high).

develop skew. Moreover, if the global clock net comprises an electrically isochronic region ($NC_{gate} \gg l^2 RC_{wire}$) in which clock loads are reasonably uniformly distributed, the clock net voltage rises virtually simultaneously at all points on the charging clock net, resulting in extremely low skew. Often this leads to lower skew than in a buffered clock fanout tree. There is also only one global clock wiring net, simplifying documentation.

On the other hand, skew can be larger and more routing dependent with a single buffer (than with some following schemes) when clock routing lengths vary significantly and wiring capacitance and resistance are significant. In such cases an isochronic net is not an accurate model, and performance depends on the way clocked loads are distributed on arms branching from the medial clock node. It is possible for neighboring flip flops to be connected to the central driver via quite different path lengths, making prelayout simulation relatively uncertain and requiring considerable postlayout tuning. Another caution is that even if no actual skew is present because a single waveform is common to all loads, the rise time of the clock waveform may show considerable loading effects, so that threshold-dependent skew arises in the clocked loads. Finally, the potential for conducted switching noise problems is high with the single-buffer configuration because the entire clock net capacitance is charged in typically under 1 ns. Power supply decoupling and ground bound problems and even current density (electromigration limits) considerations may need to be given special attention if using this configuration. It is usually recommended that the single clock buffer be physically adjacent to the clock input pin, and the clock pin should be flanked by dedicated power and ground pins that feed only the clock driver. This principle, which applies in general to clock input buffers in all clocking schemes, keeps the clock switching noise out of the core power and ground bus lines. Also, the delay through a large clock buffer may be considerable, so a lightly loaded "early clock" can be picked off from the buffer input and used to retime chip output registers, or a PLL may advance the phase to the internal clock buffer so as to align internal and external timing regardless of the buffer delay.

© 2003 by CRC Press LLC

An interesting central clock buffer design, which also has attributes of the clock trunk scheme which follows is reported in [9]. Here, the area for central clock driver fabrication is a strip across the center along one axis of the die. External clock is fed from one pin on the same axis as the buffer, and internal clock lines radiate systematically away from the central linear distributed buffer. Data flow is also highly structured and arranged to progress away from the central driver strip, further minimizing clock-to-data skew.

Four-Quadrant Clocking Approaches

In the quadrant-oriented approach, we may use up to four clock pads and four smaller clock drivers placed at the centers of the die edge, preferably also with dedicated power and ground from flanking pins. There may be one, two, or four external clock pins. Figure 61.44(a) shows a quadrant scheme tested in [24]. In Fig. 61.44(b), a single-pin quadrant-oriented scheme in 1-μm, two-layer metal CMOS achieved 0.6 ns skew among 400 registers. A four-pin quadrant approach was successfully used in [29] to develop a 90-MHz CMOS CPU. If more than one pin is used for clocking, pin count goes up but absolute delay through the clock buffers can be reduced. The maximum wiring RC delay on the internal clock net and the peak current and $L\ dI/dt$ effects through any one pin and bonding wire inductance may all be reduced in this case. Total loads on each of the four internal clock nets should be well balanced and/or the drivers sized for the actual number of loads in each quadrant. In many cases, reduction of each clocked area to one fourth of the die area can result in isochronic regions for which no further design attention other than total load balancing is required for clock routing within each region. The quadrant approach can also reduce the clock routing problem when the clock shares only two metallization layers available for all signal routing. Two other considerations apply to the quadrant schemes: (1) external tracking to multiple clock pins should be laid out with delay balancing in mind; (2) skew should be particularly considered on data paths which must cross from quadrant to quadrant, bridging timing across clock subnetworks.

Symmetric and Generalized Clock Buffer Trees

A symmetric or regular clock buffer tree [Fig. 61.45(a)] has equal fanouts from buffers at the same level, equivalent (or isochronic) passive interconnect paths at each stage, identical buffer types at each level, and equal groups of loads at each leaf of the tree. This ideal can be approximated if loads are regularly distributed and layout and routing can be controlled to ensure equal interconnect delays from each buffer to its subtending buffers. The remaining skew will primarily be due to threshold variation in buffers and terminal loads.

A more general view of the clock buffer tree that arises with irregular layouts and routing is that the buffer tree has unequal interconnect delays and differing numbers of loads at each buffer. Figure 61.45 (b) illustrates the electrical model of such a clock tree. (R and C values are all different.) The basic approach to skew control in such a generalized buffer tree is to size each buffer specifically for the individual loads it drives and the delay of the interconnect path to its input from the preceding level buffer. In practice, this means that generalized clock buffer trees may be the most handcrafted (and/or custom-tuned) of all designs, especially in a large system-level clock tree that extends down from a master clock source through multiple shelves, backplanes, connectors, circuit packs, and individual ICs. The system-level hierarchical clock tree design for the VAX 8800 is a good example described by Samaras [25]. Here, a two-phase clock was distributed to 20 large circuit packs over a 21-in. backplane with a global skew of 7.5 ns, for operation at about 50 MHz (37 % skew).

Some basic methods and principles are, however, identifiable for designing generalized buffer trees so that it is not all just careful tuning and handcrafting:

1. Inverting buffers at each level will preserve clock duty cycle better than a tree of noninverting buffers.
2. Total *delay* (root to leaves) of the clock net is theoretically minimized when driving primarily capacitive loads, by a fanout ratio $e = 2.718\ \ldots$ at each level of the tree [23]. In practice, this implies a fanout ratio of about $n = 3$, with appropriately sized buffers, if delay is to be minimized. However, $n = 3$ can lead to relatively deep trees of many buffers in which skew can build-up from threshold and time-constant variations as in (61.4).

3. If identical buffers are used within each level, then the design aim is to make sure that the load of further buffers and/or interconnect RC load is delay-equivalent for each buffer. Dummy loads may be required to balance out portions of the clock tree whose total fanout is not needed. At the end-nodes of the tree equal numbers of standard loads should be grouped together on each leaf node, within a locally isochronic region.

© 2003 by CRC Press LLC

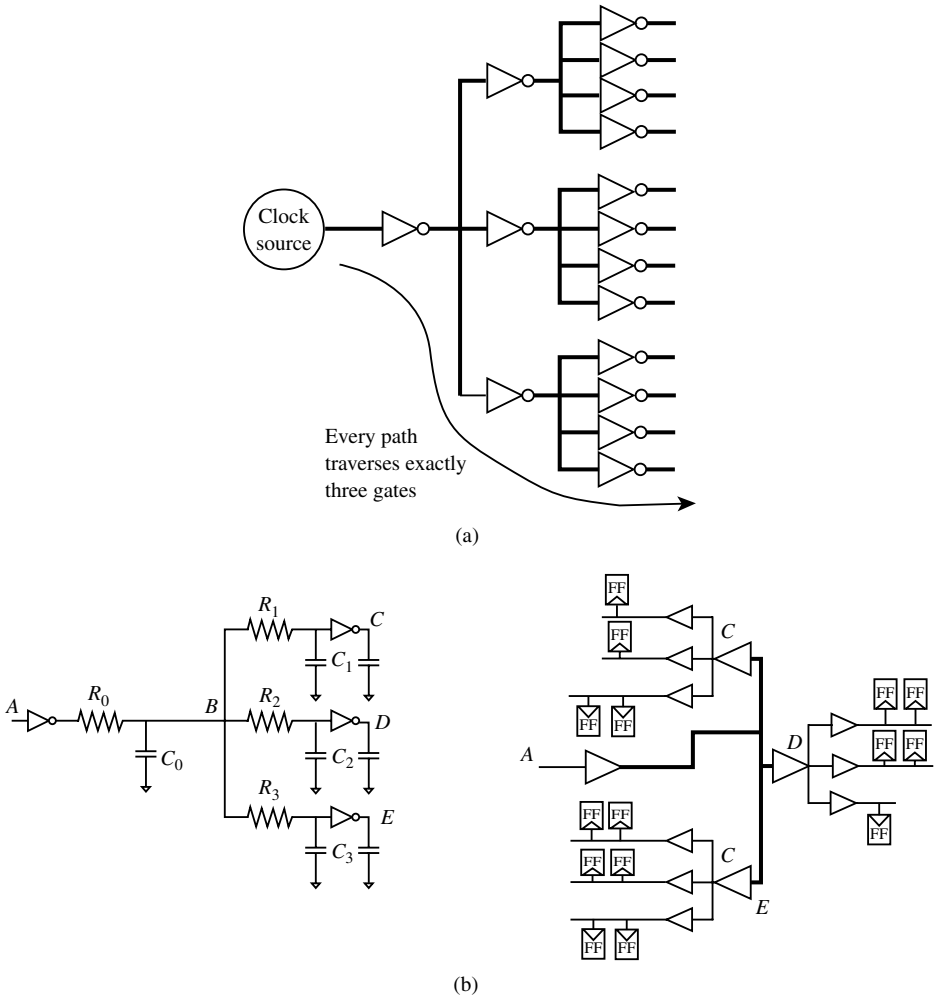

FIGURE 61.45 (a) Idealized symmetric buffer clock tree. *Source:* [Johnson and Graham, 1993], p. 348. (b) Generalized clock buffer tree where interconnects and loads are not identical.

4. If the tree is deep, the skew among members of one local clock group at the bottom of the tree may be considerably smaller than the skew than the skew between groups of clocked loads at different end-nodes of the tree. If the inter- and intragroup skews are separately characterized, however, logic path delays can be designed to take advantage of the low intragroup skew and to allow greater timing margin on intergroup paths [25].
5. The choice of clock buffer type for use in any clock tree should take into account the effects of power supply sensitivity. For example, the *bootstrapped clock buffer* of Fig. 61.46(a) can provide a very sharp rise time, although with relatively high delay through the buffer. Sharp rise times minimize skew due to switching threshold variations in the following buffers or clocked loads. The output switching time of the bootstrapped clock buffer is, however, relatively sensitive to supply voltage. On the other hand, the *phase correcting buffer* of Fig. 61.46(b) is very tolerant to supply variations, but is not as fast in its output rise time. This leads to a mixed buffer strategy in which the bootstrapped buffer is used in the relatively small population of buffers in the first few stages of a clock tree. Here, special attention can be paid to ensuring well-equalized power voltages. The phase-correcting buffer is more appropriate in later stages, nearer the more numerous individual loads, among which on-chip or wafer supply levels may exhibit more IR voltage drop variation.

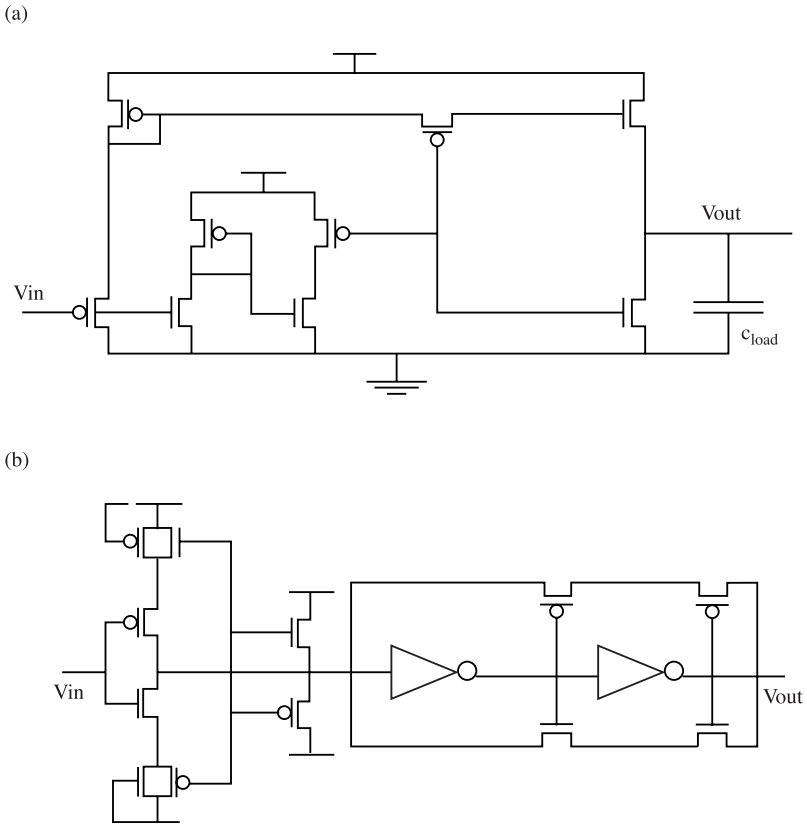

FIGURE 61.46 (a) Bootstrapped clock buffer for use in first level of a clock tree; (b) phase-correcting clock buffer for use deeper in clock tree. *Source*: [Fried 1986].

Algorithms for the generalized clock tree design problem are also emerging. The algorithm in [28] can generate a buffer design based on custom transistor sizing to drive each heterogeneous load, all with the same nominal delay. A still more general optimization approach is under development by Cirit [5]. The sizes of all buffers in the tree are jointly optimized with respect to unequal interconnect RC totals and unequal loads that each drives, as in Fig. 61.45(b). Thus, the minimum *total* tree delay is found for which all paths from root to leaf of the tree also have *equal* delay. The procedure is intended to be iterated along with placement and routing alternatives until a set of feasible buffer sizes and acceptable total delay is found.

Clock Trunk Schemes

The clock trunk concept is gaining popularity and is now supported within several CAD systems for CMOS processes with two or more metallization layers. Three variants of clock trunk structures are shown in Fig. 61.47. An input clock signal is buffered (its input pad is at the center of one side of the chip edge) and is routed either to the midpoint, or one or both ends of the internal clock "trunk". The trunk itself is a metal line specially widened for low resistance, thereby making delay and the $R_0[C_{load} + C_0]$ rise time particularly small on the trunk portion of the overall clock net. As long as the lumped capacitive loads (C_{load}) dominate the trunk's C_0, the time constant of the trunk drops as it is widened. C_0 can be kept particularly low by forming the trunk in third-layer metal. The idea is to size and drive the clock trunk so that an isochronic region is created down the middle of the die, reducing all remaining clock path distances to not more than half the die diameter and setting up a situation in which the final distribution of clock from the isochronic trunk to the loads is in line with one routing axis. This means

© 2003 by CRC Press LLC

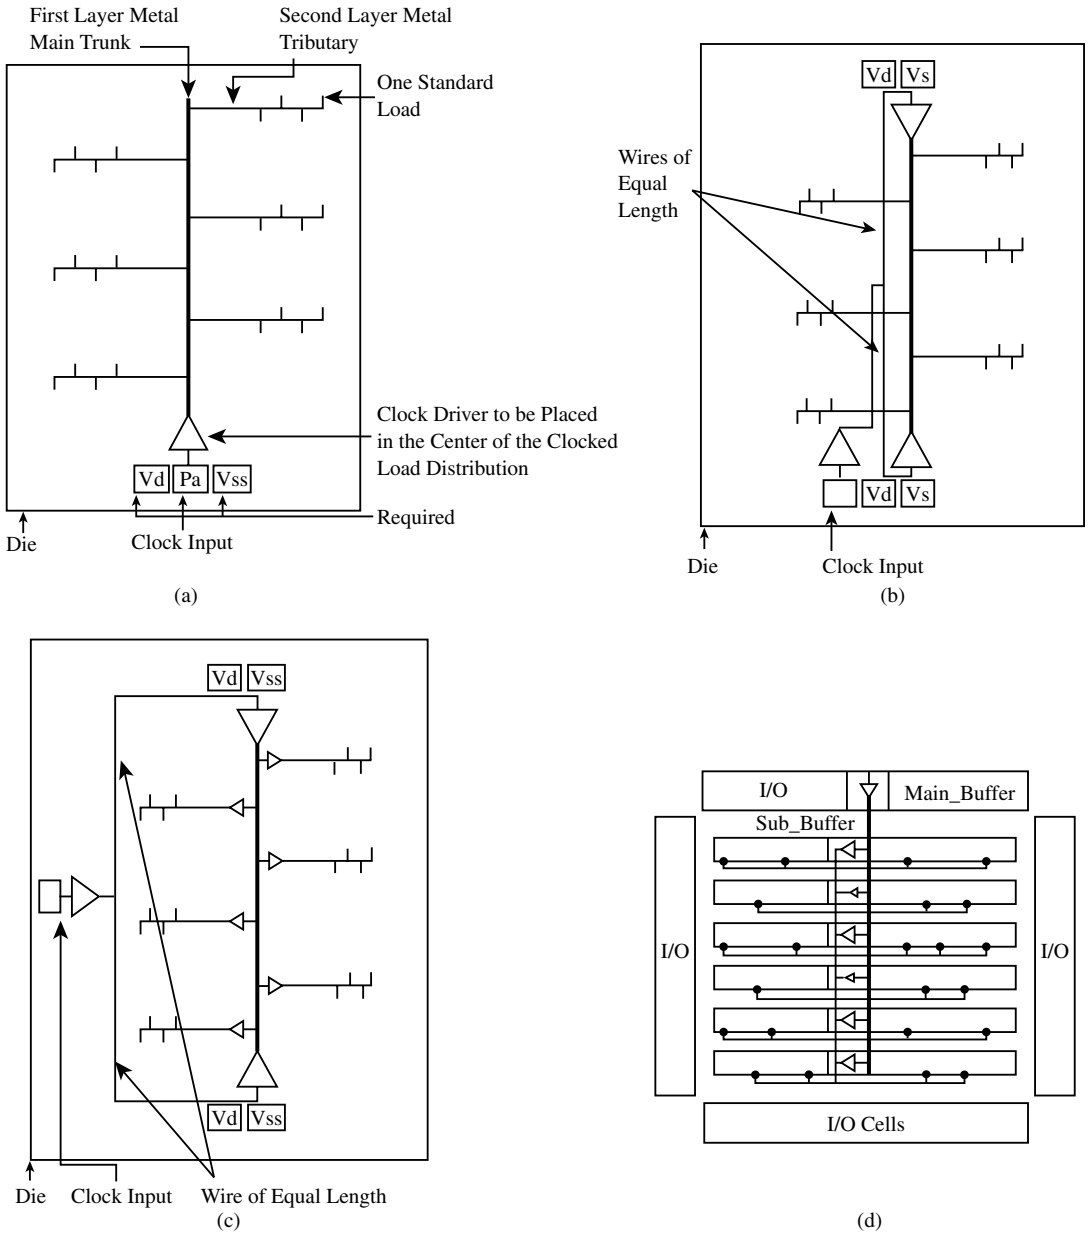

FIGURE 61.47 The clock trunk concept: (a) single-ended unbuffered clock trunk, (b) double-ended unbuffered, (c) buffered clock trunk, (d) clock trunk with shorted branch buffer outputs. *Sources:* (a)–(c): [LSI Logic 1992]. (d): [Saigo et al., 1990].

that branch routing from the trunk to loads can be exclusively contained within one metal layer and travel in a shortest direct line from trunk to load. This is highly desirable for processes in which all horizontal and vertical routing are dedicated to one metal layer or the other. Overall layout and routing is simplified and clock paths are predictable and uniform in routing and wiring type. If, however, the total fanout is very small, the wide metal trunk may add more to trunk capacitance than it decreases R_0 in the $R_0[C_{load} + C_0]$ product for the trunk. This is undesirable because for an isochronic trunk, we want C on the trunk to be dominated by its loads, not by the distributed capacitance of the trunk. In practice,

© 2003 by CRC Press LLC

therefore, the trunk scheme is typically recommended for fanouts of over 50. Below this, a single buffer scheme is recommended.

By designing with the following principles for single-ended, double-ended, and buffered clock trunks, clock nets of up to 2000 fanouts can achieve < 1.5 ns skew in 1.0- or 0.7-μm CMOS gate array technology [21]. When the clock fanout is between 50 and 500 unit loads, a single-ended trunk scheme, as shown in Fig. 61.47(a) provides a good trade-off among skew, area, and delay. A single clock driver input buffer is used to drive the trunk line, which is typically realized by six first-layer metal lines in parallel with metal filled in. Clock trunk sizing for a given fanout must set a minimum width to take current density limits into account, given that all of the clock net current flows through the trunk if the tributaries are not buffered. Tributaries of nominally constant fanout branch out in second-layer metal. To the extent possible, macro-cells and hard-coded mega-cells should be laid out with the clock trunk in mind, ideally permitting the clock trunk to be located in the middle of the logic to which it fans out.

The tributary branches may or may not be buffered with their own clock drivers, depending on the total number of loads to be driven. Buffering primarily has the effect of reducing overall delay, rise time, and total current density in the trunk, by allowing a smaller trunk driver. Form a purely skew-oriented view, however, it is better not to have the secondary drivers as long as the trunk is isochronic and the size and delay of the main driver is acceptable. When using local buffering, it is important that the branch loads on all tributaries be balanced, more so than when using an unbuffered trunk. Local buffering is, therefore, primarily a way of distributing the total buffering load so that no one buffer needs to be extremely large.

For layout software simplicity, the main trunk may be constrained to use vertical (or horizontal) routing channels only. The main trunk (or each of possibly several main trunks) should be placed as close as possible to the centroid of area of all the loads which it drives. Layout or floorplanning software for commercial ASIC design can typically assist the designer in clock trunk placement by visualizing the spatial distribution of clock loads.

When a design has between 500 and 2000 clock fanouts, a double-ended clock trunk, as in Fig. 61.47(b) or (c) is recommended. The double-ended clock drivers are internal buffers which use the I/O slots of two pins that will not be used externally thereafter. Both single-ended and double-ended clock trunk schemes use only one external clock input pin, with adjacent pins providing an AC ground and switching noise isolation by powering the drivers with dedicated V_{ss} and V_{dd} pins for the clock buffers. In general, clock input pins should always be surrounded by nondriven pins to minimize the possibility of cross talk coupling into the clock waveform. Clock pins also should be chosen so that minimal internal routing is required between the predriver associated with the input pad and the clock trunk drivers. As a clock trunk design is laid out, the spike current draw from V_{ss} due to simultaneous switching of large fanouts on the clock net should be assessed and considered in determining how many V_{ss} pins are needed in a particular design.

In the double-ended trunk scheme, some care must be taken to ensure that an equal-length path can be routed from the midpoint of the trunk, where the clock input branches to the trunk drivers at both ends of the clock trunk, and that a direct routing from the side of the die to the branch point at the center of the die is feasible. Particularly when preconfigured macro-cell function have been placed, the metallization layer needed to bring the clock predriver into the middle of the die may be blocked. This leads to the recommendation that the clock input pin be placed on the side of the die that is in line with the clock trunk [see Fig. 61.47(c)]. The line to the branch point and the two branch lines can then use the same metallization layer as the clock trunk and can be automatically provided for as part of the routing channel width reserved by the clock trunk layout software.

The two double-ended arrangements will have a basic skew given by the (nontrunk) R_0C_0 delay across one half of the chip's dimension (typically under 300 ps), plus skew due to any imbalance in buffer loads and thresholds. An advantage of the buffered clock trunk is that the capacitive load of the clock tree is distributed somewhat in both time and position across multiple buffer stages, reducing the current spikes occurring during a clock edge and their impact on ground bounce and injected power supply noise. On the other hand, a total of three or four buffer stages associated with this structure (for low skew in large

applications) may cause high delay between the clock edge used to latch incoming and outgoing data on chip and the external system clock. Clock net fanouts achievable using the clock trunk scheme in commercial gate arrays are summarized in Table 61.10.

In even larger dies with famous of over 3K flip flops, multiple symmetrically driven double-ended clock trunks can be established to control the maximum distance of any point from a clock trunk. For example, with two trunks placed one fourth of the die width in from the sides, no load is over one fourth the die diameter from a trunk, and the loading of branch buffers is half that required with one trunk. Branch lines from different trunks should not be connected together where they meet in the middle of the die. These points are far enough away in terms of delay from their common driving points that joining them could cause power-wasting buffer output fights. In a further variant on the buffered clock trunk, buffers have their ouputs ganged (i.e., shorted) by an additional vertical metal line parallel to the trunk, close to the buffer outputs. The effect of shorting the branch buffers is to equalize the propagation delay through the trunk and distribute the capacitance per buffer more uniformly. This has been found to reduce skew considerably if the branch buffers were not equally loaded and also reduced skew (although less so) in the balanced buffer case [26].

Clock Ring Configuration

The clock ring approach shown in Fig. 61.48 combines aspects of the clock trunk, quadrant, and the single large buffer approaches to achieve a combination of moderately low skew, and moderately low delay without the possibly high routing-dependent skew of the pure single-buffer scheme. The ring approach also simplifies overall clock and signal routing conflicts in a two-layer metal process. The external clock is buffered at entry with a moderate- to large-scale buffer, which drives a clock ring that follows the die perimeter. The ring is not a widened trunk because typically less than 50 other buffers

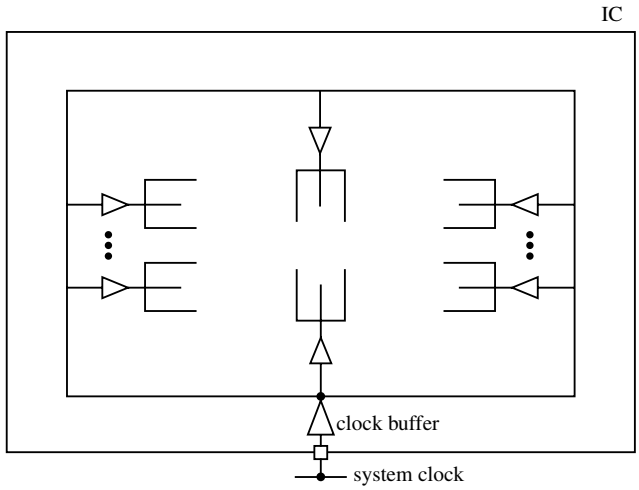

FIGURE 61.48 The clock ring concept.

© 2003 by CRC Press LLC

are driven off the ring, not the entire clock net. Therefore, with relatively low C_{load} on the ring, it is not widened. The extra capacitance of a widened ring would be relatively high (on a square die, the total ring length will be four times the length of a corresponding central trunk) and only increase skew and delay. The ring drives secondary buffers sized to drive balanced groups of flip flops in the core of the chip. The aim of the ring on a large die is not to create a wholly isochronic perimeter, although this could be approached by driving the ring at multiple symmetric locations. Rather, the ring establishes a relatively low-skew reference perimeter from which any interior clock load can be reached either by a purely vertical path or purely horizontal path (i.e., in a direct line of a single metal layer) no longer than one half the die size. The worst-case routing distance from the ring is the same as in the clock trunk scheme, but two thirds of all locations are within half that distance in the ring, whereas only one-half of all uniformly distributed loads are within half of the maximum distance of a central trunk. In practice, with good load balance on the secondary drivers, clock skew of 0.8 to 1.0 ns has been obtained in a designs of up to 30K gates. If the secondary drivers are well balanced, skew in this architecture will depend primarily on the R_0C_0 delay from the ring driving point to its far side, around the periphery, typically 0.8 ns for a die of 350 to 400 mil. Relatively low chip delay is obtained by using the clock signal on the ring as an "early clock" with which to time I/O latches. The ring is electrically closed as this helps distribute the subbuffer capacitance and equalize delays, especially if driven at two opposing points.

H-Trees

The H-Tree is an area-efficient regular structure most suited to clock distribution in systems in which the synchronized modules are identical in size and placed in regular array. Figure 61.49 illustrates a 256-module H-tree tested on a 4-in. wafer by Keezer and Jain [17]. The scheme balances the R_0C_0 delay through the clock network by geometric symmetry so that the delay is nominally constant from the root to any leaf node. Loads are clocked only at leaf nodes of the tree. The minimum feature size of the process can be assumed to set the line width of the H-tree at its leaf nodes and each preceding level has progressively wider lines to maintain constant current density and to minimize impedance mismatch effects (at wafer scale and above) when no branching buffers exist. The H-tree is driven by a buffer at its root and may or may not have additional buffers at branching points. ASIC manufacturers have been able to achieve skew below 500 ps at fanouts of > 5000 with experimental H-tree layouts in third-layer metal [22].

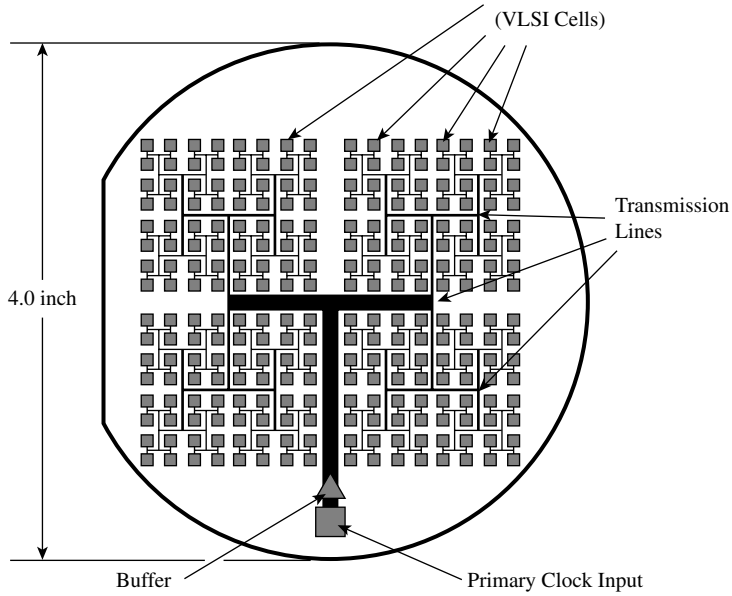

FIGURE 61.49 The H-tree concept illustrated in the form of a 256-cell passive H-tree for Wafer-scale integration. *Source:* [Keezer and Jain, 1992].

© 2003 by CRC Press LLC

The H-tree approach is most practical only if an entire layer in a multilayer PCB or a third or fourth metallization layer in CMOS can be dedicated for H-tree clock distribution. Otherwise, the H-tree may encounter (or cause) a large number of routing blockages or require poly links which will disrupt the H-tree performance. In addition, many VLSI designs include memory cells or other hardcoded cells that are incompatible with the ideal symmetry of the H-tree. However, if a suitable layer is available for H-tree layout, it may be applied to random-logic designs by considering each leaf of the node as a clock supply point for all clocked loads within an isochronic region around each leaf node. The whole die is then tiled with overlapping isochronic regions, each fed from out of the plane by a leaf of the overlying H-tree. Each leaf of the H-tree might also use a variably sized buffer to drive the particular number of clocked loads of the random logic layout that fall in its particular leaf node zone.

Kung and Gal-Ezer [18] have given an expression for the time constant of an H-tree, which characterizes the total delay from root node to leaf:

$$\tau_H = 1.43\, N^3 \left(3 - \frac{2}{N}\right) R_0 C_0 \tag{61.6}$$

where an $N \times N$ array of leaf nodes is drives. Absolute delay rises as N^3 for large N. This in itself does not limit the clocking speed because, at least theoretically, more than one clock pulse could be propagating toward the leaf nodes within the H-tree. As a practical matter, however, the delay of the H-tree expressed in (61.6) is essentially a rise time effect on the clock waveform. A slow rising edge out of the H-tree can lead to significant skew due to threshold variations in the leaf node buffers. These considerations apply to the on-chip context in which the H-tree clock network is dominated by RC diffusion delay effects. Equation (61.6) also describes an unbuffered H-tree. By placing buffers at selected levels of the overall tree, total propagation delay through the tree will increase, but the bandwidth of the tree may be preserved by effectively reducing N to the portions of the overall tree between buffers, in (61.6). In contrast to the rapid bandwidth fall-off on-chip, at the multi-chip module level of system integration an H-tree may be designed from an impedance-controlled transmission line standpoint to obtain very high clock bandwidth. In experiments of this type, Bakoglu [3] has achieved 30 ps of skew at 2 GHz with a 16 leaf H-tree covering a 15×15 cm wafer area.

In an H-tree the total clock path length doubles each time one moves up two levels from the leaf nodes toward the root. Based on this, Kugelmass and Steiglitz [19] have shown that given σ_b and σ_w as the standard deviation of buffer delay (if present) and wire delay, respectively, the total delay of an H-tree considering buffers and wires has variance:

$$\sigma^2 = \sigma_b^2 \log_2(N) = \sigma_w^2 2\left(\sqrt{N} - 1\right) \tag{61.7}$$

and that the average case skew between any two leaf nodes is bounded by:

$$E[\text{skew}] = \sigma_w 4\sqrt{\sqrt{(N-1)}\ln(N)} \tag{61.8}$$

where N is large and wire length effects dominate. Average case (or expected) skew is the maximum difference between clock times, averaged over many design trials, not the average clock time difference in any one design. Kugelmass and Steiglitz [19] also give results for the probability that a sample value of the skew exceeds the mean skew by a given factor in either an H-tree or a binary tree, based on assumptions that all wire length and buffer delay variables are independent and identically distributed:

$$P(\text{skew} > E[\text{skew}] + a) \le \left[1 + \left(\frac{a}{E[\text{skew}]}\right)^2 48\ (\ln N)^2 / \pi^2\right]^{-1} \tag{61.9}$$

where a is the amount of time by which the mean skew is exceeded. These expressions may be used to estimate skew-limited production yield at a given target clock speed.

Delay, Skew, and Rise Time Comparison

The five clock distribution schemes described thus far were studied in a unified, experimental way by Nigam and Keezer [24] using HSPICE simulations. They compared each scheme on a 5-in. wafer holding an 8×8 grid of modules to be clocked. Each module presented at a total load of 2 pF and the interconnect R and C values were taken for a typical 2-μm double-metal CMOS process. Clock distribution lines were 10 μm wide for the buffer tree and the H-tree, except for its trunk, which was 40 μm. The clock trunk schemes used a 20-μm trunk width. All interconnect was modeled as distributed RC, with transmission line delay effects included. The results are tabulated in Table 61.11 and give an excellent overview of the relative characteristics of each method. The H-tree has essentially no skew, but has the highest delay and slowest clock edge, which can translate into skew due to threshold variations in the loads. The clock trunk has good skew and moderate delay. The best overall performance is achieved by the four-quadrant scheme, essentially by virtue of reducing the clocking area to one fourth of the overall size of the other clock networks.

Balanced Binary Trees

A balanced binary tree (BBT) is an unbuffered clock distribution tree in which each branch node has exactly two subtending nodes, and the delay from the root to all leaf nodes is made constant by placing branch points at the "balance point" of the two subtending trees from any node. Balanced binary trees are not simply clock buffer trees with fanouts of two. The significance of the BBT is that constant delay is achieved through multiple levels, without any buffers, and the BBT can be constructed by a fairly simple algorithm. Passive BBTs also may be used in practice to implement delay-equalized fanout networks between the active buffer levels of a larger buffered clock tree. The BBT concept should not be confused with the buffered clock tree concept in general, however. The key is that the generalized buffer clock tree does not have path delay equivalence if its buffers are removed, whereas the BBT has this property.

The basic ideas and methods of generalized balanced tree synthesis are explained in [6]. The clock tree that results has two branches at every node. Clocked loads appear only at the leaves of the tree. The line lengths at each level can be different than those at other levels of the tree, and the two line segments that are children of any node also can be of unequal lengths. The key, however, is that at each branch the total distance from the branch point to any subtending leaf via one outgoing path is equal to that in the other outgoing direction.

Figure 61.50 illustrates the basic procedure for BBT synthesis. The process works from the bottom up, by considering all leaf node positions, i.e., clock entry points for modules or isochronic local regions. Leaf nodes are subjected to a generalized matching or pairing process in which each node is paired with the other node closest to it in the Manhattan street length sense within the available routing channels. A first-level branch point is then defined at the midpoint on each line joining the paired leaf nodes. A

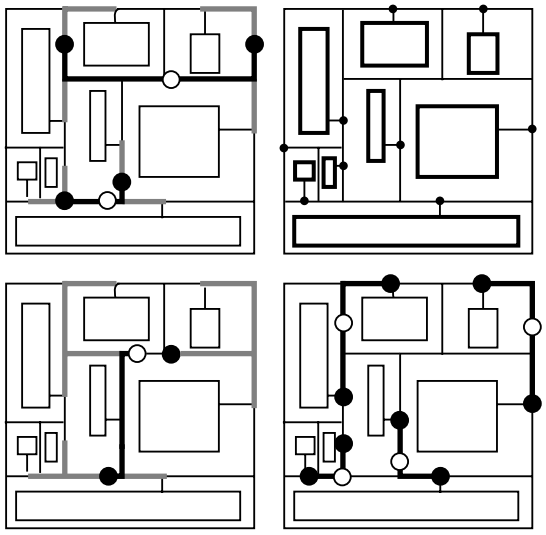

FIGURE 61.50 BBT synthesis in an 8-terminal net. Solid dots are roots of subtrees in the previous level; hollow dots are roots of new subtrees computed at the current level. *Source*: Cong et al., 1991].

similar pairing of the first-level branch points then defines a new set of line segments, each of which has two leaf nodes symmetrically balanced at its ends. Second-level branch are then defined at the RC balance point on each line joining first-level branch points, and so on. Each iteration consists of finding the minimum path length matching of pairs of branch points from the previous iteration and defining the next set of branch points at the time-constant balance points on the line between just-matched, lower-level branch points. Assuming leaf nodes present equal loads, the first-level branch points are the midpoints of the pair-matching line segments. After that, the balance point for level i is the point on the line segment joining matched level $(i - 1)$ branch points at which the total RC wiring time constants (simply total length if all wires and layers are identical) to the leaf nodes in the right and left directions are equal. This is repeated until only two branch points remain to be matched. A line is routed between them and driven by the clock signal at the final balance point, which defines the root of the BBT.

Clock trees developed in this way are in one sense highly structured and symmetric in that the total delay from root to any leaf is nominally constant, like the H-tree. Unlike the H-tree, however, the actual layout is irregular, allowing the BBT to accommodate the actual placement of cells and modules and to cope with the limited and irregular routing channels available in designs that do not use a completely regular layout.

Skew in BBTs has been considered theoretically and experimentally. Kugelmass and Steiglitz [19] showed that in a BBT with independent variations in the delay at each stage of the tree, with σ_0^2 variance, the expected skew is fairly tightly bounded by:

$$E[\text{skew}] \le \frac{4\sigma_0}{\sqrt{2\ln 2}} \ln N \tag{61.10}$$

where N is the number of leaf nodes of the tree.

Using the previous expressions we can compare the H-tree to a BBT. The comparison shows that when the regular structure of an H-tree is feasible, it is of relative merit for large fanouts because the expected skew grows more slowly ($O(N^{1/4}(\text{In } N)^{1/2})$) than the BBT tree in which expected skew grows as $O(\ln N)$. For comparison, assuming 10,000 leaf nodes and the same σ_w per unit wiring length, the expected skew of the H-tree is about one half that expected of the BBT. This outcome is primarily because the BBT must be deeper (have more levels) than the H-tree for the same fanout.

© 2003 by CRC Press LLC

Experimentally, Cong et al. [6] produced a large sample trials of 16- and 32-node BBT clock trees, synthesized on a 1000 × 1000 grid. It was shows that the BBT resulted in less than 2% of the skew from a corresponding minimum spanning tree (MST) for clock distribution to the same loads, even though the BBT had 24 to 77% more total routing length than the MST. The MST benchmark characterizes the skew that would typically result if the clock was routed as an ordinary signal net, with no special concern about skew.

An example of balanced clock tree synthesis supported by a gate array provider is [22], in combination with a three-level clock buffer tree hierarchy. Skew of < 500 ps is achieved in 0.5 μm designs of up to 13,440 clocked loads. By using appropriately sized buffers and wire width at each level of the balanced tree, clock rise time is typically 0.8 to 0.9 ns at the terminal nodes. The clock tree compiler is invoked after floorplanning. The compiler takes into account the resistance and capacitance of different wire types, the length and width of wires, and the input capacitance of clock pins and buffers. Up to three active buffering levels can be used, with fanouts of up to 64, 14, and 15, respectively, from buffers at each level. The fanout subnet driven by each buffer is laid out as a (passive) BBT, so that the leaves of one balanced tree are the buffers that act as the roots of further passive binary balanced subtrees driven by the next buffering level. At the lowest level, local buffers each drive up to 15 loads via a final four-stage passive BBT.

Clocking Schemes Involving Phase-Locked Loops

A PLL is a negative-feedback control system in which the phase (and, implicitly, frequency) of a voltage-controlled oscillator (VCO) or phase shifter is brought into alignment, or to a predefined static phase offset, with respect to the phase of a periodic reference signal. The application of PLLs is most often to control skew and clock delay problems primarily at the multichip and interboard levels of system design.

Figure 61.51(a) shows how a PLL can be used to lock the on-chip clock phase at a selected point on-chip, to an external phase reference. Figure 61.51(b) shows the mid-trunk phase on a single-ended clock trunk being made to match the external phase reference. Here, the feedback line from the middle of the trunk to the PLL input is assumed to have negligible delay in itself because it is a metal line with only one standard load. Similarly, in the double-ended clock trunk scheme, the sense line can be connected one fourth of the way along the clock trunk. This will lock the internal system clock to the reference timing at two points on the clock trunk, as shown in Fig. 61.51(c), reducing overall skew to one fourth of that in the single-ended clock trunk scheme. The phase-sense line needs to be connected to the clock trunk at only one point because, by symmetry, the corresponding point from the other driver is similarly phase locked.

In general, when the phase-sense line has negligible delay, the clock phase at the sense point is driven into lock with the reference phase. Thus, in generating clock signals we can null out the delays of large buffers or drivers in the output circuits as well as their process and temperature-dependent variations, and, in general, coordinate clock and data phases at the inputs to another chip at any remote point by bringing the phase-sense line back from the actual point where the phase-controlled relationship is desired. In this way even the delay of an off-chip driver can be cancelled out by including it within the PLL feedback loop. If delay in the phase-sensing feedback path is not negligible, then its effect is to advance the phase at the desired control point. The feedback delay can be compensated by a matching delay in the forward path from the VCO to the phase-sensing point, or at the PLL input. An inverter in the feedback signal path is also a convenient way to cause a 180° phase shift between referenced and VCO without requiring any loop delay.

With the addition of frequency divider (divide by N) in the feedback path, as in Fig. 61.51(d), the VCO operates at N times the frequency of the reference clock input. For $N = 2^n$ frequency multiplication, the feedback divider can be a simple ripple counter of n toggle flip flop stages. For other multipliers, a synchronous counter is usually used. The delay-matching element at the PLL phase detector input compensates for delay from the feedback path divider. On-chip frequency multiplication can ease a number of system-level design problems. The overall system clock rate need not be equal to that of the fastest chip in the system. Transmission line effects across the relatively long distances of PCBs or

backplanes can be reduced by operating at a lower clock frequency outside of the system ICs. The lower frequency of system reference distribution may also reduce power, and usually assists in meeting radiated emission specifications for electronic equipment. Because a PLL regenerates the clock in each IC, a considerable amount of clock edge slew rate control can be used on the external system clock, further

easing EMI and power supply switching noise problems. The difficulty of retaining clock waveform integrity getting on-and off-chip at high frequencies through inductive packaging and bonding leads is also eased for the same reason.

PLLs for CMOS

A block diagram of a PLL is shown in Fig. 61.52(a). The VCO exhibits a positive monotonic frequency of oscillation in response to a control voltage, characterized by the slope of its frequency vs. voltage curve. The loop filter, $H(f)$, is of a general low-pass characteristic, often of an all-poles design to avoid any jitter peaking (or AC gain) in the closed loop transfer function of the PLL. The loop filter must provide a DC coupled path between the phase detector and VCO. The phase (and/or frequency) detector compares the VCO output phase to the input reference phase and generates an output signal that is either of a DC nature or has a DC component that is proportional to the phase difference between the reference and feedback signal. The phase detector is characterized by the rate of change in the DC component of its output vs. phase input difference in volts/radian.

A phase detector that is commonly used because of its all-digital nature and suitability for CMOS integration is Gardner's phase-frequency detector (PFD) [11] with charge pump outputs. The PFD produces an output that goes toward V_{DD} or V_{SS} in the presence of a negative or positive frequency offset, respectively, thereby slewing the VCO toward the lock frequency. Once in frequency lock, the PFD produces pump up/pump down signals that vary in proportion to the time difference between reference and feedback clock edges at the PFD input. These pulse-width modulated signals drive a charge pump with a tristate buffer arrangement to either hold, bleed off, or supply charge to a capacitive storage element (i.e., the loop filter), thereby adjusting (and filtering) the voltage on the VCO control node to minimize the phase difference at the phase detector inputs.

© 2003 by CRC Press LLC

For CMOS clocking system applications, the VCO is usually a form of a stable multivibrator in which the switching speed dependence of a CMOS inverter on its *n*-transistor pulldown current is exploited, as shown in Fig. 61.52(b). The VCO control voltage regulates the current flow in, and hence the speed of, each inverter stage through the extra *n*-transistor stage added to each inverter. Any odd number of such stages connected in a loop will oscillate, but now the relaxation period is voltage controlled. Weste and Eshragian [31] describe a 13-stage "current-starved inverter" VCO based on this approach. A related VCO design is based on varying the load capacitance seen by each inverter (in a chain of inverters) by applying the VCO control voltage to an *n*-MOSFET in series with the gate of another transistor configured as a capacitive load [16]. An on-chip RC loop filter can also be constructed from a CMOS transmission gate biased as a resistor and MOS gates used as capacitors (source and drain both connected to V_{SS}) [31].

If frequency multiplication is desired, a PLL with a true VCO is required. Otherwise, many PLL applications can use a voltage-controlled delay line (VCDL) in conjunction with a "raw-clock" input signal, as in Fig. 61.52(c). All the phase-lock feedback principles are the same, except we phase-shift the raw-clock input as required, rather than controlling the VCO oscillation phase. This eliminates the risk of the PLL ever failing to lock-in and may be simpler to fabricate. On the other hand, system design must take into account a more limited range of phase-shifting ability (a full half-cycle of phase control range may require a lot of delay stages) and to make sure initial delays are nominally centered within the positive-only delay control range of the VCDL. Another more subtle point is that while a VCO introduces a perfect integrator ($1/s$ term) in the PLL closed loop response, a VCDL does not. A VCDL, therefore, should not be simply substituted for a VCO without revisiting the closed loop response characteristics for noise bandwidth and possible jitter peaking.

Special power, grounding, and testing considerations apply when a PLL is used. A PLL is basically a linear circuit, so noise is especially important. Particularly when a frequency multiplying PLL is used, the VCO power supply should be well decoupled from system noise, and the input phase reference should be highly stable, as the PLL output clock will have N times the reference's phase noise. Noise voltages coupled into the analog PFD output and LPF signal path are similarly converted into phase noise that is N times worse than in a $\times 1$ PLL. Leadless on-chip decoupling capacitors are recommended as are dedicated power and ground pins for the PLL. The R and C components for the loop filter are often off-chip. In this case it is important that they are connected (depending on the $H(s)$ configuration) to the same analog ground reference as the VCO and PFD. The VCO output, or a divided down version of it, should be brought to an external pin for lock-in validation and as an aid in possible global system clock tuning. For testability, several other separate pins are typically required for independent access to input and output of the PFD, LPF, and VCO each. An on-chip PLL can require up to six or more pinouts.

Anceau's PLL Scheme

Anceau [1] developed a PLL-based approach for large systems in which modules are well-defined, relatively independent, and could be entirely self-timed if not for the need to avoid metastability in communication with other modules. Anceau recognized two natural system scales which are isochronic below different maximum frequencies. One is a global region encompassing the entire system, with a clock period determined by propagation distance delays, or, on-chip, by RC diffusion delays. The isochronic rate for this scale defines a slower clock rate for a system-wide communication bus. The second type of clocking region is smaller local regions which can run at full speed and are characterized by critical logic path delays and lumped capacitive loads within modules, not distance-dependent delays. Each smaller region will be free to operate in an almost self-timed mode.

The clocking style within each module (e.g., logic type and number of clock phases) can be as appropriate for the individual modules. Skew at the highest clock speeds in the system need be considered only within each module, except that timing must be controlled when reading the common data bus to avoid metastability. This is done by reference to the active edge of the slower-rate communications clock (comm_clk), formed by dividing down the master module clock frequency. The rising edge of comm_clk strobes the enabled driver data onto the bus. All other nondriving modules in the comm_clk cycle read the bus on an internal clock edge that is kept away in time form this transition in comm_clk, for

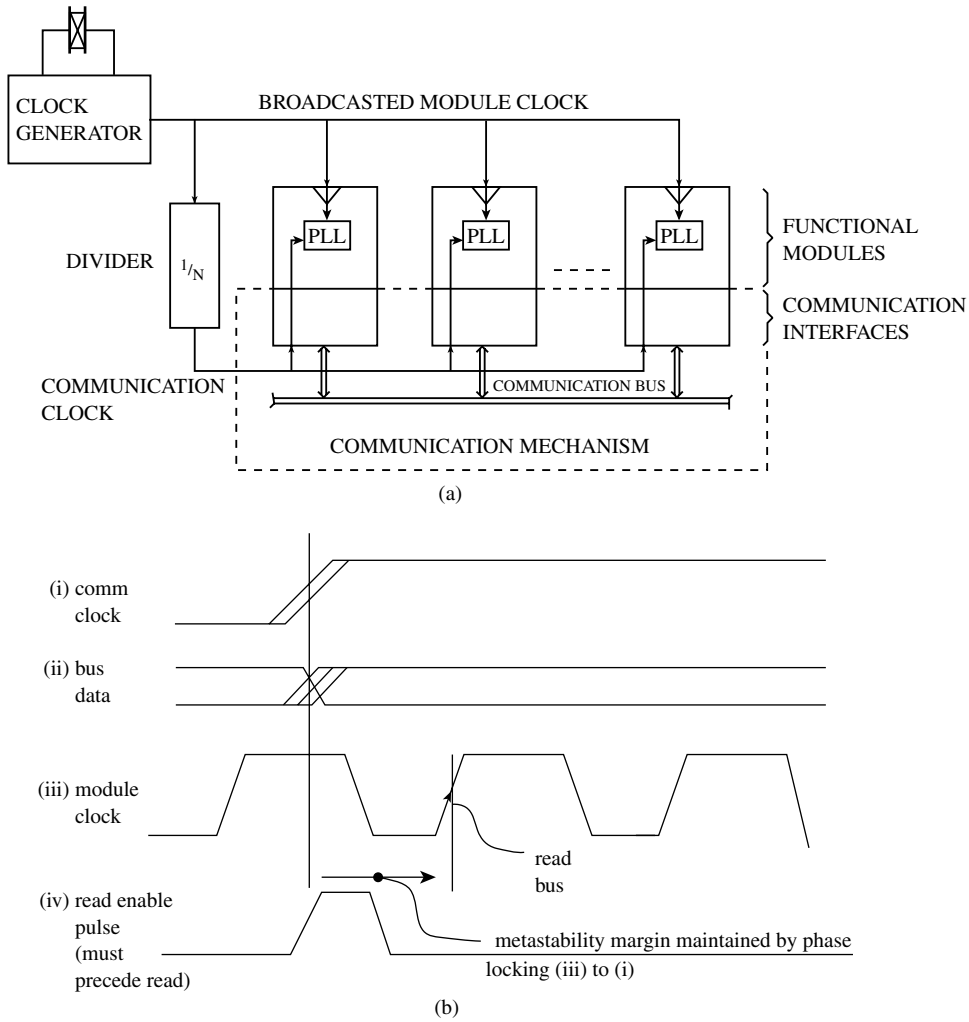

FIGURE 61.53 Anceau's scheme for metastability avoidance: (a) system architecture, (b) interface timing (*Source*: Adapted from [1].)

metastability avoidance. Figure 61.53 illustrates the overall scheme. A PLL phase locks the module clock at a predefined angle relative to the comm_clk, thus keeping the raw module clock away from the transition times in the lower rate communication clock. The read timing is then safe because it is always preceded by the comm_clk transition on which new date were strobed to the bus. A monostable triggered by the comm_clk edge can be used inside each module as a delay generator to prohibit any bus read in the metastable region. This way, as long as modules write to the bus only on the comm_clk edge, other modules that read the bus will never do so at a moment when the bus data are still in transition.

Grover's Interval-Halving PLL Scheme

A novel PLL-based approach to clock distribution in "electrically" large systems can synchronize all clocks in a large system on a single clock line [13, 14]. In this scheme any number of nonisochronic points arbitrarily located on a single- or double-conductor reference line independently derive clock that is in absolute phase-lock to a common system-wide reference time. The central principle is that the time between appearances of an isolated pulse traveling down and back on a reference line is the same regardless of the point of observation, as shown in Fig. 61.54(a). This figure plots the trajectory in space-time of an isolated pulse that travels from a site at one end of a line and is returned at the end of the line to its

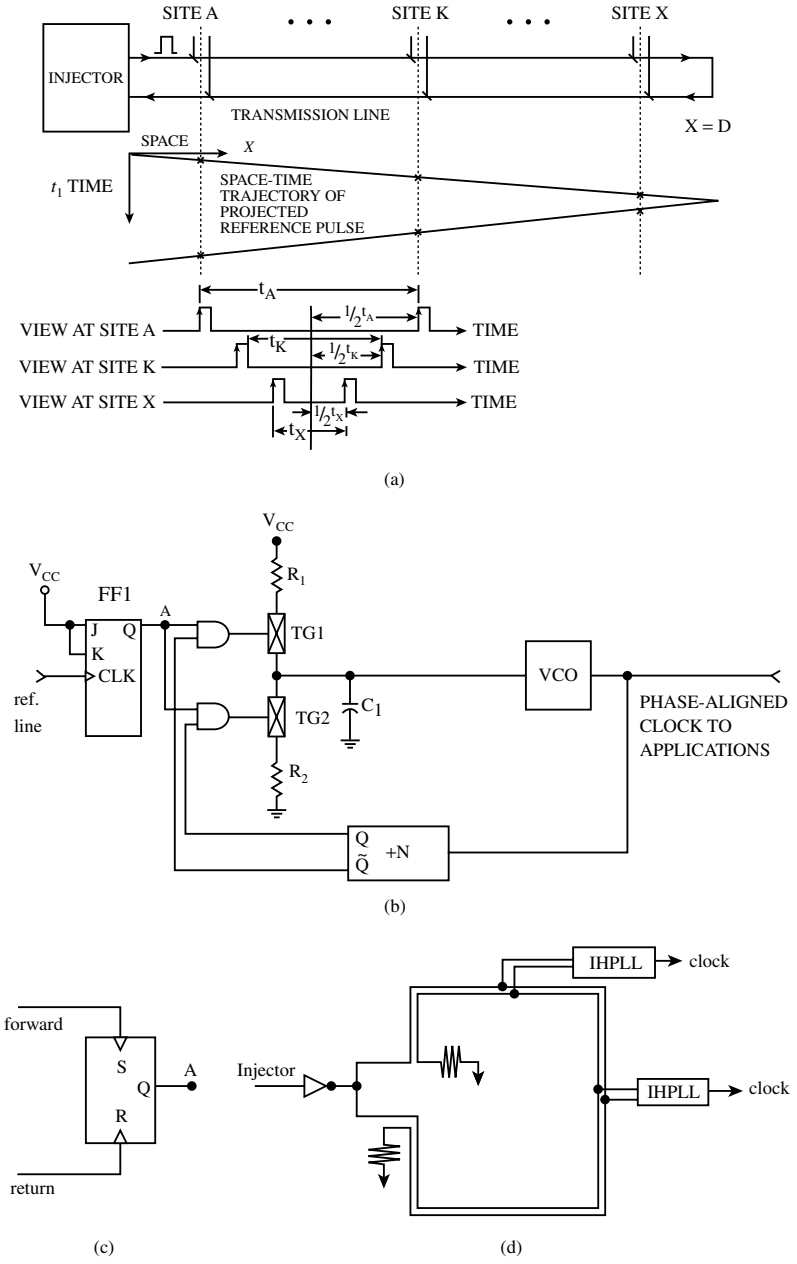

FIGURE 61.54 Grover's interval-having clock distribution scheme: (a) interval-having reference-time principle, (b) IHPLL circuit for single-line skew-compensated clock distribution, (c) phase detector for 2-line operation, (d) driving two lines rather than one looped line. *Source* (a) (b): [Grover, 1994].

origin (where it is electrically terminated). Figure 61.54(a) is drawn for the most general case of physically separate go and return conductors, looped at the right-hand end ($x = D$), but the space-time trajectory of the isolated pulse is identical if the line is a single conductor open-circuited at the end and driven by an impedance-matched source. Equivalently, a tristate buffer can terminate and regenerate the returning pulse at the end of the line for on-chip use. In either case, it is evident that the instant in time that is halfway between the outgoing and returning pulse edges is the same for all points of observation on the line, regardless of the propagation velocity of the line, i.e.,

© 2003 by CRC Press LLC

$$\frac{t_1[x]+t_2[x]}{2}=t_1[D]=t_2[D]\equiv t_{\text{ref}} \tag{61.11}$$

where $t_1[x]$, t_2 $[x]$, are the times when the travelling pulse edge passes position x in Fig. 61.54(a), and $t[D]$ is the time the reference pulse edge reaches (and departs) the reflection point. This time, called t_{ref}, is the midpoint between the two pluses as seen at every point of observation on the line.

This principle is adapted for single-line, skew-compensated clock distribution by periodic injection of a reference pulse onto a single conductor, reflection of this pulse at the end of the reference line, and generation of a local clock at all stations, such clock being phase-locked to the interval mid-time by a special interval-halving PLL (IHPLL) circuit, as outlined in Fig. 61.54(b). The phase detector in the IHPLL is considerably simpler than the conventional PFD used in many CMOS PLL designs. This method can be adapted easily to a two-line operation, in which a full duty cycle waveform, rather than a narrow pulse, can be used to drive the looped reference line path. The reference line can be looped at one end and driven at the other, or split into two terminated lines, routed together as a pair, and driven together as shown in Fig. 61.54(c). In the latter case, all modules lock to the reference edge arrival at mid-path, rather than at its end.

In either of the two-conductor configurations, an edge-triggered, set-reset flip flop function [Fig. 61.54(d)] is the required phase detector. The two-conductor IHPLL approach avoids the need for an end-reflection or a tristate returning line driver, but requires layout of the reference line so that distances from the end are the same on both directions of the path at every tapping point. This is not hard to achieve on-chip, as the two halves of the looped path could be laid out identically. At the system level, however, the single-line variant has the advantage that uncontrolled cable and tracking lengths can be used without concern about delay equivalence in the return path, and an absolute minimum of cabling, connectors, and tracking is required for clock distribution. The interconnect is the same as that for a system in which clock is directly wired to all modules with a single line. However, this would normally be possible only if the whole system were one isochronic region.

Grover [13] reports experimental skew under 1 ns over 30 m on a coaxial cable which has an uncompensated delay of 147 ns. It was also shown that in the presence of the effects of the transmission line on the traveling reference pulse, the linear component of switching time error on the traveling reference pulse contributes no skew to the resultant clock phase. A phase-shifter variant of this scheme uses a separate line to distribute raw-clock, which is then adaptively phase shifted at each point into the low-skew global phase by a voltage-controlled delay under the same feedback control sensing arrangement. Two-line operation, phase shifter, and other variations are described further in [14].

With this scheme, hierarchical clock distribution networks with delay-controlled cabling, delay-tuning, and numerous temperature- and load-dependent intermediate buffers may be replaced by one conductor with arbitrary routing. Both EMI and conducted noise are reduced by buffer driver elimination and because of the reduced average power of the reference pulse compared to the full clock signal. It may also be possible to add new clock-deriving taps in service, offering a growth path that is not limited by a predesigned clock–tree fanout limit. In many applications hybrids of reduced-depth clock trees, fanning out from skew-compensated roots on a single-line clock system of this type, may give the best combination of techniques.

Anceau's and Grover's schemes are similar in that a reference line is distributed to all modules and a PLL generates a local clock at each module. However, in the Anceau scheme modules do not run phase synchronously, Actual skew between modules remains arbitrarily high at the module clock frequency because the comm_clk line is set slow enough to be isochronic over the whole system. Actual delay in comm_clk, which is significant at the higher module rate, is not compensated at modules. Each module derives only enough information to coordinate its bus accesses with other modules, at the slower comm_clk frequency. In Grover's scheme, however, truly synchronous full-speed global clocking of all modules is achieved by returning the signal on the reference line (by reflection or looping) and exploiting the interval-halving time-reference principle and IH-PLL to cancel global skew. Gate-to-gate interaction

© 2003 by CRC Press LLC

on any clock cycle is feasible between modules in this case, as opposed to interaction only through the metastable-avoidance bus interface protocol.

Clock Tuning in Large Systems

In large systems, clock tuning at the chip, circuit pack, shelf, and rack levels of physical equipment may be required for the highest performance. Circuits to permit clock tuning can be a tapped delay-line circuit with a programmable selector, or (on a circuits card) a printed-in set of loops to be shunted out as needed by a suitcase jack, or a voltage-controlled varactor clock delay buffer. All of these are described in [15]. In general, to aid in the tuning process, one pin on each IC should be devoted to give external observability of the worst-case (if known) clock phase form inside the IC. This way the tuning process can compensate for the delays through I/O pads and clock buffers in large ICs.

Tuning begins by designing cable lengths, tracking, and connectors so that clock paths have nominally equivalent delays. The active tuning process then measures and adjusts relative delay starting from the master clock source to predefined levels of tuning points (TPs) electrically farther from the master clock source, denoted by TP_0. The delay measurement and adjustment repeats through lower level tuning points until the clock on in every IC is tuned. In going from the first to successive tuning points, it is preferable to refer delay measurements directly back to TP_0 each time. This may, however, be physically unmanageable, in which case delay tuning to level TP_n can be relative to TP_{n-1} although overall error relative to TP_0 will be higher in the relative tuning scheme. For systems that must grow in service, operational (i.e., in-service) signals should be the basis of the delay measurement, not requiring off-line signals or patterns.

One convenient way of indirectly measuring delay between points that are not easily accessed simultaneously for oscilloscope measurements is to make an oscillator out of the signal path to be measured. If the number of inversions in the path between TPs is odd, then a multiplexer can be switched to loop the tuning point signal at TP_n back to the TP_{n-1} driving point. A frequency counter can then measure the oscillation frequency, providing data to support automatic clock delay adjustments at the subordinate tuning point.

One mainframe computer used an automatic tuning scheme in which a clock phase-shifter chip produced multiple, slightly time-shifted copies of the clock on each system PCB. Individually selected delayed clock instances were then supplied to each IC on the board through a programmable crosspoint matrix IC. Each clock-receiving IC also provided several internal clock observation outputs to support delay measurements down to the gate level. After automatically measuring the delays of the observable internal clocks in up to 30 ICs per board, the on-board clock selection matrix was programmed, giving each IC its best clock phase for overall system timing margins and minimal skew [30].

Future Directions

Current-Steered Logic

One way of reducing power supply noise injection from clocking is with current-steered logic. Experiments on differential current mode flip flops in CMOS predict very short setup times (300 to 500 ps). Such devices would be very quiet electrically and much less susceptible to varying load effects on delay than on conventional CMOS. On the other hand, such devices might be about twice as large as conventional CMOS flip flops and require more power. Using the bi-CMOS ability to integrate ECL type structures with CMOS may, however, be part of the solution for clocking very high speed medium-scale integrated devices.

Reduced Voltage Swing

Another potential method for reducing clocked load power consumption is to reduce voltage swings. Some experiments indicate a significant reduction in clock-related power and ground noise, but skew and delay objectives are more difficult to meet as the devices slow down in response to lower switching voltage swings.

© 2003 by CRC Press LLC

Mixed Technology

Here, clock speed increases are envisaged by using current mode logic circuits selectively to implement critical timing paths in otherwise all-CMOS systems. New power reductions may also be obtained with ECL-based, high-speed, serial-multiplexed interfaces to replace wide buses which have many parallel CMOS drivers.

$\overline{Q}$ Elimination

Most logic families provide flip flops with both Q and $\overline{Q}$ outputs as standard cells. An approach that could potentially have clock-related switching current and power is to eliminate the $\overline{Q}$ output buffer and develop corresponding logic synthesis tools to utilize inverted inputs and other logic means to assemble logic function without the $\overline{Q}$ outputs form flops. In one experiment of which the author is aware, $\overline{Q}$ buffers were removed, halving overall flip flop power consumption, at the cost of only a 5% degradation in clock-to-Q delay.

Dedicated Layer for Clock Distribution

A number of workers are advocating or are already using dedicated third-layer metal for clock distribution. This affects process cost, but the advantages can be significant in high-performance applications. Third-layer metal is lower than other layers in resistance and capacitance. By moving the clock net, which is the largest single net in many designs, out of the other layers, routability of all other signals is improved and floorplanning simplified. Moreover, the clock tree can avoid uncertain delays due to unpredictable routing or due to polysilicon links in series when routing in fewer shared signal layers. In addition, noise due to clocking can be more easily isolated in the third-layer metal approach.

Optoelectronic Clock Distribution

Optical clock distribution takes advantage of the three-dimensional nature of imaging optics to remove all but the last-stage buffering levels of the clock distribution tree from the plane of the circuit, thereby eliminating multiple stages of buffering and metallization for clock routing. Figure 61.55 is an overview of the basic idea proposed by Clymer and Goodman [7]. The optical clock signal is generated off-chip and drives a laser diode at the top of the figure. The optical beam is expanded onto a transmission

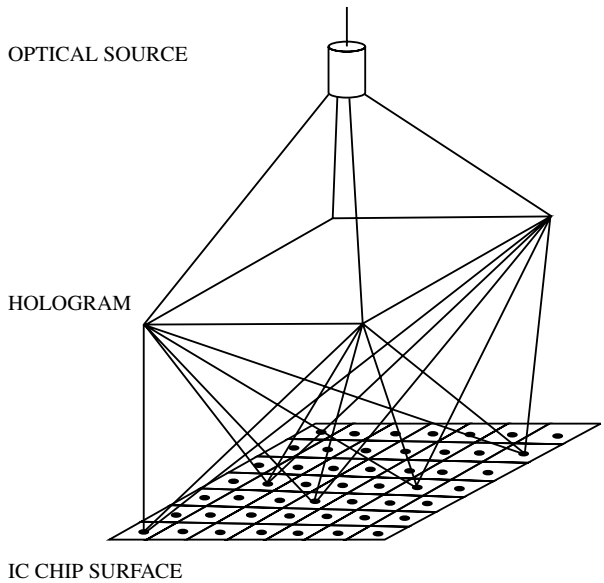

FIGURE 61.55 Clymer and Goodman's concept for wafer-scale optical clock distribution. *Source*: [Clymer and Goodman, 1986].

© 2003 by CRC Press LLC

hologram, which focuses the light intensity onto predefined locations where optical detectors are fabricated into the wafer or die. The optical signal is detected, amplified, and used to drive a local clock generator-buffer which supplies a local isochronous regions. The optical path length differences are not equalized in this scheme because the optical path velocity is so high as to make the all optical path delays negligible as compared with the diffusion and lumped capacitive delays that determine the clock rare of the electronic system. When sources, detector, and packaging for this type of approach are developed, the potential exists for very low skew — high-speed clock distribution, with greater on-chip densities by eliminating most clock routing. One of the main challenges is in attaining uniform response times from the optical detector-amplifier combination (which tend to be sensitive to feature size variations) and the development of sources in the optical wavelength range for photodetectors that can be fabricated within the conventional CMOS circuit environment.

Reconfigurable Clock Nets

In WSI systems, where a single short in very large clock net may disable an entire wafer-level system, Fried [10] advocates methods of restructuring a clock net to enhance yield, primarily through the addition of a controllable tristate output stage to clock buffers within the clock distribution network. This way failed portions of the clock net can be isolated, or, with redundant interconnect and buffers, they may clocked by an alternate path. In particular, tristate buffers may be programmed on or off to select clock for each module from redundant connections to the central clock net, or to simply isolate failed clock net subregions from the drivers of unfailed portions.

61.3 MOS Storage Circuits

Josephine C. Chang and Bing J. Sheu

In a large digital system, a sequence of operations must be performed for a particular function. The results of each operation depend on the results of previous operations. Therefore, the outputs of a logic circuit block typically depend not only on present input signals, but also on the history of the inputs. A combinational logic circuit becomes more useful if it is combined with memory elements. To construct a sequential system, the most common and straightforward way is to employ a central clock to synchronize the sequence of operations.

© 2003 by CRC Press LLC

Instead of using memory elements in a sequential system, we can used dynamic logic circuits to store temporary data. With the building blocks of inverters and transmission gates, the MOS transistors can be used as dynamic storage components to store data temporarily on the device capacitances. Dynamic storage is widely used in MOS technologies because of the simplicity of the required circuitry. Because a memory element such as a static circuit latch occupies a large area and consumes power, elimination of latches has a positive effect on circuit density and power consumption. However, the disadvantages of dynamic logic gates include high transient power disturbances and less noise margins in some applications [1].

Dynamic logic circuits design is based on the synchronized movement of charge through the MOS circuit. A typical capacitance value associated with a logic gate is on the order of a few femtofarads, with means the amount of charge $Q = CV$ dynamically stored on the capacitance is on the order of femtocoulombs. Therefore, perturbations from ideal behavior can become critical to the operation of a circuit.

Dynamic Charge Storage

The MOS technologies have two attractive feature that lead to an efficient way to store data momentarily. These two features are the extremely high input impedance of MOS transistor and the ability of a MOS transistor to function as a nearly ideal electrical switch. In order to store the charge on a capacitive node, the node must be isolated from both the power supply and ground. Various types of storage nodes can be realized in CMOS technologies. For example, charge can be stored at a node between sources (or drains) of two MOS transistors such as nMOS–nMOS, pMOS–nMOS, and nMOS–pMOS [2]; or the source (or the drain) terminal of one MOS transistor connected to the gate terminal of a second MOS transistor. Because the stored charge will leak away over time, this circuit is termed *dynamic storage circuit.*

Figure 61.56 shows the schematic diagrams of three combinations of source-drain connection. The distinction among the three connection types comes from the difference in voltage transmission levels for nMOS and pMOS gates.

Dynamic charge storage requires clocking the data at a sufficiently high rate so that the charge on the various nodes does not lead away significantly. Typically, this requires a minimum refresh rate of 500 Hz to 1 kHz, corresponding to a charge storage time of about to 2 ms.

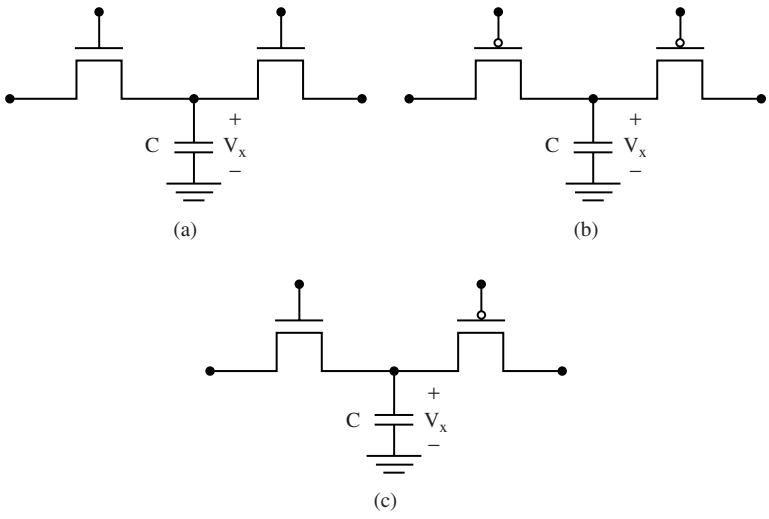

FIGURE 61.56 MOSFET source-drain connection storage nodes. (a) nMOS-nAMOS; (b) pMOS-pMOS; (c) nMOS-pMOS.

© 2003 by CRC Press LLC

nMOS–nMOS

An nMOS transistor is perfect for transmitting logic 0 signals, but imperfect for transmitting logic 1 signals due to the threshold voltage loss through the transistor. The voltage level of V_x which can be stored on the capacitor C is therefore limited by

$$0 \le V_x \le \left(V_{DD} - V_{th,\,n}\right) = V_{\max} \tag{61.12}$$

where

$$V_{th,\,n} = V_{th0,\,n} + \gamma_n\left(\sqrt{2\phi_{Fn} + V_{\max}} - \sqrt{2\phi_{Fn}}\right) \tag{61.13}$$

Charge storage on an nMOS–nMOS node is affected by the leakage paths through the p-type bulk to the ground. This affects the long-term storage of a logic 1 value.

pMOS–pMOS

A pMOS–pMOS node is the complement storage component of an nMOS-nMOS node. The voltage level of V_x is limited by

$$V_{\min} = \left|V_{th,p}\right| \le V_x \le V_{DD} \tag{61.14}$$

where

$$V_{th,p} = V_{th0,p} + \left|\gamma_p\right|\left(\sqrt{\left|2\phi_{Fp}\right| + \left(V_{DD} - V_{\min}\right)} - \sqrt{2\left|\phi_{Fp}\right|}\right) \tag{61.15}$$

Because both p-channel MOS transistors have n-type bulks which are connected to V_{DD}, this type of storage node receives leakage current from the power supply. The logic 1 values can be held indefinitely, but the logic 0 values can only exist for a limited period of time.

nMOS–pMOS

A complementary nMOS–pMOS storage node can benefit from both nMOS and pMOS in transmitting logic 0 and logic 1, respectively. The voltage level which is stored on the capacitance is in the range of

$$0 \le V_x \le V_{DD} \tag{61.16}$$

If the maximum input value of V_{DD} is transmitted through the pMOS transistor and the minimum input value of 0 V is transmitted through the nMOS transistor. On the other hand, if the case is reversed, the maximum input value is entered through the nMOS transistor and the minimum input value is entered through the pMOS transistor, then the voltage range is reduced to

$$\left|V_{th,p}\right| \le V_x \le V_{DD} - V_{th,\,n} \tag{61.17}$$

This type of operation should be avoided because it greatly reduces the noise margins. In a standard nMOS–pMOS storage node both leakage paths to the power supply and ground exist. The ability to retain logic 0 and logic 1 values depends on which leakage path dominates.

Source-Gate Connection

This type of storage node is the connecting point between the source terminal of a pass transistor and a gate terminal of another MOS transistor [3]. Electrical charge can be temporarily stored on or removed

© 2003 by CRC Press LLC

from the gate terminal of the second transistor. When the gate terminal of the pass transistor is at a logic low value, the pass transistor is turned off, and the charge on the gate terminal is isolated. This charge determines the stored logic value. If the stored charge is perfectly isolated, the logic value would be stored indefinitely. In a practical situation, the isolation is less than perfect, primarily because of leakage through the reverse-biased diode operation between the source diffusion region of the pass transistor and the substrate. In addition, leakage also can occur through the pass transistor. With the continuous advances in VLSI technologies, subthreshold leakage through the channel of the pass transistor becomes more important due to scale-down in device sizes. Leakage currents alter the node voltage, which may lead to a logic error.

Two major problems arise in maintaining the integrity of a stored logic state. First is the parasitic conduction paths in the transistors that lead to charge leakage. Leakage currents alter the node voltage, which may cause a logic error. The second problem is charge sharing, which occurs when two isolated storage nodes become connected by a switching event and must equalize their voltages by redistributing charge. Charge sharing may result in a logic error, or may block logic propagation entirely.

Charge Sharing

Beside charge leakage, a problem called charge sharing may also damage the integrity of a stored logic state. Charge sharing occurs when a dynamic charge-storage node is used to drive another isolated node in a switching network [4]. Typically, when two capacitors with different voltages are connected by a pass transistors, as shown on Fig. 61.57, charge sharing may occur. When the pass transistor is turned on, the voltages on the capacitors equilibrate to some intermediate value. In Fig. 61.57, capacitors C_1 and C_2 are in parallel when the transmission gate is conducting. This forces the voltages across C_1 and C_2 to be equal. If the two capacitors are charged to different initial voltages, charge sharing will occur when the transmission gate turns on. Let the initial voltage charge on C_1 be V_1 and Q_1, and the initial voltage and charge on C_2 be V_2 and Q_2. The initial charge balance equation is

$$Q_1 + Q_2 = C_1V_1 + C_2V_2 \tag{61.18}$$

After the transmission gate turns on, the final charges on C_1 and C_2 become Q_1' and Q_2', respectively, and both capacitors are charged to the same value V'. The final charge balance equation is

$$Q_1' + Q_2' = \left(C_1 + C_2\right)V' \tag{61.19}$$

By applying the charge-conservation principle, we can obtain

$$V' = \frac{C_1V_1 + C_2V_2}{C_1 + C_2} \tag{61.20}$$

and

$$Q_1' = \frac{C_1}{C_1 + C_2}\left(C_1V_1 + C_2V_2\right) \tag{61.21}$$

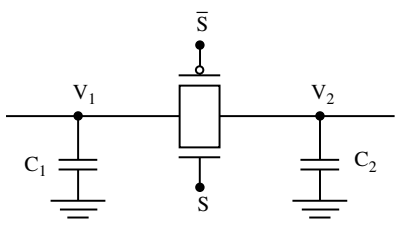

FIGURE 61.57 Charge-sharing-prone structure.

© 2003 by CRC Press LLC

A precharged circuit might work incorrectly due to charge-sharing errors, which could occur inside the pulldown network or at the output circuit. To control a precharged circuit, a gated clock can be present only at the input of the bottom transistor, while all other inputs to the gates of transistors in series in the pulldown chain must have a stable signal over the same clock phase to prevent charge-sharing problems. A *sneak path* is created when two pass transistors in series are both turned on at the same time and one is connected to V_{DD} while the other is connected to the ground. Charge can leak through this sneak path.

Shift Register

A frequent use of dynamic storage circuits is the shift register. Shift registers are most often used to provide temporary storage of digital signals. The shift register storage can be used as a simple way to delay the arrival of a signal for a specific number of clock cycles. Shift register storage is also frequently used as the temporary memory for a sequential logic circuit. In general, shift registers provide dense, limited access memory for many applications in digital integrated circuits.

Simple Shift Register

Figure 61.58 is the schematic diagram of a multistage MOS shift register, with each stage composed of a pass transistor and an inverter [5]. The nonoverlapping clock waveforms Φ_1 and Φ_2 are used. Assume that a logic signal is placed at the input of the first shift register stage while the Φ_1 clock is low and the transmission gate of the first stage is turned off. Next, when the Φ_1 clock goes high, if the signal at the input to the first stage is held constant, it will be propagated to the input of the inverter in the first stage. After a short delay, the output of the first inverter will provide the inverted logic signal to the input of the second shift register stage. At this time, the Φ_2 clock is low and the transmission gate in the second stage will not pass this signal. When the clock values change so that Φ_2 becomes high, the transmission gate of the second stage will propagate the output signal of the first stage to the second inverter, and then the output of the second stage is produced. This signal will be stopped by the transmission gate of the third stage because Φ_1 is low while Φ_2 is high. This sequence continues through the shift register chain as the clock signals alternate, causing the input signal to propagate through the shift register stages. The data are stored on the capacitances associated with the gate terminals of the inverter. The transmission

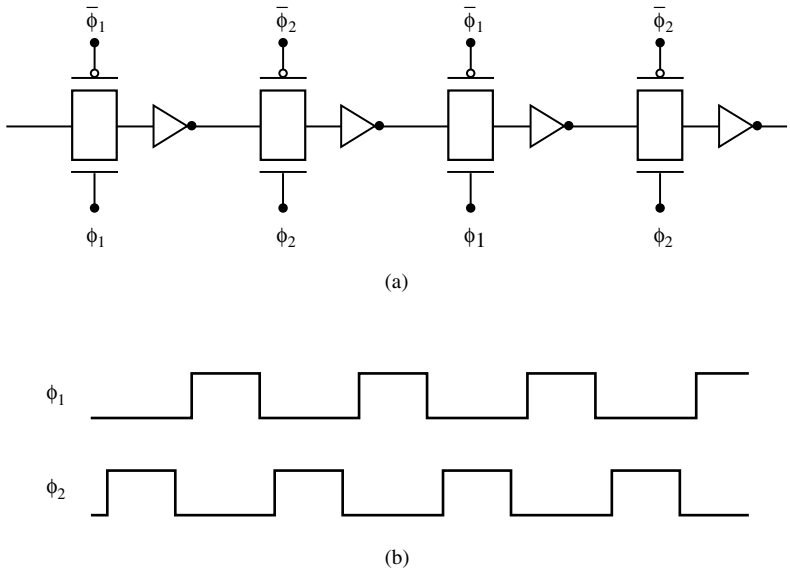

FIGURE 61.58 (a) A four-stage MOS register. (b) Nonoverlapping waveforms of $\phi_1$and ϕ_2.

© 2003 by CRC Press LLC

gate acts as the switch that lets charge flow into and out of the capacitors when they are turned on. The charge is trapped at the capacitor when the transmission gate is turned off.

Each time the Φ_1 clock changes to a high value, the shift register input signal will propagate to the gate of the first inverter and the output signal of the first stage will be produced. A sequence of alternating Φ_1 and Φ_2 clock signals will cause an input signal to propagate through the whole structure at the rate of two stages of the shift register for each complete cycle of the clock signals. After N clock cycles, a logic input value will have shifted through $2N$ stages of the shift register chain. When a two-phase clock is used to control a shift register, it is important that the two clock phases do not overlap. If both phases of the clock were high simultaneously, a data value could propagate through multiple stages during the clock overlap time. This would cause erroneous operation of the shift register.

Parallel Shift Register

Several copies of the multistage shift registers can be combined in parallel with the same clock lines to form a parallel shift register to transmit a group of signals in lock-step fashion. Such a parallel shift of 8, 16, or 32 data bits is often used in microprocessor circuits. The basic structure of this set of shift registers demonstrates two principles which are important for the efficient geometrical layout of digital circuits. The data for the shift register flow from left to right while the control signals (Φ_1 and Φ_2 clocks) flow from top to bottom. Such an orthogonal structure of data paths and control signals within a circuit module is widely used to provide a regular organization of logic circuits within a VLSI chip. Physical layout of the shift register stages can be mirrored with respect to the ground and V_{DD} lines. This mirroring technique allows shared power and ground connections and reduces required circuit layout area. It is important to minimize the size of the basic shift register stage because this stage is repeated many times in a large shift register.

Clocked Barrel Shifter

A *barrel shifter* is a wraparound shifter that forms a very useful switch array [6]. The basic layout is shown in Fig. 61.59. The inputs are labeled I_i; the shift controls $\Phi_2 \cdot$ SHi, and the outputs O_i. The input lines

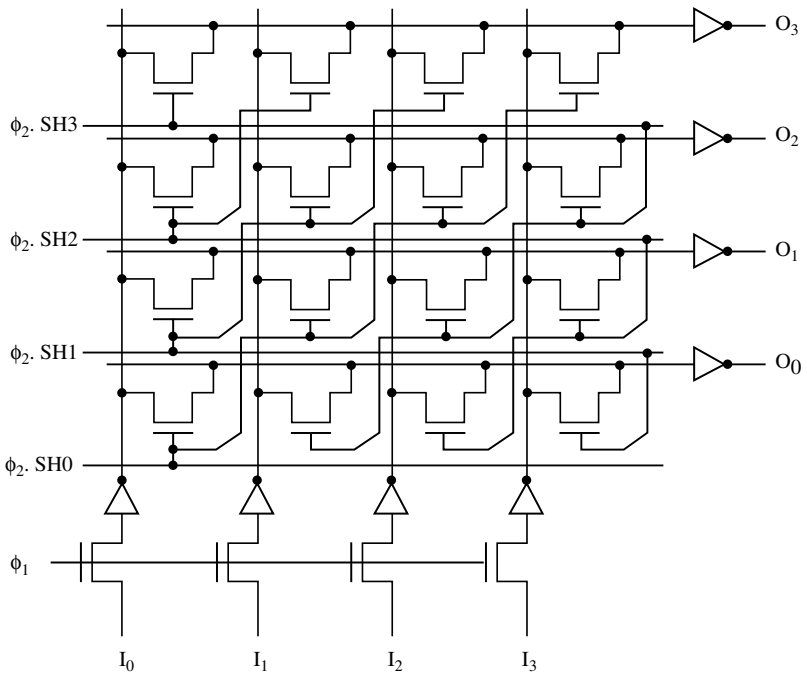

FIGURE 61.59 A four-bit clocked barrel shifter.

© 2003 by CRC Press LLC

run horizontally while the output lines run vertically. The operation of the first shift register stage is the same as explained earlier. In the second stage for four output signals from the four inverters in the first stage can be shifted without changing the order, or each signal can move up one, two, or three locations.

Dynamic CMOS Logic

The dynamic CMOS logic design consists of dynamic circuits based on precharging the output node to a particular level when the clock is at the logic 0 level. During the precharge phase, the inputs to the circuits change. When the clock is at the logic 1 value, the output of the logic gate may be pulled to a complementary value, depending on the input conditions.

The choice of using static or dynamic logic is dependent on many criteria. When low-power performance is desired, it appears that dynamic logic has some inherent advantages in a number of areas including reduced switching activity due to hazards, elimination of short-circuit dissipation, and reduced parasitic node capacitances. Static logic circuits have advantages on charge sharing and precharge operation.

Static circuits design can exhibit spurious transitions due to races. These spurious transitions dissipate extra power over that required to perform the computation. The number of these extra transitions is a function of input patterns, internal state assignment in the logic design, delay skew, and logic depth. Although it is possible with careful logic design to eliminate these transitions, dynamic logic intrinsically does not have this problem because any node can undergo at most one power-consuming transition per clock cycle [7].

Short-circuit currents are found in static CMOS circuits. However, by sizing transistors for equal rise and fall times, the short-circuit component of the total power dissipated can be kept to <20% of the dynamic switching component. Dynamic logic does not exhibit this problem, except for those cases in which static pullup devices are used to control charge sharing or when clock skew is significant. Dynamic logic typically used fewer transistors to implement a given logic function, which directly reduces the amount of capacitance being switched and thus has a direct impact in the power-delay product.

Precharge-Evaluate Logic

The schematic diagram of a basic precharge-evaluate logic is shown in Fig. 61.60. It consists of an nMOS logic structure whose output node is precharged to V_{DD} by a pMOS precharge transistor; and conditionally discharged by the *n*-transistor network connected to the ground. Alternatively, an *n*-transistor precharge to the ground and a pMOS logic structure to conditionally discharge to V_{DD} may be used. A single-phase clock Φ is used for high-speed operation. For the former case, the precharge phase occurs when the clock

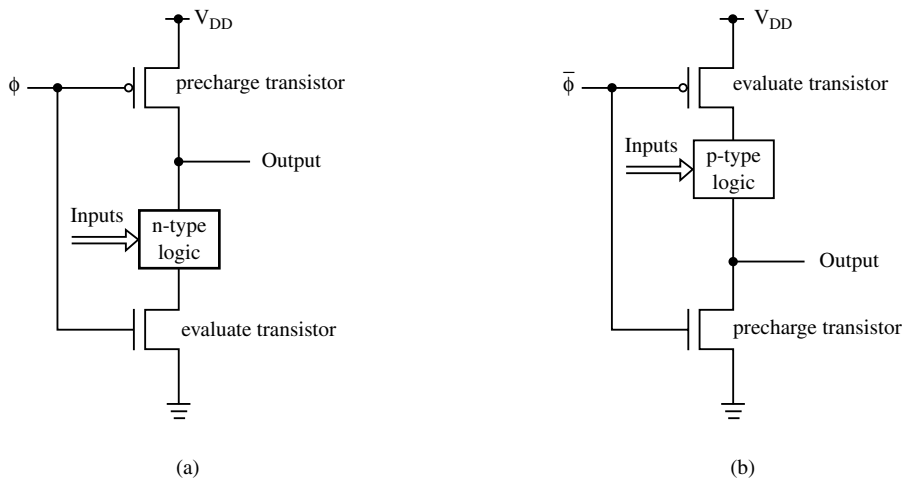

FIGURE 61.60 A precharge-evaluate logic gate.

© 2003 by CRC Press LLC

Φ is low. The path to the ground is activated via the *n*-transistor network when the clock Φ is high. The input capacitance of this logic gate is the same as a pseudo-nMOS gate which has a single *p*-transistor, with the gate connected to the ground, as a load device. The pullup time is better than a pseudo-nMOS gate by virtue of the active switch but the pulldown time is increased due to the ground switch.

Clocked CMOS Logic (C^2MOS)

Clocked CMOS logic gates were originally used to build low-power dissipation logic gates. The reasons for the reduced dynamic power dissipation stem mainly from metal–gate CMOS layout considerations. The main use of such logic structures is to form clocked structures that incorporate latches or interface with other dynamic forms of logic structure. The gates have the same input capacitance as regular complementary gates, but larger rise and fall times due to the serially connected clocking transistors.

The schematic diagram of a clocked CMOS logic gate is shown in Fig. 61.61. In this circuit, the clocked transistors are placed in series with the transistors in the *p*- and *n*-type logic blocks. The primary use of C^2MOS is in dynamic shift registers. In a C^2MOS dynamic shift register, the *p*-type logic black is a *p*-transistor network and the *n*-type logic is an *n*-transistor network. All transistors can normally be chosen as minimum-size devices because each stage is only required to drive the capacitance of an identical shift register stage.

Although the C^2MOS circuit requires the same number of transistors, external connections, and clock phases as the standard CMOS dynamic shift register, the layout is greatly simplified because the source/drain regions of the two *p*-channel transistors can be merged, and the corresponding regions of the two *n*-channel transistors can be merged. This feature helps to reduce circuit capacitance, number of contacts, and layout area.

Operation of the C^2 MOS circuit is quite simple. The gates of the pMOS pullup transistor and the nMOS pulldown transistor of the inverter are both connected to the input signals. For a valid logic input, one of these transistors is turned off while the other is turned on. Clocked transistors placed in series with the pullup and pulldown transistors serve to connect these transistors to the output node when the clock Φ is high. If the input signals match the *n*-type logic portion, the output storage node will be discharged. Otherwise, the output storage node will be charged. When the clock Φ is low, the output node will remain in its present state. In contrast to other clocked logic circuits, the output of C^2MOS is available during the entire clock cycle, although it is actively driven only when the clock is high. A C^2MOS circuit is more susceptible to interference from the load circuit attached to the stage because the load capacitance is the storage node for the dynamic charge.

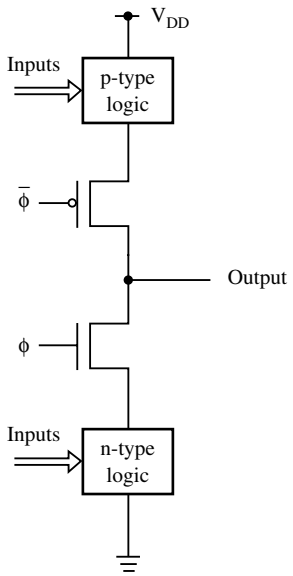

FIGURE 61.61 A clocked CMOS logic gate.

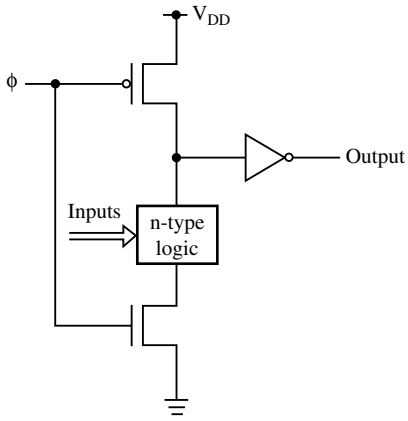

FIGURE 61.62 A domino CMOS logic gate.

Domino CMOS Logic

The domino logic gate design can provide glitch-free cascades of nMOS logic structures. It is a modification to the clocked CMOS logic gate to allow a single clock to precharge and evaluate a cascaded set of dynamic logic blocks. A domino logic gate consists of two elements: a precharge-evaluate logic stage followed by a static inverter buffer at the output, as shown in Fig. 61.62. The logic gate can be built in two forms: mostly *n*-transistors and mostly *p*-transistors. During the precharge phase when clock Φ is low, the output node of the dynamic gate is precharged high, and inverted by the static buffer to provide a logic 0 output for the domino CMOS gate. As subsequent logic stages are driven by this buffer, transistors in subsequent logic blocks will be turned off during the precharge phase. When the gate is evaluated, the node voltage of the logic stage is conditionally pulled down according to the input signal values. If the logic condition of the gate is satisfied, the node voltage is pulled down. It is inverted by the static buffer to provide a logic 1 output. Each gate in sequence can make at most one transition ($1 \rightarrow 0$). Hence, the buffer can only make a transition from ($0 \rightarrow 1$). In a cascaded set of logic blocks, each state evaluates and causes the next stage to evaluate in the same manner as a stack of dominos fall. Any number of logic stages may be cascaded, provided that the sequence can evaluate within the given clock phase. A single clock can be used to precharge and evaluate all logic gates within a block.

The structure has some limitations. First, only noninverting structures can be constructed. Second, each logic gate must be buffered. Finally, in common with a clocked-CMOS gate, charge redistribution can be a problem. The effects of these problems can be minimized. For example, in complex logic circuits, such as arithmetic logic units, the necessary XOR gates may be implemented conventionally as complementary gates and driven by the last domino circuit. The buffer is often needed to drive large capacitive load and does not contribute to any extra cost.

Static storage of charge can be realized by a domino logic gate by including a weak *p*-transistor. A weak *p*-transistor is one that has low gain which is realized with a small W/L ratio. It should have a small gain in order not to fight with the pulldown transistors, yet to balance the effects of leakage. This will allow low frequency or static operation when the clock is held high. In this case, the pullup speed could be an order of magnitude slower than the pulldown speed. Notice that the precharge transistor may be eliminated if the time between evaluation phases is long enough to allow the weak pullup to charge the output node.

A domino logic gate has advantages over a simple precharge-evaluate logic structure. For example, the static buffer provides output-driving capability to either V_{DD} or the ground. In the precharge-evaluate logic gate the output can be favorably driven only to the ground in response to logical conditions, not to V_{DD}. When the logic condition of the precharge-evaluate gate is not satisfied, dynamic charge storage at the output must maintain the logic 1 value. The dynamic logic portion of a domino CMOS gate always has a fanout of 1, thereby simplifying device sizing within the gate structure.

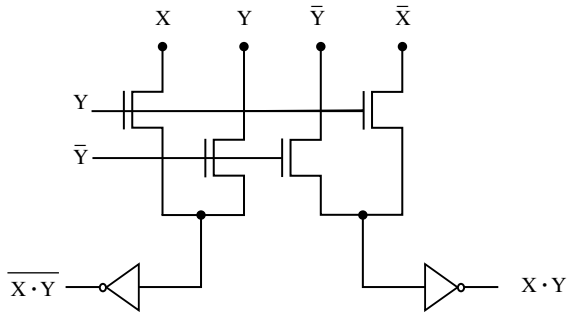

FIGURE 61.63 A CPL AND/NAND cell.

Complementary Pass-Transistor Logic (CPL)

The CPL gate is constructed by using an nMOS pass-transistor network for logic function and eliminating the pMOS latch [8]. It consists of complementary inputs and outputs, nMOS pass transistor logic network, and CMOS output inverters. Figure 61.63 is the schematic diagram of a CPL AND/NAND cell. The pass-transistors function as pulldown and pullup devices. Thus, the pMOS latch can be eliminated, allowing the advantage of differential circuits to be fully utilized. One attractive feature of the CPL gate is that complementary outputs are produced by the simple four-transistor circuits. Because the logic 1 value level of the pass-transistor outputs is lower than the supply voltage V_{DD} by the threshold voltage of the pass-transistors, the signals must be amplified by the output inverters. In addition, the CMOS output inverters shift the logic threshold voltage and drive the capacitive load. The logic threshold shift is necessary because that of the output inverter is lower than half of the supply voltage, due to the lowering of the logic 1 value.

The CPL gate is attractive because fewer transistors are required to implement important functions. However, a CPL gate has two basis problems. First, the threshold drop across the single-channel pass-transistor results in reduced current drive and hence slower operation at a reduced supply voltage. This is important for low-power design because it is desirable to operate at the lowest possible voltage levels.

Second, because the logic 1 input value at the regenerative inverters is not V_{DD}, the pMOS device in the inverter is not fully turned off, and hence direct-path static power dissipation could be significant. To solve these problems, reduction of the threshold voltage has proven effective, although if taken too far it will incur a cost in dissipation due to subthreshold leakage and reduced noise margins.

Cascade Voltage Switch Logic (CVSL)

The CVSL gate is a differential style of logic circuit design requiring both true and complement signals to be routed to the gates [9]. Two complementary nMOS switch structures are constructed and then connected to a pair of cross-coupled *p* pullup transistors as shown in Fig. 61.64(a). When the inputs switch, node voltages Q and $\overline{Q}$ are either pulled up or down. Positive feedback applied to the *p* pullup transistors causes the gate to switch. The logic trees may be further minimized from the fully differential form using logic minimization algorithms. This version is slower than a conventional complementary gate employing a *p*-tree and an *n*-tree because during the switching action, the *p* pullup transistors must compete with the *n* pulldown tree. The schematic diagram of a dynamic charge-storage version of the CVSL logic gate design is shown in Fig. 61.64(b). It consists of two domino logic gates with complementary input logic trees. The advantage of CVSL gate over a domino logic gate is the capability to generate a complete logic function rather than just the noninverting logic function. However, extra silicon area is needed.

NORA CMOS Dynamic Logic

NORA logic is capable of handling signal race problems in transmission pates [10]. It is based on dynamic CMOS logic, but uses latches instead of transmission gates to control signal flow. In a NORA logic

FIGURE 61.64 A CVSL gate. (a) Static version. (b) Dynamic version.

dynamic nMOS and pMOS, logic circuits are cascaded into a C²MOS latch. Figure 61.65 shows the schematic diagrams of both Φ stage and $\bar{\Phi}$ stage. Static inverters are provided at the outputs of dynamic circuits to realize logic inversion. This allows direct implementation of arbitrary functions without modification. In the Φ stage, the logic circuit used $\Phi = 0$ for precharge and $\Phi = 1$ for evaluation. The latch accepts data when $\Phi = 1$ and holds the data when $\Phi = 0$. No new data can be accepted during the hold time. The operation in the $\bar{\Phi}$ stage is similar when reversing clock signals are used.

By alternating Φ and $\bar{\Phi}$ clock stages makes NORA chains well suited for pipelined logic. The schematic diagram of a generic structure of a NORA chain is shown in Fig. 61.66 [2]. Logic flows through the chain at a rate set by the clock. The problem of logic races by using transmission gates as latches between logic circuits has been eliminated because of the dynamic C²MOS latch circuit.

61.4 Microprocessor-Based Design

Roland Priemer

Introduction

During the past two decades, microprocessors (μPs) have become components that are routinely and widely used in machines and systems that engineers design. This is due to their flexibility and ability to perform tasks at a low cost. Because they are programmable, μPs are used to achieve operations of devices and systems with complexity that we have come to take for granted. Engineers are embedding microprocessors into systems that are being employed in virtually all fields of human endeavor.

The competition among the numerous manufacturers of microprocessors has brought about a great variety of microprocessors to increase their suitability in ever-widening fields, more products, and new markets. Moreover, turnaround times have become short enough and costs have come down enough so that system and application engineers have the option of specifying the design of a customized microprocessor to meet their application's specific performance requirements.

This section is intended to introduce the reader to design with a microprocessor. It is assumed that the reader is acquainted with the material that is generally covered in an introductory course on digital systems. The goal is to help the designer who is not experienced with the design of microprocessor-based systems to come to a basic understanding of what is involved. Two representative and significantly different microprocessors are used to do this: the Zilog Z80, an enduring general-purpose microprocessor, and the Motorola M68HC11, also called a microcontroller. These and similar microprocessors have been used in many diverse kinds of dedicated applications.

The design and development of the hardware and software are two broad aspects to utilizing a microprocessor. Here, the emphasis is on digital hardware design. To understand the role that a microprocessor plays in the design process we need to understand the operation of several major building blocks: memory, architecture of a microprocessor, the system bus and timing of bus signals, and the supportive devices used to interface these building blocks together. At the level of design to be considered here, hardware and software are and should remain inseparable. From both points of view we gain a better understanding of the other. However, due to space limitations, no significant presentation of programming in assembly language is included in the sequel. Instead software is only utilized to see how it influences hardware requirements and how it makes hardware work.

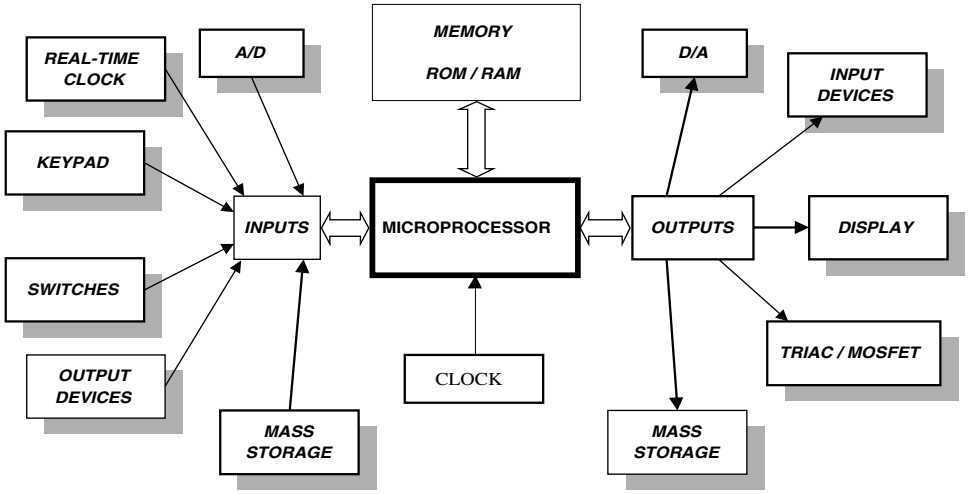

FIGURE 61.67 Conceptual diagram of a microprocessor-based system.

Features of a Microprocessor-Based System

Conceptually, Fig. 61.67 depicts a microprocessor-based system. The inputs to the microprocessor are all binary (can only assume one of two values) or digital signals. However, the origins and meanings of these signals can be very diverse. Inputs can be due to manually activated switch closures from buttons or keypads or they can be due to switches that are embedded within sensors that detect, for example, presence or absence of an object, pressure that is over or under a certain level, temperature that is above or below a particular temperature, presence or absence of an ultrasound or light beam, voltage that is above or below a desired value, etc. An input can come from a real-time clock. Inputs can also be information about the status or readiness of devices that receive outputs.

A single digital signal is called a bit, and it can assume only one of two logic values, i.e., logic 1 or logic 0, which in the circuits that we will use correspond to 5 or 0 volts, respectively. Typically, these circuits are designed to accept as logic 1 any voltage in the range of 3.5 to 5, and accept as logic 0 any voltage in the range of 0 to 1.5. Voltages in the range of 1.5 to 3.5 will produce indeterminate results. Digital hardware using other voltage levels is also available. Of particular interest for portable applications are microprocessors using 3 volts and 0 volts. Unless explicitly noted, all signals are voltages as they vary with respect to a common reference.

Taken together, n bits that are labeled, for example, with $d_{n-1}\ d_{n-2}\ \cdots\ d_1\ d_0$ can have any one of 2^n different binary combinations or binary assignments. A group of $n = 8$ bits is called a byte, which can assume any one of 256 different binary assignments. Another commonly used quantity is $2^{10} = 1024$, which is denoted by $1K$. Thus, for example, $16K = 2^{14} = 16{,}384$.

Inputs can be analog in origin, and the microprocessor receives the result of sampling and analog to digital (A/D) conversion of an analog signal. Usually, analog signals are electrical signals generated by transducers that sense physical quantities of interest, such as speed of a motor, weight of an object, sound of someone speaking, stress of material under test, temperature in a building, electrocardiogram of a patient, acceleration of some structure, wind direction, oil pressure in an engine, etc. The possibilities are endless. Thus, a microprocessor (the program it is executing) can receive information about time and the state of the world in which it is intended to operate.

The memory module of Fig. 61.67 serves several purposes. First, it contains the binary instruction codes of the program that is executed by the microprocessor. The program instruction codes are another kind of input to the microprocessor. Memory also may be used for temporary storage and later retrieval of data produced by the program as it executes the algorithms that process the inputs. And, memory may contain various kinds of data tables that are referenced according to the instructions of the executing

© 2003 by CRC Press LLC

program. In contrast to the memory module, which must respond in time comparable to microprocessor speed of operation, slower mass storage devices also provide inputs that may be programs that will be transferred to memory for subsequent execution or that may be data that will be utilized by an executing program.

An important feature of using a microprocessor is that the functionality of an application is achieved mainly with software and the interaction through hardware between the software and the application environment. From a mass production viewpoint, this is almost a matter of trading hardware, a repeated expense, for software, a one-time expense, whenever possible. Thus, we are not concerned with designing a general-purpose computer; instead, we want to design the hardware that is sufficient to support the software that comprises the functionality of an application. Furthermore, using a microprocessor can achieve more than this because with programmed hardware we can realize fundamental tasks such as conditional checking, storage, waiting, arithmetic, and timing, to mention a few, and higher level tasks such as complex algorithm calculations, decision making, control of machines, management of data, and so on. When programmed properly, a microprocessor provides the ability to perform tasks that are difficult or impossible to achieve with any other kind of means or hardware.

The outputs from the microprocessor in Fig. 61.67 are all digital signals. Like inputs, the meaning and destination of outputs can also be very diverse. Outputs can be one bit quantities that are intended to turn on and off, for example, light and sound indicators and devices such as, for example, TRIACs that can control AC power supply to equipment like AC motors, lights, heaters, and transformers, and, for example power MOSFETs that can control DC power supply to equipment like solenoids, relays, DC motors, and lights. As for inputs, here too the possibilities are endless. Outputs may be necessary to control the input devices or inform them of the readiness to receive inputs.

Outputs can also be 8, 16, or other multi-bit quantities that are, for example, printer control and text character codes, data to be placed in mass storage, a binary value to be transferred to a digital to analog (D/A) converter to synthesize an analog signal, data to be placed in memory, codes of characters to be displayed or communicated elsewhere, protocols to establish communication links, and many other possibilities.

The clock module produces a voltage pulse train, called the system clock. Since microprocessor activity occurs due to level changes of the system clock, the speed at which the microprocessor executes instructions depends on the frequency of this pulse train. For example, if some particular microprocessor can fetch and execute an instruction in eight clock cycles, and it can be clocked with a frequency of 8 MHz, then the microprocessor can execute the instruction in 1 μ sec. For most microprocessors the number of clock cycles required to fetch and execute an instruction varies with the kind of instruction.

With all of the preceding modules interconnected to achieve a particular task, it will be the activity of the microprocessor, which is determined by the software that it executes, that controls the acquisition of inputs, processes the inputs, implements the intended functionality of the system, and generates and controls the placement of outputs.

Figure 61.68 shows a more functional structure of a microprocessor-based system than that of Fig. 61.67. An important feature of this structure is the use of a set of common communications paths, called the system bus, between all major modules. To identify any particular device, the microprocessor

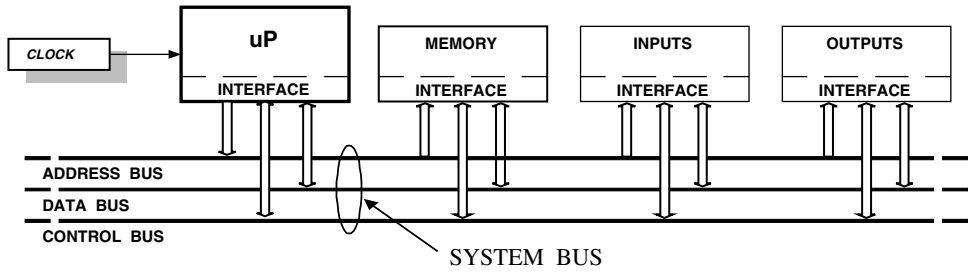

FIGURE 61.68 System block diagram.

© 2003 by CRC Press LLC

places a binary number, called an address, on the m bit address bus. Actually, the electronic circuitry that comprises the microprocessor sets the voltages on the m address bus conductors to some combination of 0 and 5 volts. 2^m different addresses can be placed on the address bus. Every other module receives the address, and only the particular device that recognizes its own address, which is assigned and incorporated by the system designer, is supposed to respond. The data bus simultaneously transfers n bits of data from the microprocessor to any device or from any device to the microprocessor. The control bus informs all modules about the kind of activity that is presently occurring or is about to take place on the system bus.

Usually, the different modules in the system have different operating characteristics. It is the purpose of the interfaces to make compatible the modalities of these different modules. It is often interface design that is the focus of an overall hardware design effort. We will work with microprocessors that produce an m = 16-bits wide address which permits 2^{16} = 65,536 = 64K different addresses, and that use an n = 8-bits wide data bus. Also, depending on the kind of control signals provided by a microprocessor and the kind of control signals that are preferred or required on the control bus, a microprocessor may also require an interface circuit to the system bus.

The different standard system bus definitions are numerous. For example, the public availability of the definition of the IBM PC bus has permitted the connection of innumerable different accessories, produced by many different manufacturers, to this bus. Such accessories were designed to be compatible with the definition of this bus standard. Such standardization contributed to the wide success of the PC. However, in a dedicated application, adherence to a bus standard may not be necessary, particularly when no need exists to interconnect many major modules. Here, we use the particular control signals of the microprocessor to form the system control bus as needed.

Memory

Almost all of the internal and external activity of a microprocessor depends on the ability to store, transfer, and retrieve data. A designer must understand how these operations take place. By way of presenting some memory devices, some terminology and supportive hardware are also introduced.

A circuit for a memory cell is shown in Fig. 61.69. It is also called a binary cell (BC). Here, the activity of the flip flop is determined by the logic signals at the points labeled S, for select, and R/$\overline{\text{W}}$, for read or write. The small circles attached to the OR gates and the buffers are called bubbles, and they mean logical complement. Thus, the buffer followed by a bubble is a NOT gate, and the flip flop is made with two NOR gates. Another commonly used notation for logical complement is a small right triangle, as shown in the figure.

Note that we are using positive logic so that logic 1 means that a signal is high (5 volts) and logic 0 means that signal is low (0 volts). When an operation or activity is enabled by taking a control signal high (low), then we say the control is active high (low). More briefly and without regard to the required level, an operation is enabled by asserting (or activating) its control signal(s).

The read and select control inputs of the binary cell are active high, while the write control input is active low, which is indicated by the bar over the W. To store a bit in the binary cell, the sequence of

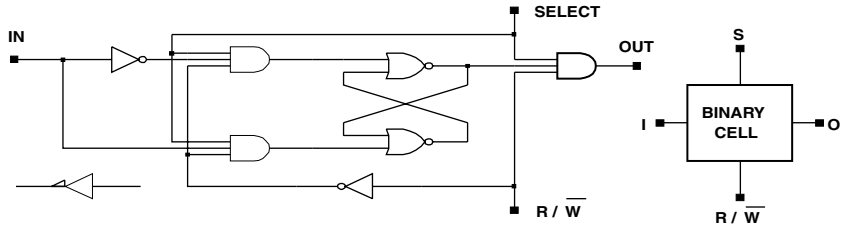

FIGURE 61.69 Circuit of a binary cell with select and R/$\overline{\text{W}}$ control.

© 2003 by CRC Press LLC

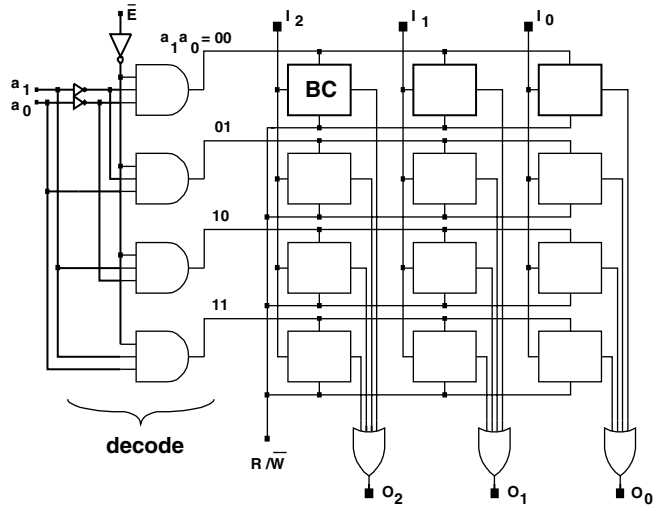

FIGURE 61.70 A multi-word read/write memory circuit.

operations is (1) select the cell, (2) apply an input, and (3) momentarily take the R/$\overline{W}$ control signal low. Thus, the write operation is complete.

A set of binary cells that can be read or written in parallel is called a register, and the set of bits that a register can hold is called a word. A 4 words × 3 bits per word memory module is shown in Fig. 61.70. The $m = 2$ bits input a_1a_0 is decoded with the 2×4 decoder, which has its own active low enable control. When enabled, the decoder output selects, according to its inputs, just one register (row of binary cells) for a read or write operation. The binary assignment to a_1a_0 is called the address of the word to be referenced. For a read operation, the OR gates receive the bits of the selected word, while all other OR gate inputs are logic 0. For a write operation all binary cells in a column receive the same input bit, while only the binary cell in the selected row accepts it. With additional columns we can increase the register length to n bits per word, and with an $m \times 2^m$ decoder we can have a memory size of 2^m registers, while only requiring m address bits to specify any particular memory register that is the object of a read or write operation (memory reference).

Figure 61.70 implies that the system data bus must consist of an n bit unidirectional input bus to transfer data from memory to the microprocessor and an n bit unidirectional output bus to transfer data from the microprocessor to memory. Practically, to reduce the number of communication paths, an n bit bidirectional system data bus is preferred. This can be accommodated by connecting to each memory input/output bit pair, say the ith pair, an arrangement of tristate buffers as shown in Fig. 61.71, where d_i can be connected to the ith bit of the system data bus. When both buffers are in tristate (high impedance state), which occurs when $\overline{E}$ is high, then d_i is independent of O_i and I_i. Thus, the memory module can be electrically disconnected from the system bidirectional data bus. When $\overline{E}$ is asserted, then R/$\overline{W}$ controls the direction of data transfer. Figure 61.72 shows a more concise notation for the entire memory

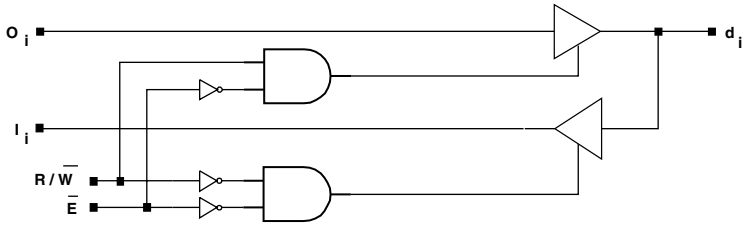

FIGURE 61.71 Unidirectional to bidirectional bus conversion.

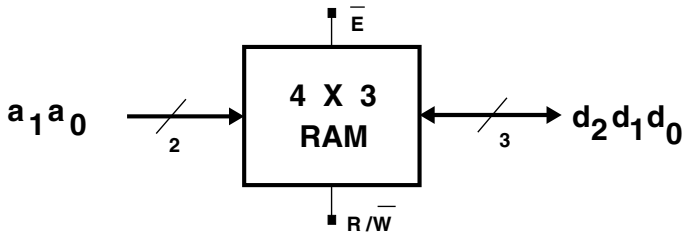

FIGURE 61.72 A memory module.

module. Here, the two address lines are grouped into one bus, and the three bidirectional data lines are grouped into another bus.

Because no particular address sequence is required for reading or writing data to this memory, it is called random access memory (RAM). Stored data remains intact as long as power is supplied to the circuit. Therefore, this memory is called static RAM, contrary to another memory type, called dynamic RAM, in which the logic content of a binary cell is not based on the state of a bistable circuit, but is based on the presence or absence of charge on a cell capacitor. Because charge on capacitors dissipates, dynamic RAM must be periodically refreshed, which requires additional control circuitry. However, dynamic RAM can be fabricated to achieve much higher bit densities than that of static RAM, resulting in the substantially lower cost of dynamic RAM.

RAMs in various sizes and package types are available. Commonly available static RAMs range in size from 256×1 to $128K \times 8$ (a 128 K byte RAM), and the function and number of the control signals also varies a little. Commonly available dynamic RAMs range in size from $16K \times 1$ to $16M \times 1$ (a 16 megabit RAM). Important parameters for each RAM type are the read and write cycle times, which must be less than the width of read and write time windows allowed by the devices that will reference this memory.

Larger RAM modules are constructed by the cascade and parallel connection of smaller RAMs. This is illustrated in Fig. 61.73, which shows a $32K \times 8$ RAM made from $16K \times 4$ RAMs. If $\overline{E}$ is asserted, which takes the entire module out of tristate, then address bit a_{14} enables either RAMs 1 and 2 or RAMs 3 and 4 to access the data bus. The remaining address bits select a particular 4-bit register within each $16K \times 4$ RAM. Here, RAMs 1 and 3 hold the upper half of each data byte, while RAMs 2 and 4 hold the lower half of each data byte.

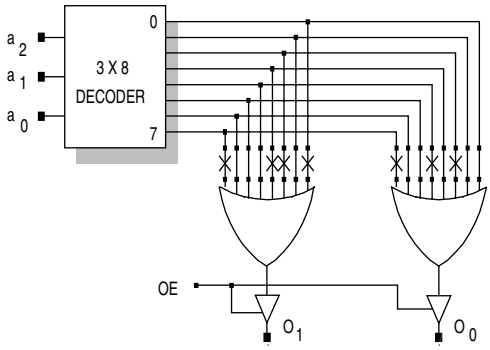

FIGURE 61.74 An 8 words × 2 bits per word programmable ROM.

Whenever power is removed from the circuits of static or dynamic RAM, the data content is lost, and such memory devices are said to be volatile. To provide software for execution immediately after power is applied to a microprocessor, ROM (read-only memory) is used. Figure 61.74 shows an 8 words × 2 bits per word ROM that has been, for example, programmed with the data given in the table. By opening (indicated with an ×) the connections called links, the ROM is programmed. These links remain open through power-down and power-up cycles, and thus, a ROM is said to be nonvolatile. The tristate buffers are controlled by the output enable (OE) signal so that the ROM output can be electrically disconnected from a system data bus, which may then be used for transfer of data among other devices. An important parameter of a ROM is its read cycle time.

By providing a manufacturer a table of contents, a ROM can be programmed at the time of fabrication. Blank (unprogrammed) ROMs are available that can be one-time programmed (OTP) in the field. These are called PROMs for programmable read-only memory. There are also PROMs that can be erased by exposing the integrated circuit (IC) to a certain level of ultraviolet light for several minutes. Erasing is made possible by using an IC package with a clear window just above the IC. These are called EPROMs for erasable programmable read-only memory. After an EPROM had been erased, it can be programmed again.

Another EPROM type is the EEPROM, which can be electrically erased by essentially overwriting previously stored data. However, the write cycle time is significantly longer than the write cycle time of conventional RAM. Commonly available PROMs and EPROMs range in size from $2K \times 8$ to $1024K \times 8$ (a 1 megabyte ROM). Commonly available EEPROMS are not as large as other ROMs, and they cost more than other ROM types. Like RAM modules, larger ROM modules can be made by combining smaller ROMs in a manner illustrated in Fig. 61.73.

Figure 61.75 is an $8K \times 8$ EPROM and the package pin assignment. To place a byte into a particular ROM register, or program the ROM, the register address and intended content must be supplied first at the address and data pins, respectively. Then in addition to V_{CC}, the V_{PP} supply must be provided, the chip enable is asserted, and the $\overline{\text{PGM}}$ input is activated for a particular time duration. An instrument called a PROM programmer is used to do this. Some PROM programmers work by connection to a computer such as an IBM PC, and, in conjunction with software running on the PC, it can program a wide variety of PROMs, which are selected from a menu of those PROMs supported by the software, with code in a file that it receives from the PC.

A programmed ROM can serve several purposes. Most computers have a ROM that contains program code that is always executed at power-up. Typically, this software (or firmware) is a utility (called a boot) that transfers software from a mass storage device to RAM. Then, after this transfer is complete, or perhaps after some additional ROM resident initializing code has executed, the software in RAM starts to execute. In a dedicated application, such as the microprocessor-based system that controls a car engine, it is more likely that ROM will contain all of the application software for use whenever the system is powered up.

© 2003 by CRC Press LLC

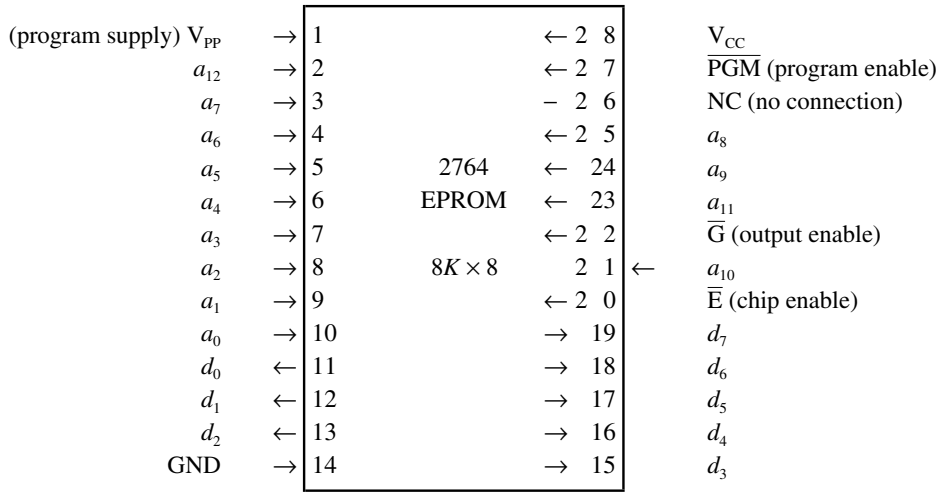

FIGURE 61.75 Pin assignment of a typical (the 2764) EPROM.

ROM is also used for other purposes. For example, by connecting three variables to the address inputs of the ROM given in Fig. 61.74, this ROM can, through programming, be used to realize any two Boolean functions of three variables. ROMs are used to hold tables of data. For example, multiplication can be performed through table look-up. If the 4-bit binary codes of two digits that we want to multiply are used to form an 8-bit address of, for example, a 256×8 ROM, then the upper and lower halves of the retrieved data could each be the 4-bit binary codes of the product digits. The idea is that the address is formed with the input(s) of an operation (or argument of a function), and the precomputed and stored data are the output of the operation (or value of the function). Often EEPROMs are used to hold tables of data that are generated during program execution, which must be available after a power-down and power-up cycle. A battery-backed RAM also can be used for such purposes.

Another way to use a ROM is for signal generation. By using a counter to supply an address sequence to a ROM, each bit of the data as it is clocked out of the ROM could be used as a control signal of some process. The frequency of the clock that drives the counter determines real time, and the variation between 0 and 1 of any particular data bit determines the resulting control signal shape. On the other hand, if the data word sequence coming from a ROM is submitted to a D/A converter, then a ROM can be used to generate an arbitrarily shaped analog signal that is repeated each time the counter repeats its count sequence.

The kind of memory that is used, its size, and the addresses to which any particular memory will be responsive must meet the requirements of an application. This information is often given in the form of a system memory map. The size of this map is the range of addresses that a microprocessor can specify.

With $m = 16$, an address in binary is denoted by $a_{15}\ a_{14} \cdots a_1\ a_0$. The most significant address bit a_{15} splits the entire 64*K* word memory space into two 32*K* word blocks and 0*xxx xxxx xxxx xxxx*, where *x* means "don't care," is any address in the lower 32*K* word block, while 1*xxx xxxx xxxx xxxx* is any address in the upper 32*K* word block. Similarly, address bits $a_{15}\ a_{14}$ together split the entire memory space into four 16*K* word blocks. If $a_0 = 0$, then the address is an even number, while if $a_0 = 1$, then it is an odd number.

Sometimes it is more convenient to use hexadecimal notation. The symbol \$ will be placed in front of all numbers written with hexadecimal notation. Thus, \$*XXXX* is any 16-bit number in hexadecimal notation, while \$*XX* is any 8-bit number. As the most significant hexadecimal address digit changes by \$1, the address changes by 4*K*.

Suppose a design must include 8*K* bytes of EPROM starting at address \$0000,1*K* bytes of EEPROM starting at address \$4000, and 32*K* bytes of RAM starting at address \$8000. The ROM, EEPROM, and RAM must be responsive to addresses in the ranges \$0000 to \$1FFF, \$4000 to \$43FF, and \$8000 to \$FFFF,

© 2003 by CRC Press LLC

respectively. Because the three most significant address bits split the memory space into eight 8*K* word blocks, the ROM should be enabled when these address bits are $a_{15}a_{14}a_{13} = 000$, and then the remaining address bits $a_{12} \cdots a_0$, covering an 8*K* word space, are the address input to the ROM. Similarly, the EEPROM should be enabled when $a_{15} \cdots a_{10} = 01000$, and then the remaining address bits $a_9 \cdots a_0$, covering a 1*K* word space, are the address input to the EEPROM. The RAM should be enabled when $a_{15} = 1$. Thus, the size and desired position of a memory device determine how to place it in the memory space. The other important aspect of interfacing memory to the system bus and eventually to a microprocessor is that a memory module must be responsive to control signals issued by the microprocessor to present and accept data in certain particular time windows. This will be considered further when we look at the timing of microprocessor control signals. An alternative mode of operation would be for the microprocessor to automatically wait for a response signal from memory whenever it references memory before completing the memory reference cycle.

A memory map for this design is shown in Fig. 61.76. Here, we see the size, kind, and position in the memory space of the microprocessor of actual memory devices. When possible, it is also useful to describe the location and purpose of particular program code modules.

Assuming that the EPROM contains program code, some example instructions are placed at the beginning of this memory. These are binary numbers that are machine instruction codes for the Z80 microprocessor. The Z80 microprocessor is a type of processor that, after being reset, fetches instruction codes starting at address $0000. The first instruction, $ED $56, is the Z80 machine code that selects its method 1 for responding to interrupts. Another commonly used notation for hexadecimal is to attach the suffix H. The next instruction, 31H, is the machine code that loads the stack pointer register with an address given by the next two bytes, $F000. These instructions could be the part of a program that initializes the processor. To understand how an instruction is processed, it is useful to study the architecture of a microprocessor.

For programming convenience, programs are usually written using mnemonics of instruction codes that are indicative of instruction activity. The set of mnemonics and associated notational convention for all of the instruction codes that a particular microprocessor can execute form the assembly language of the microprocessor. Different microprocessors, with different instruction sets, have different assembly languages. Furthermore, different manufacturers adopt different mnemonics for their microprocessor instructions sets, causing another variation among assembly languages. However, in principle, many

FIGURE 61.76 Memory map, sample ROM content, and assembly language source.

© 2003 by CRC Press LLC

common attributes remain from one assembly language to another. A program written in assembly language must be converted into machine code for storage and eventual execution. A program that performs this conversion is called an assembler. From the viewpoint of the assembler, an assembly language program is an input character string, and the machine code output is another character string.

Microprocessor Architecture

Employing a microprocessor in a dedicated application does not require detailed knowledge about its internal behavior. However, it is useful to have some insight about how instructions, i.e., their codes, are processed (executed) by hardware. Understanding the relationship between software and hardware can affect the selection of a particular microprocessor and the design process. Moreover, the hardware designer should also understand the programming model of a microprocessor.

From a programmer's viewpoint, a microprocessor is defined by its programming model and its instruction set, which together comprise the architecture of the microprocessor. The programming model consists of the set of internal registers that are involved in the execution of operations as specified by the instruction set. These registers do different specialized tasks. The purpose, capability, and number of these registers can vary greatly from one microprocessor to another.

Basically, within the programming model, microprocessors have four kinds of registers. Address registers are used to form and hold addresses to be used for referencing memory and other devices to obtain program instruction codes and their operands and to specify source and destination memory locations for data read and write operations. Data registers can be the source of data for an operation or the destination for the result of an operation. Operational registers have associated hardware to perform, for example, logical and arithmetic operations. Finally, status/control registers configure the operation of the microprocessor and support different kinds of conditional instructions.

An operational register possessed by most microprocessors is the accumulator. It is commonly denoted by register A. Figure 61.77 illustrates how an A register functions within a microprocessor. Associated with register A are the arithmetic logic unit (ALU) and the condition code register (CCR) or status register (SR). Inputs to the ALU can come from register A, register B, and the CCR, and its activity is determined by the function select word $f_{k-1} \cdots f_1 f_0$. Register A receives its input from the ALU, and register B receives its input from the n bit internal data bus. The activity of this circuit is determined by the control signals that are applied at all of the points labeled with triangles. For example, by asserting the E (enable) input of register A, the n bit word coming from the ALU is latched (loaded) into register A. The content of register A can be placed on the internal data bus by asserting the control signal of the n tristate buffers connected to its output. The content of the internal n bit data bus can be latched into register B by asserting its E control input.

Figure 61.78 illustrates how the ALU performs its task at the gate (bit) level. Notice how the function select lines determine, as they do for the multiplexers of all the other bits, which multiplexer input is latched into the ith flip flop of the accumulator when its E control input is asserted. For example, if $f_{k-1} \cdots f_0 = 0 \cdots 0$, then the accumulator will be complemented, as if the microprocessor has just read in the machine code for the complement accumulator instruction, which has the Z80 assembler mnemonic CPL. Thus, the machine codes of instructions such as ADD A, B; RLA; INC A; LD A, 80H; etc., eventually determine the binary assignments of these function select lines to accomplish the instruction tasks. As

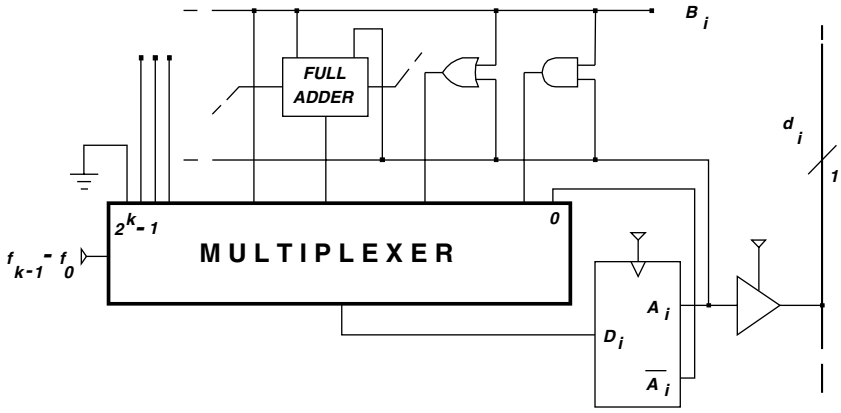

FIGURE 61.78 Bit level activity of an ALU.

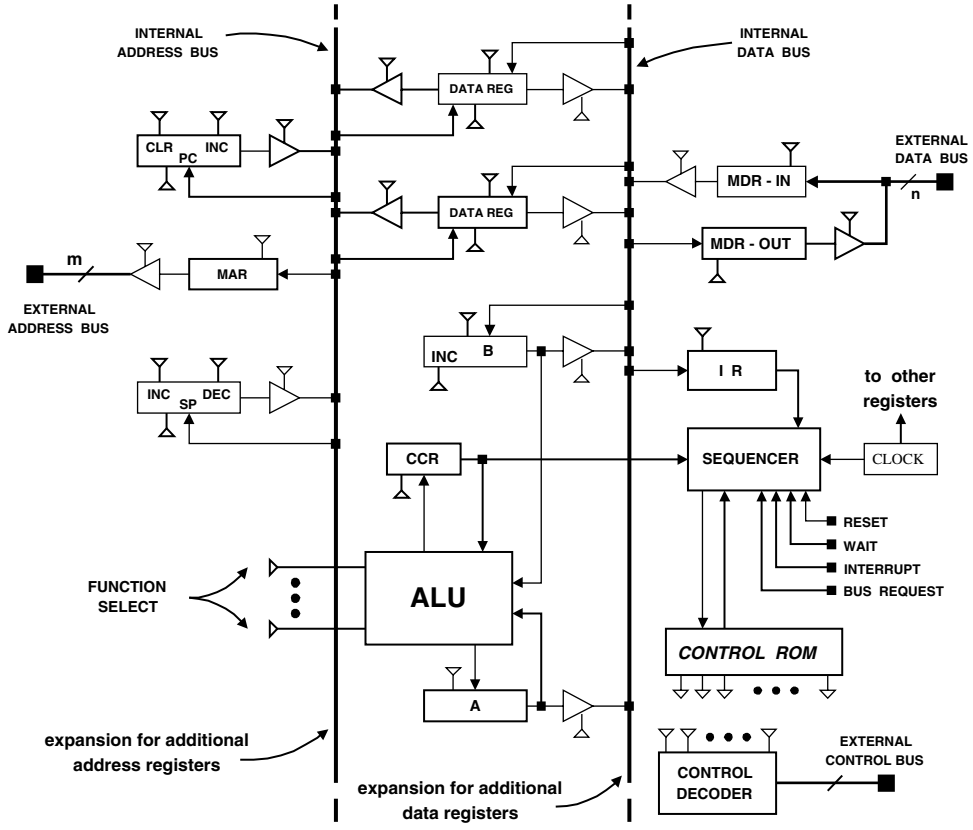

FIGURE 61.79 Data paths of a microprogrammable microprocessor.

many as 2^k different operations can exist involving the accumulator that can be achieved by this ALU structure.

All of the control bits required in Figs. 61.77 and 61.78 come from memory called control ROM or microstore. Figure 61.79 illustrates the data paths of a microprogrammable microprocessor. Each word, consisting of perhaps 16 to 128 bits, in control ROM is called a microinstruction. The busing of microinstructions throughout the microprocessor is not shown in Fig. 61.79. Instead, these interconnections are indicated by labeling with the small triangles.

© 2003 by CRC Press LLC

Figure 61.79 also illustrates a level of design called the register transfer level. Still another level of greater detail is required before a level of IC design detail is reached that shows the interconnection of transistors, resistors, diodes, and conductors. This is the logic gate level. However, at that level, the detail of design would probably be too much and detract from an understanding of microprocessor operation. Here, the intent is to exemplify how hardware processes an instruction code.

Each microinstruction is partitioned into a set of fields, and one of these fields holds the accumulator function select line assignment. Other fields hold data that signify (1) which registers are the source of data for the internal and external buses, (2) which registers are the destination of data on the internal and external buses, (3) register activity control such as clear, increment, decrement, load, and tristate, (4) a *j* bit address of the next microinstruction, and (5) the external control word that informs external devices of the present microprocessor activity. Each microinstruction coming out of control ROM can cause many activities to take place at the same time within the microprocessor. The other registers in the diagram of Fig. 61.79 perform the following tasks:

MAR — Memory address register. It holds the address that the microprocessor can place on the external address bus, and it is loaded from the internal address bus by asserting its enable input.

PC — Program counter. This register holds the address of the next instruction or instruction operand. It can be cleared, loaded, and incremented by asserting appropriate enable inputs. To fetch program code (either an instruction code or instruction operand(s)), its content is transferred to the MAR. Usually, after each time its content has been used to fetch a byte of program code, its content is incremented.

SP — Stack pointer. It holds an address that points to RAM that can be used for temporary storage. It can be loaded, incremented, and decremented by asserting appropriate enable inputs. Certain instructions can cause its content to be transferred to the MAR for a memory read or write operation. The RAM that is referenced with the SP is called the stack. Typically, the SP is implicitly decremented before (after) writing to the stack, and it is implicitly incremented after (before) reading from the stack. Thereby, the stack is a last in and first out memory area that is used to support, among other things, subroutine calls.

MDR-IN — Memory data register in. It receives its input from the external data bus, and it can drive the internal data bus.

MDR-OUT — Memory data register out. It receives its input from the internal data bus, and it drives the external data bus.

IR — Instruction register. When the microprocessor is executing an instruction fetch from external memory, this register receives the content of the MDR-IN register, which is then assumed to be an instruction code.

CRR — Condition code register. Each bit in this status register is indicative of the result of some previous microprocessor operation. The meaning of the flags (bits) in the CCR vary from one microprocessor to another. Typically, this register contains: (1) a carry flag that is set or reset depending on whether or not the previous add or subtract instruction produced a carry or required a borrow out of the most significant bit of the arithmetic operation, (2) a zero flag that is set if the previous instruction produced a zero result and reset if the instruction result is not zero, (3) an interrupt enable flag that can be set or reset by an instruction to allow for software control over whether or not the microprocessor can respond to maskable interrupts, and (4) other flags. Usually, a microprocessor's instruction set includes program flow control instructions that are conditioned on these status flags such that if the flag is set (reset), then the instruction is executed, and if the flag is reset (set), then the instruction is not executed (skipped).

Sequencer. The sequencer consists mainly of a ROM and some sequential logic. It uses the instruction code and status register flags to form an address to its own ROM from which it obtains a *j* bit microinstruction address that is applied to the control ROM. Furthermore, in response to asynchronous external control signals, such as reset, interrupt, bus request, wait, and others, it generates addresses of microinstructions that cause activity appropriate for these inputs.

© 2003 by CRC Press LLC

Control decoder. Depending on the input coming from control ROM, the decoder generates external control signals that are intended to be used to inform external devices about the present activities of the microprocessor and to synchronize activities on the external address and data buses.

Data register. This register is used for the temporary storage of data. Usually, there are several registers like it. Some can also drive the lower byte of the internal address bus, while others can also drive the upper byte of the internal address bus. Still others can receive data from the upper or lower byte of the internal address bus. Some may have low level arithmetic/logic capabilities.

The execution of each microprocessor instruction involves the execution of a set of microinstructions, called a microprogram. Thus, the functionality of a microprocessor's instruction set is determined by the microprograms stored in control ROM. After system reset or the completion of each instruction, unless an external asynchronous input is active, the microprogram that performs an instruction fetch is executed. It uses the content of the program counter (PC) to point to the instruction, and it increments the PC so that the PC points to an instruction operand or the next instruction. Then, depending on the instruction code and status register content presented to the sequencer, a particular microprogram is executed to complete execution of an instruction. If an instruction code requires that operands be fetched, then the PC is further incremented so that after an instruction has executed, the PC is pointing to the next instruction.

Microprograms for program flow control instructions such as JUMP or BRANCH elsewhere cause the PC to be loaded with the address operand of the instruction. Moreover, microprograms for instructions such as CALL or BRANCH subroutine first cause the stack pointer (SP) to be used for storing in the stack the content of the PC before loading the PC with the address operand. Then, the microprogram for an instruction such as RETURN, which is used to terminate a subroutine, causes the SP to be used for retrieving from the stack the address of the instruction following the CALL subroutine instruction, which is then loaded into the PC.

This architecture can be expanded to include additional address registers and other special-purpose address registers such as index registers, another PC and SP, additional accumulators and data registers, and so on. The widths of the address and data bus can be increased, contingent upon fabrication issues. Moreover, algorithmic instruction types can be supported because executing the desired activity of an instruction is a matter of writing a microprogram to accomplish all of the required register-to-register transfer activities.

Design Using a General-Purpose Microprocessor

The Z80 is a general-purpose microprocessor, and it is available in a 40 pin DIP (dual in-line package). It is an 8-bit machine, i.e., its data bus is 8 bits wide. From a software development viewpoint, this machine has numerous features, as an examination of its extensive instruction set and programming model, which is given in Fig. 61.80, will show. It has an accumulator (A), status or flag (F) register, six

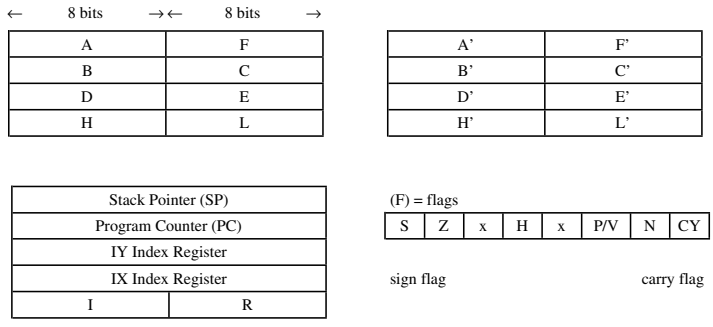

FIGURE 61.80 Z80 programming model.

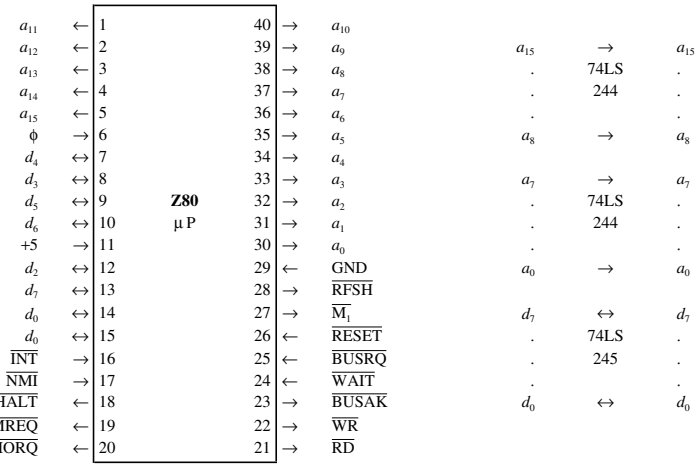

FIGURE 61.81 Pin assignment of the Z80 microprocessor.

data registers (B, C, D, E, H, and L) that can be paired for use as address registers (BC, DE, and HL), a stack pointer (SP), a program counter (PC), two index registers (IX and IY), a register (I) that is used by its indirect vectored interrupt processing method, and a 7-bit counter register (R) that can be utilized for dynamic RAM refresh. Furthermore, it can quickly change programming context by swapping with the alternate (primed) register set. Among its over 600 instructions are data transfer, arithmetic, logical and rotate, branch (or jump), stacking, I/O, program control, exchange block transfer, search, and bit manipulation instructions. Due to space limitations, the information given here is necessarily limited. Complete information can be found in textbooks or the data book from the manufacturer.

The pin assignment of the Z80 is shown in Fig. 61.81. Power is supplied at pins 11 and 29, and a conventional crystal controlled oscillator is used to provide the system clock ϕ at pin 6. If the load of each system address bus bit is only one or two TTL loads, then the outputs $a_{15}\ a_{14} \cdots a_1\ a_0$ can drive the system address bus. However, to accommodate a greater load, two unidirectional tristate octal buffers, as shown in Fig. 61.81, can be used. These buffers also have hysteresis, which helps to produce sharper bus signals. Similarly, it is likely that the Z80 data signals $d_7\ d_6 \cdots d_1\ d_0$ must be buffered to accommodate system data bus loading. A bi-directional buffer, as shown in Fig. 61.81, can be used for this. Z80 control signals must be used to control buffer direction. Also, define the system data bus by terminating it with pull-up resistors. The Z80 control signals perform the following tasks:

$\overline{\text{RESET}}$ — This active low input resets the interrupt enable flag, clears registers I and R, causes all control signals to become inactive, sets the interrupt processing method to method 0, and clears the PC. When this input is released, the Z80 starts to fetch the first instruction code (op-code) from the memory register with address held by the PC.

$\overline{\text{MREQ}}$ — This output becomes active whenever the Z80 is performing an operation, such as op-code fetch or instruction operand fetch, that references an external device with a 16-bit address. It indicates that the address bus holds a valid address. The devices that respond are said to be positioned in the memory space.

$\overline{\text{IORQ}}$ — This output becomes active whenever the Z80 is executing either an IN, for input, or an OUT, for output, instruction, both of which reference external devices with an 8-bit address that is placed on $a_7 \ldots a_0$. It also indicates that the address bus holds a valid 8-bit address. The devices that respond are said to be positioned in the I/O space, which is separate from the memory space.

$\overline{\text{RD}}$ — This indicates that an external device must place valid data on the data bus, which the Z80 will soon accept.

$\overline{\text{WR}}$ — This indicates that the Z80 is driving the data bus with valid data.

© 2003 by CRC Press LLC

$\overline{M_1}$ — This output is active while the Z80 is fetching an op-code. The only other time it becomes active is in response to a maskable interrupt.

$\overline{HALT}$ — This output becomes active when the Z80 has stopped fetching additional instructions due to having executed a HALT instructions. The microprocessor can only continue instruction execution upon activation of an interrupt input.

$\overline{WAIT}$ — This input, when active, causes the Z80 to hold constant its address and control signal outputs until this input is released (no longer active). When referenced, a slow memory or I/O device can cause the Z80 to wait by asserting the $\overline{WAIT}$ input until sufficient time has elapsed to allow the device to respond to the reference.

$\overline{RFSH}$ — When active, this indicates that $a_6 \cdots a_0$ hold the content of counter register *R*, which, along with an active $\overline{MREQ}$, can be used to refresh dynamic memory.

$\overline{NMI}$ — Whenever this nonmaskable interrupt input goes through an active low edge, an internal flip flop is set, and other interrupts are disabled. The interrupt is said to be latched. At the completion of every instruction, this flip flop is checked, and if it is set, then the Z80 first stacks the PC and then loads the PC with $0066, where the first op-code of an interrupt service routine should be located. This way of loading the PC in response to an interrupt is called a direct interrupt, and it is intended for an unconditional and fast response to, for example, battery low detected, temperature too high detected, or some other urgent situation, because it requires no further action from the interrupting device.

$\overline{INT}$ — At the completion of every instruction the Z80 checks this maskable interrupt input. If it is active and interrupts have been enabled with the EI instruction, then interrupt processing commences according to the interrupt method stipulated by the IM *i*, $i = 0$, 1, or 2, instruction. If $i = 1$, for direct method, the PC is first stacked, and then it is loaded with 0038H, the address used to obtain the first op-code of an interrupt service routine. If $i = 0$, for vectored method, the Z80 acknowledges the interrupt by asserting the $\overline{IORQ}$ line while the $\overline{M_1}$ signal is active. This unique activity is then interpreted externally to be an interrupt acknowledge signal, denoted by $\overline{INTA}$. In response to the $\overline{INTA}$ signal, the interrupting device then has the opportunity to place the op-code for the one byte Z80 instruction RST, N on the data bus, where N = 0, 1, …, 7. Then, the Z80 stacks the PC and loads it with an address given by 8N. Thus, depending on N, a 3-bit code embedded within the RST instruction, the first op-code of the interrupt service routine can be located in one of eight locations. If $i = 2$, for indirect vector method, the PC is first stacked, and then the Z80 acknowledges the interrupt by asserting the $\overline{INTA}$ signal. In response to the $\overline{INTA}$ signal, the interrupting device must then place a byte given by *xxxxxxx*0 on the data bus. The Z80 then uses this byte as the low address byte and the content of the I register as the high address byte to fetch two consecutive bytes from memory that are then loaded into the PC. Thus, the I register points to a 256-byte block of memory, where one of 128 interrupt vectors can be selected by the byte provided by the interrupting device.

$\overline{BUSRQ}$ and $\overline{BUSAK}$ — The first signal is an input that indicates to the Z80 that an external device wants to take control of the system bus. The Z80 completes execution of the present machine cycle, takes its address, data, and tristate control signals into tristate, and acknowledges the request with an active $\overline{BUSAK}$ signal.

Most of these signals are representative of the kinds of control signals that microprocessors have. Their usefulness becomes more apparent as we look at the timing of microprocessor activity and the impact this has on the design of hardware so that the microprocessor can accomplish read and write data transfers. Figure 61.82 shows a Z80 timing diagram for an op-code fetch, and Fig. 61.83 shows timing diagrams for the other memory and I/O references. For the purpose of studying the timing of events we do not need to know actual binary assignments on the address and data bus lines. Therefore, the convention in these diagrams is intended to indicate when these signals either become relevant for the operation at hand or switch to the present binary assignment, whatever it may be, from some previous binary assignment.

© 2003 by CRC Press LLC

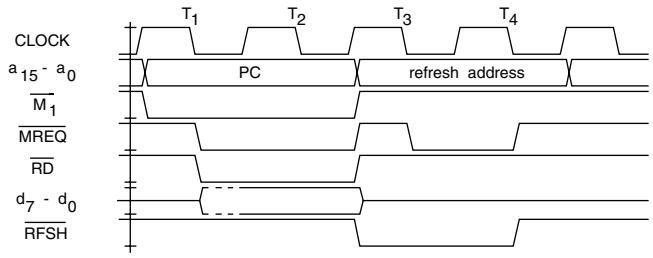

FIGURE 61.82 Z80 timing diagram for an op-code fetch.

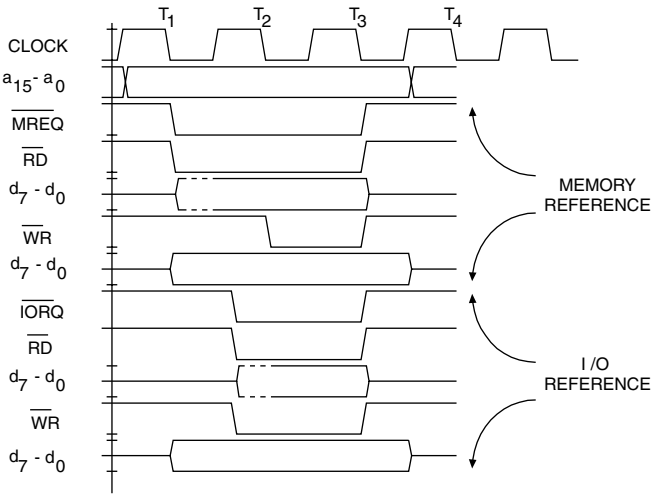

FIGURE 61.83 Z80 timing diagrams.

As we look at timing diagrams, it will also be useful to see how these signals are used. Figure 61.84 shows a schematic of a microcomputer designed according to the memory map of Fig. 61.76. Whenever possible, labeling is used to indicate connections.

Depending on the instruction, the Z80 uses from 4 to 23 clock cycles to execute an instruction. A group of clock cycles within the execution time of an instruction that accomplishes a major activity is called a machine cycle. Each clock cycle within a machine cycle is labeled with T_i, i = 1,2, ⋯, and all activities occur at either leading or trailing clock edges. To better understand such groupings, suppose that after executing many instructions that were retrieved from ROM, the Z80 is about to execute the next few instructions located in memory shown in Fig. 61.76.

The program counter is set to PC = 1075H, pointing to the op-code at memory location 1075H. This is the op-code for load accumulator with data using the two bytes that follow the op-code to form an address to point to the data, i.e., LD A, (C000H). This is a 3-byte instruction and, according to the Z80 manual, it requires 13 clock cycles, which are grouped into four machine cycles, to execute.

Referring to Fig. 61.82, at the leading edge of the first clock cycle of the first machine cycle of this instruction the Z80 asserts the $\overline{M_1}$ signal, and it drives the external address bus with the address 1075H. At the trailing edge of clock cycle T_1, it asserts the $\overline{MREQ}$ signal and the $\overline{RD}$ signal. At the time the $\overline{RD}$ becomes active the Z80s data bus input register is enabled to follow the content of the external data bus. At the leading edge of clock cycle T_3, the Z80s data bus input register is disabled from following the external data bus, and the content of this register is accepted as an op-code.

During the time interval from the trailing edge of T_1 until just before the leading edge of T_3, which is slightly less than 1.5 clock cycles, external hardware has the opportunity to place the addressed data,

© 2003 by CRC Press LLC

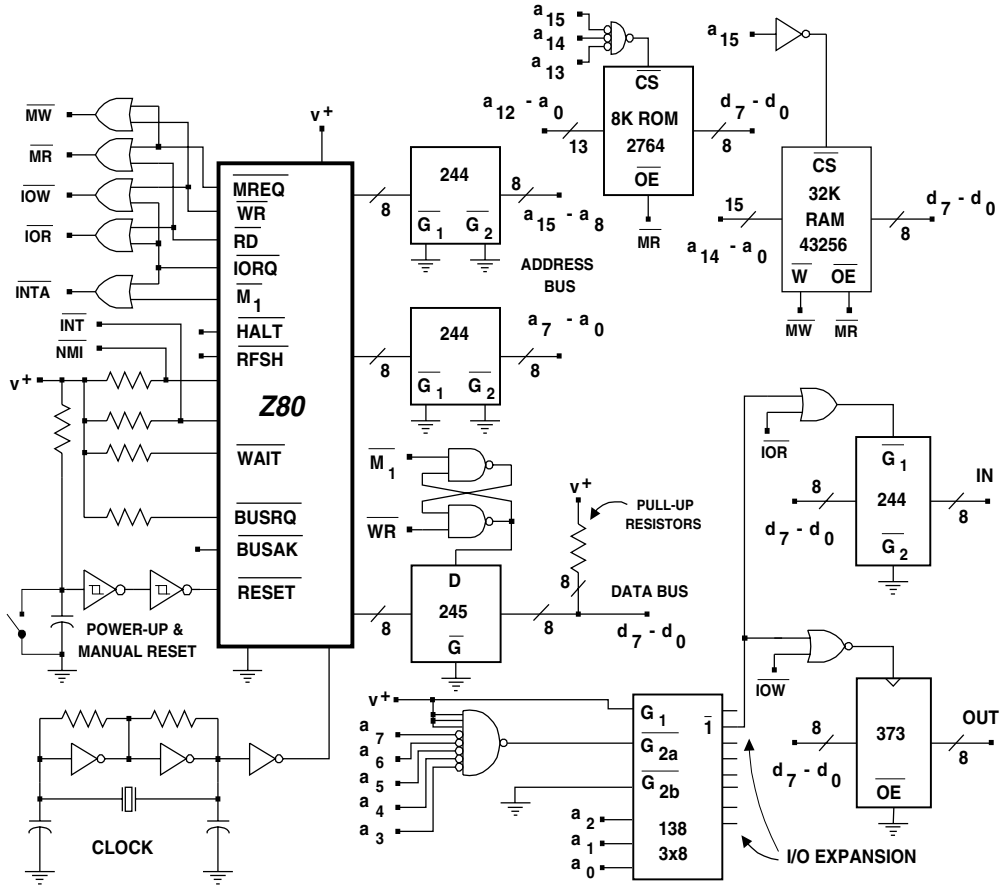

FIGURE 61.84 Z80-based microcomputer.

which will be processed as an instruction op-code, on the data bus. A designer must ensure that external hardware is fast enough to do this in a timely manner. If it is necessary to use an external device with an access time that is greater than this allotted time, then a counter, called a wait state generator, can be used. Once the slow external device detects (by address and control signal decode) that it is supposed to put valid data on the data bus, then it enables the wait state generator, which should be driven by the system clock, to activate the $\overline{\text{WAIT}}$ input of the microprocessor for a number of clock cycles that will give the device an opportunity to place data on the data bus. Each clock cycle is called a wait state (labeled with T_w), and the number of wait states needed will depend on the access time of the device being referenced. If several external devices need to generate different numbers of wait states, then the outputs of the wait state generators of all such devices can be OR'd to present just one wait input to the microprocessor. Therefore, the machine can run as fast as each different external device will allow.

During the next two clock cycles, the received op-code is interpreted so that the Z80 becomes set to perform two more memory references, called machine cycles M_2 and M_3, to fetch each byte of the address operand. Machine cycle M_1 consists of four clock cycles, and while the Z80 is processing a retrieved op-code during clock cycles T_3 and T_4, the address bus is available for dynamic RAM refresh. During machine cycle M_4 the address C000H, which was obtained during M_2 and M_3, is placed on the external address bus, and execution of this instruction is completed by transferring the content of memory location C000H to the accumulator. Machine cycles M_2 and M_3 each require three clock cycles, as does machine cycle M_4. If whenever this RAM module is referenced, it issues wait states, then the actual number of clock cycles required to execute this instruction will be more than 13 clock cycles.

© 2003 by CRC Press LLC

Notice that the op-code determines the kind and number of additional machine cycles that are necessary to complete execution of an instruction. It also determines how much the PC must be incremented. Thus, whenever execution of an instruction has been completed, the PC is pointing to an op-code of the next instruction. Furthermore, virtually all activity involves some kind of synchronized register-to-register transfer.

The op-code at location 1078H is the code for the 1-byte instruction, ADD A, B. Because this addition requires no additional memory reference, it requires four clock cycles (one machines cycle) to execute. The next instruction, i.e., OUT (01H), A, is a 2-byte instruction, and it requires three machine cycles to execute. Because this is an OUT instruction, during machine cycle M_3 the Z80 does the following: (1) transfers the address 01H, which it obtained during M_2, to the lower byte of the memory address register to drive the lower byte of the system address bus; (2) transfers the content of the accumulator to the data bus out register at the trailing edge of T_1 to drive the external data bus, which, as shown in Fig. 61.83, incurs a setup delay; (3) activates the $\overline{\text{IORQ}}$ control signal at the leading edge of T_2, which incurs a setup delay; and (4) activates the $\overline{\text{WR}}$ control signal, which also incurs a setup delay, until the trailing edge of T_3. Thus, the I/O device that is supposed to receive the content of the accumulator has slightly less then 1.5 clock cycles during which it must capture the content of system data bus. By decoding the address, which for an I/O device is called an I/O port address, and the control signals, an I/O interface can enable an external register to start to follow the data bus shortly after $\overline{\text{IORQ}}$ and $\overline{\text{WR}}$ have become active. Then, by the time that the $\overline{\text{WR}}$ signal becomes inactive, the external register should hold the content of the data bus.

Interfacing

The circuitry, or more broadly, the method that makes compatible the operations of devices so that these devices can exchange signals (data or codes), is loosely called an interface. The devices on opposite sides of an interface can be different in many ways. Interfacing two devices can encompass a variety of requirements, such as (1) impedance matching, (2) voltage or current level conversion, (3) translation of control signal meanings, (4) protocol conversion, (5) signal timing alignment, (6) electrical isolation, (7) exchange of status information, (8) data format conversion, and (9) resolution of other incompatibility issues.

Figure 61.84 gives some examples of the goals of interface design. The unidirectional and bidirectional buffers make compatible the drive (current source) capability of the microprocessor and the drive requirements of the address and data bus. The particular control signals of the Z80 are interfaced to the system control bus with combinatorial logic to provide drive as well as more explicit control signals. The interfaces between the memory devices and the system bus utilize the address bus to position memory in the desired locations in the memory space. We must be certain that only one device can be a source to the data bus at a time. The interfaces also utilize control bus signals to produce the particular kinds of control signals required by the memory devices and to activate memory at times compatible with microprocessor timing.

Figure 61.84 also shows an input and output port. The interface for this parallel I/O port also utilizes the address bus and, instead of using control bus signals that go active due to memory reference instructions, it uses control bus signals that go active due to the IN and OUT instructions of the Z80. For output, it decodes the control bus and the lower half of the address bus to enable (clock) the octal latch to capture the content of the data bus at the right time and in response to the intended (its own) address $01. Thus, by executing an output instruction, like the one located at address $1079 in Fig. 61.76, the octal latch receives the content of the accumulator. For input, the interface decodes the address and control bus to enable (take out of tristate) the octal buffer, which permits it to drive the data bus with its input at the right time and in response to the intended address. Thus, by executing an input instruction such as IN A, (01H), the accumulator will receive the byte at the buffer input. Depending on the address decode logic, the I/O port can be positioned anywhere in the I/O space of the microprocessor.

© 2003 by CRC Press LLC

By using the $\overline{\text{MREQ}}$ control signal, instead of the $\overline{\text{IORQ}}$ control signal, and the entire address bus, I/O ports can also be positioned in the memory space of the microprocessor. The variety of conventional memory move instructions can then be used for I/O. Some microprocessors, such as the M68HC11, do not have I/O space separate from memory space and instructions for I/O in addition to memory move instructions. Instead, no distinction is made between memory and I/O references. This eliminates the need for explicit control signals that interface hardware requires to distinguish memory and I/O references.

One or more parallel I/O ports can serve many different applications. With circuits such as those given in Fig. 61.85, a bit of an output port can turn on and off a light or sound indicator, or DC or AC power supply to a load. With a set of bits, software can produce codes that control a device such as a printer. Because the octal latch in Fig. 61.84 has a tristate output, output enable could be controlled by address and control signal decode from another microprocessor to place the octal latch output on another data bus. Thus, data transfer between two machines is accomplished. Also, software can produce binary time functions to control some process. An analog signal can be generated by outputting to a D/A converter, as shown in Fig. 61.86.

A program can receive information through a parallel input port. This may be the position of a set of switches, as shown on Fig. 61.87, or the output of some kind of an encoder, such as a keypad encoder, rotating shaft position encoder, A/D converter, as shown in Fig. 61.88, or even data from another microprocessor.

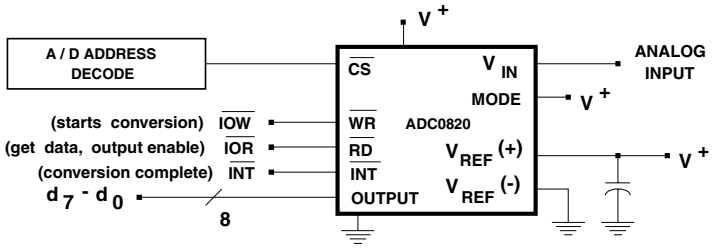

FIGURE 61.88 Write-controlled A/D that includes sample and hold.

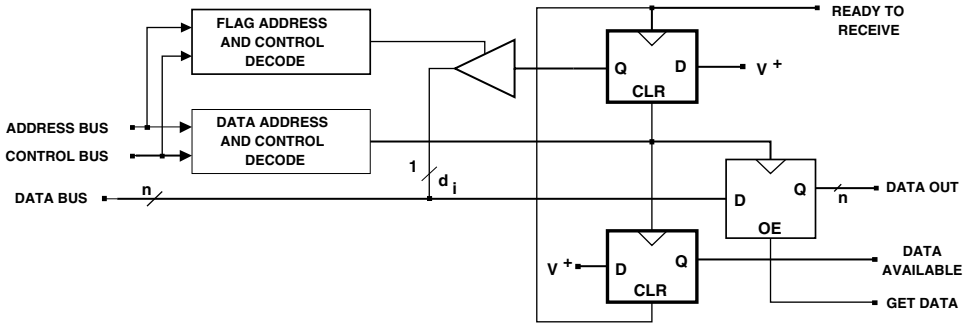

FIGURE 61.89 Output port with hand-shaking.

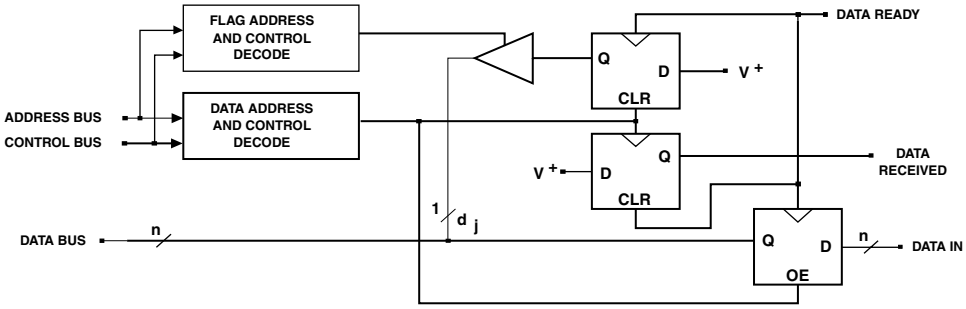

FIGURE 61.90 Input port with hand-shaking.

For data transfer from one system to another, the sender needs to know if the intended recipient is ready to receive data, and, if data has been sent, has it been received? To facilitate asynchronous transfer of data, consider the output interface shown in Fig. 61.89. This interface is the output port given in Fig. 61.84 and additional circuitry to support ready-to-receive and data-available flags. The sender can poll (obtain and check) the ready-to-receive flag by inputting the data at the address assigned to flags. If data bit d_i is reset, then continue polling the ready-to-receive flag. If it is set, then write data to the address assigned to be the data port, indivisibly reset the ready-to-receive flag, and set the data-available flag. Thus, the sender cannot find that the ready-to-receive flag is set until the recipient had found that the data-available flag is set, obtained the data, and set the ready-to-receive flag, however little or much time this takes. Notice that setting the ready-to-receive flag indivisibly resets the data-available flag. Therefore, the recipient cannot find that data is available until it is new data, however little or much time this takes. A provision must be made to clear (reset) these flags at system reset. The exchange of status information and the action among the flags is called hand-shaking. Figure 61.90 shows an input interface that includes hand-shaking. Here, too, a provision must be made to clear the flags at system reset.

© 2003 by CRC Press LLC

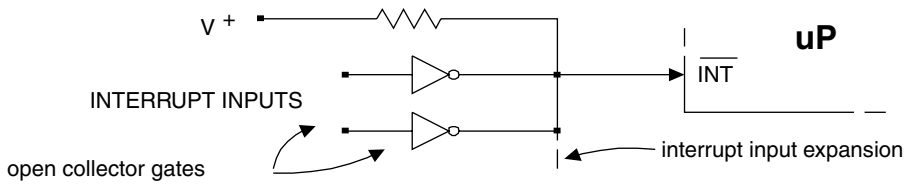

FIGURE 61.91 A wire OR'd circuit.

To accomplish data transfer, the I/O methods of Figs. 61.89 and 61.90 require that a program must continually poll the flags concerned with I/O. This works as long as the microprocessor is not required to do anything else. If the microprocessor must be used to do other tasks, then I/O can be serviced by either periodically polling I/O status flags or by using I/O status flags to interrupt the microprocessor while it is executing some program. Periodic polling of status flags may or may not be satisfactory. This depends on now much and how often I/O occurs.

Interrupt processing of the Z80, as well as the M68HC11, starts by asserting an interrupt input of the microprocessor. If more than one device must interrupt the microprocessor, then using a microprocessor with many interrupt inputs might be useful. Or, all interrupt sources can be wire OR'd with open collector gates, as shown in Fig. 61.91 to produce one interrupt signal. For example, the flip flop output for the ready-to-receive flag in Fig. 61.89, and the flip flop output for the data-ready flag in Fig. 61.90 could each be connected to an inverter input in Fig. 61.91. Either or both flags can then interrupt the processor. Any number of additional open collector gates could be added to include additional interrupt sources. By this method, the microprocessor discovers the occurrence of an interrupt, but must find out which device caused the interrupt.

If the Z80 is operating in direct interrupt mode, then the interrupt service routine, which starts at address 0038H, can input the status flags, check which flags are set, and respond with service priority determined by the software. Thus, any number of interrupts can be accommodated.

If the Z80 is operating in indirect vectored mode, then an interrupt causes it to respond with an active $\overline{\text{INTA}}$. The processor then accepts a byte from the data bus that must be provided by the interrupting device, and this byte, along with the content of the I register, is used as an address to get the service routine address from memory that is then loaded into the PC. Thus, the I register points to an interrupt vector table, and each interrupting device can point to the address of its own service routine.

If more than one interrupt source exists, then because only one device is allowed to drive the data bus, a priority must be established, in which the interrupting device with highest priority is serviced first. A daisy chain can be used so that hardware determines priority. This is shown in Fig. 61.92. The

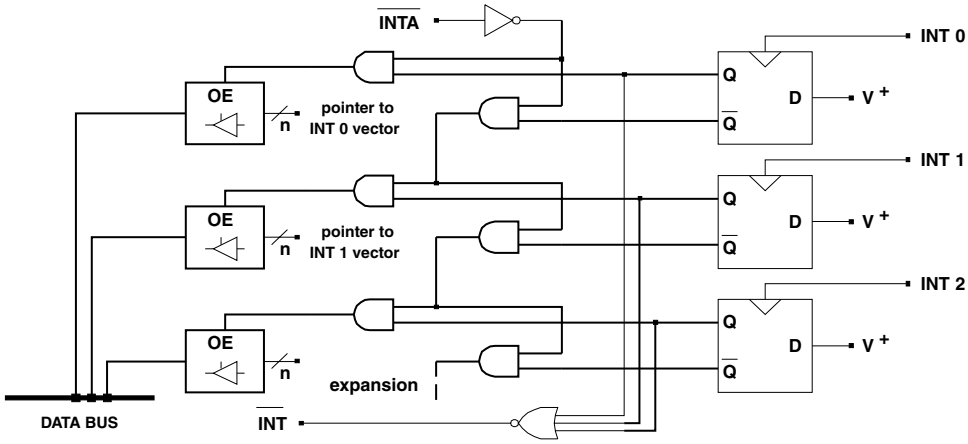

FIGURE 61.92 Priority with a daisy chain.

© 2003 by CRC Press LLC

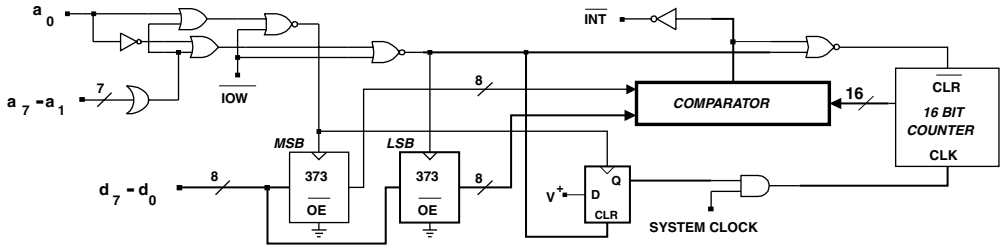

FIGURE 61.93 Timer-counter circuit.

device connected to the top of the chain has the highest priority. The $\overline{\text{INTA}}$ signal propagates down the chain until it is blocked by a set status flag. This condition is then used to place a response to $\overline{\text{INTA}}$ on the data bus.

In applications such as control, it is often necessary that a program keep track of elapsed time. This can be accomplished with a circuit like the one shown in Fig. 61.93. The 16-bit counter is clocked by the system clock or a clock derived from the system clock. The state of the counter is compared to the output of two registers, and a match, which clears the counter, is then used to interrupt the microprocessor. Thus, through I/O ports, software can set the time interval between interrupts, which can be disabled (a write to the LSB) or enabled (a write to the MSB), and thereafter the microprocessor can be periodically interrupted to perform tasks in real time.

Solutions to interfacing problems are not unique. Variables such as the number of I/O devices, I/O device characteristics, amount of I/O, required response times, hand-shaking, software and hardware trade-offs, cost of parts and eventual manufacture, etc. all influence interface design. Also, usually numerous options are available to solve a particular problem. All of this requires an understanding of system (microprocessor) bus activity to properly time the occurrence of data transfer events. Then there are issues of response to asynchronous events and status information about data transfer, polling and interrupt processing, and hardware and software tradeoffs.

Solutions to common I/O problems such as parallel I/O, serial I/O, timer functions, etc. are often available within single IC packages. Typically. manufacturers of microprocessors provide a family of compatible ICs for each microprocessor. This can simplify the design task and reduce package count. Also, to reduce package count, consideration should be given to combining gate-level hardware into a single package of a programmable logic device (PLD).

Design Using a Microcontroller

The M68HC11 is a microcomputer within a single IC package. It is available in a 48-pin DIP and a 52-pin LCC (leaded chip carrier). In addition to the microprocessor, it can be configured for a variety of resources within the same package. These additional internal resources can be ROM (PROM or EPROM), RAM, parallel I/O ports, serial I/O ports, EEPROM, timer, and an A/D converter. Through a reserved bank of 64 status/control and I/O registers, software can select modes of operation of this additional hardware from a multitude of options. With these additional resources, especially the timer and A/D converter, the device is also called a microcontroller.

The programming model of the M68HC11 is shown in Fig. 61.94. Registers A and B are both accumulators, and they can be used together as accumulator D for 16-bit add, subtract, multiply, and divide instructions. The machine language (op-codes), instruction set, and mnemonics are not the same as for Z80, and thus the M68HC11 has its own assembly language.

The microprocessor also has different modes of operation. One of four modes is determined by the inputs at two pins labeled MODA and MODB. These modes are MODB = 0, MODA = 0, special bootstrap, (01) special test (10) normal single chip, and (11) normal expanded. We now consider the single chip and expanded modes of operation.

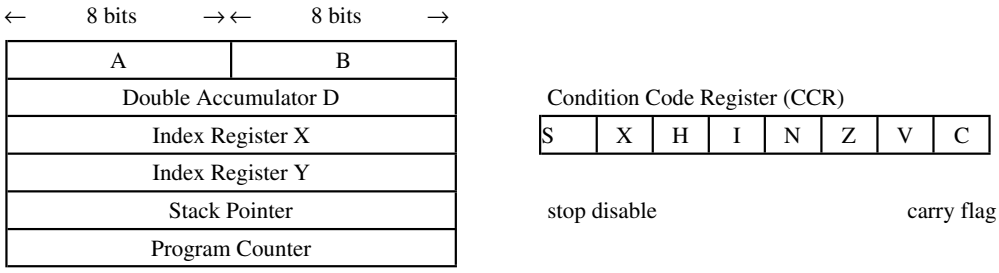

FIGURE 61.94 Programming model of the M68HC11.

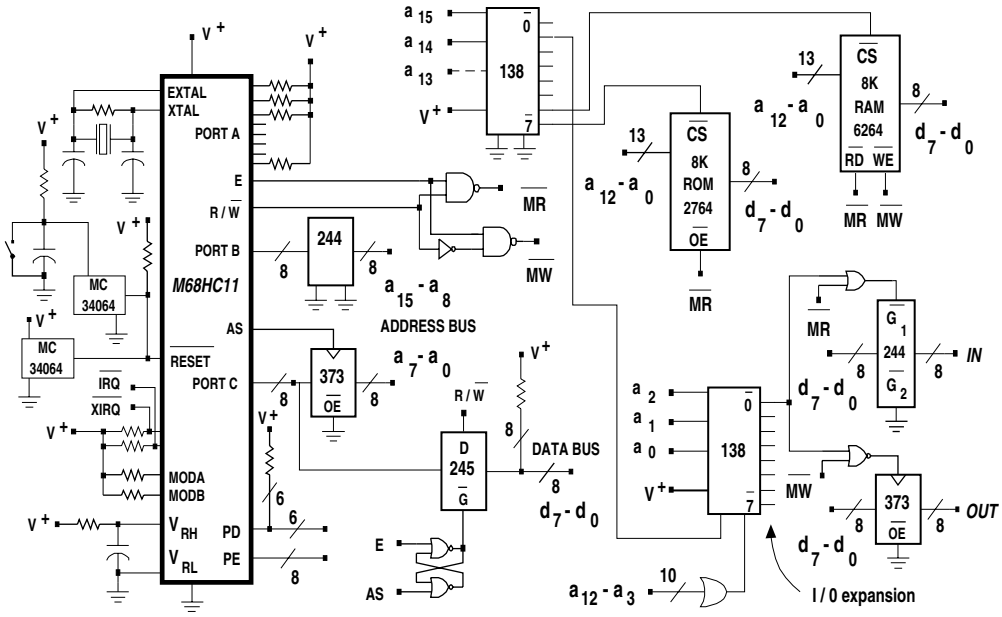

FIGURE 61.95 M68HC11A8-based microcomputer.

The M68HC11A8 is a version that has eight analog input channels, and in the normal expanded mode of operation its pin functions are shown in Fig. 61.95, which gives a diagram of a conventional microcomputer. Notice the selection of the normal expanded mode. For convenient reference, 38 of the 52 pins are grouped and labeled as follows: port A = pins 27 to 34, port B = pins 35 to 42, port C = pins 9 to 16, port D = pins 20 to 25, and port E = pins 43 to 50. The remaining pins are used for power supply (V_{SS} = pin 1 and V_{DD} = pin 26), the crystal for the internal clock circuit (pins 7 and 8), $\overline{\text{RESET}}$ (pin 17), nonmaskable interrupt ($\overline{\text{XIRQ}}$ = pin 18), maskable interrupt ($\overline{\text{IRQ}}$ = pin 19), control bus (AS = pin 4, E clock = pin 5, and R/$\overline{\text{W}}$ = pin 6), and analog input range (V_{RL} = pin 51 to V_{RH} = pin 52).

Port B provides the upper address byte. Port C is the data bus, and, to economize on the package pin count, the lower address byte is time multiplexed with the data bus. The control signal AS, for address strobe, signifies when the data bus contains the lower address byte. The 74HC373 captures the lower address byte when AS is active. Thus, the external system address bus consists of port B and the output of the octal latch. The remainder of the control bus consists of the R/$\overline{\text{W}}$ signal and the E clock signal, which has a frequency equal to one fourth of the system clock frequency.

Because all I/O is memory mapped, the timing of system bus activity is especially straightforward. Figure 61.96 shows M68HC11 timing for all external memory references. After the lower address byte has been captured, the E clock goes high, the data bus is available for data transfer, and the R/$\overline{\text{W}}$ signal

© 2003 by CRC Press LLC

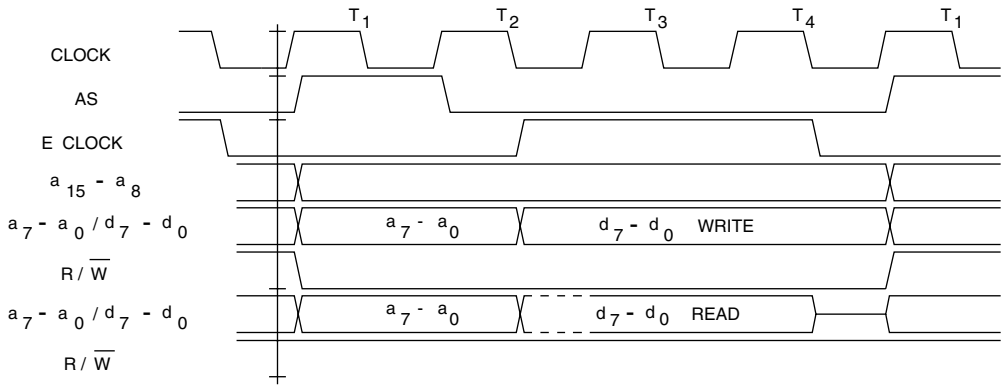

FIGURE 61.96 M68HC11 timing diagram for external memory references.

determines the direction. The E clock and the R/$\overline{W}$ signal together control read and write operations. During a read operation, the M68HC11 begins to follow the data bus at the leading edge of the E clock, and it accepts the content of the data bus at the trailing edge of the E clock. Thus, external hardware has slightly less than 2 clock cycles to provide valid data. During a write operation, the microprocessor begins to drive the data bus with valid data at the leading edge of the E clock. Thus, external hardware has slightly less than 2 clock cycles to follow the data bus, and at the trailing edge of the E clock it must accept the content of the data bus. All external memory references require one E clock cycle.

At power-up, an active low reset is accomplished with the MC34064 device in Fig. 61.95. The output of this device switches low whenever its input supply is below a particular limit, and the output goes into tristate whenever its input exceeds a particular limit. Upon reset, the microprocessor initializes internal registers to default conditions, and then it reads memory locations $FFFE and $FFFF to obtain the reset vector that it loads into the PC. Thus, a designer can locate code that is to be executed at reset almost anywhere in the memory space.

Interrupt processing occurs in a similar way. Just prior to fetching each op-code the microprocessor checks the $\overline{IRQ}$ input. If it is active, and if the I bit (interrupt mask) in the CCR is reset, then the microprocessor stacks nine bytes from registers in its programming model, disables further interrupts by setting the I bit, and then it reads memory locations $FFF2 and $FFF3 to obtain a vector that is loaded into the PC. The vector is the address of (points to) the first instruction of the $\overline{IRQ}$ interrupt service routine, which means that a designer can locate this service routine almost anywhere in the memory space.

The response to many interrupting sources can be handled in the same way as is illustrated by Figs. 61.89 to 61.91, where the flags of interrupting devices are wire OR'd into one interrupt input to the microprocessor. Then, upon an interrupt, the service routine must first find out which device caused the interrupt. The control bus does not provide any special means to accomplish this. Moreover, as the service routine responds to each interrupt, a provision must be made to clear each associated interrupting flag.

With the same vectored method, the M68HC11 is designed to accommodate numerous other external and internal sources of interrupts such as internal timer overflow, illegal op-code, software interrupt, nonmaskable interrupt, to name a few. Each interrupt is associated with two particular memory locations within the vector table, where its vector must be placed. This provides flexibility, and it does not require additional hardware for a reaction by an interrupting device to further control signals.

With the resources and method of interrupt processing of this microprocessor, the memory map of an M68HC11-based system is somewhat fixed. Figure 61.97 is the memory map of the system given in Fig. 61.95.

Through access to the system bus, additional memory and I/O ports can be added to this system. However, some restrictions exist. Internal address and control signal decoding positions the internal EEPROM block to start at memory location $B600. Because of its long write cycle time, we cannot store data into this memory with simply a regular memory write instruction. Nonvolatile memory must be

© 2003 by CRC Press LLC

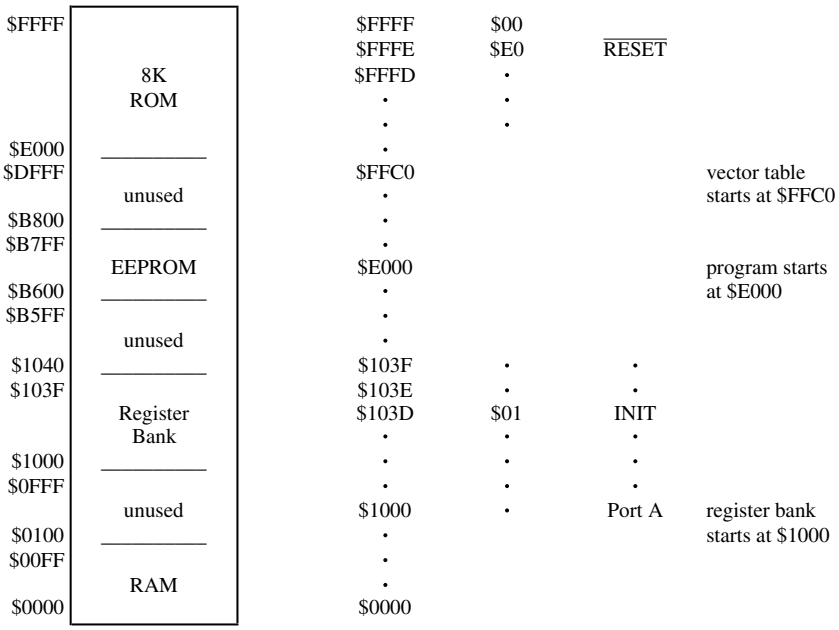

FIGURE 61.97 Memory map and sample ROM content.

located at the top end of the memory space to hold the vector table. The positions of the internal RAM and the control register block are programmable. The default locations are given in Fig. 61.97. They can be positioned to start at any 4*K* boundary according to the data stored in the INIT register, which has address $103D after reset.

Many pins of the M68HC11 serve more than one purpose. For example, the mode select inputs are read during reset to determine the mode of operation. Thereafter, MODA is an active low output that becomes active during the first E cycle of each instruction. This is useful for debugging to know when the data bus must hold an op-code. The MODB pin can be used to provide standby power to maintain the content of the internal RAM when V_{DD} is not present.

Port A can serve as three input pins (PA0 to PA2), four output pins (PA3 to PA6), and one pin (PA7) that can be configured for I/O depending on the data direction control bit labeled DDRA7 in the PACTL register at memory location $1026. From a programmer's viewpoint, port A is a memory register with address $1000, and the register that controls its I/O functionality is another memory register.

The M68HC11 has a free-running 16-bit counter that is clocked by the output of a programmable prescaler, which is clocked by the E clock. The two bytes of the counter can be read through buffers at locations $100E (high byte) and $100F (low byte). All M68HC11 timer functions are based on this counter. The 29 registers at locations $100B to $1027 are all concerned with using and configuring various kinds of timer functions. Thus, software can initiate a periodic real-time interrupt (RTI), which has an associated RTI vector located at $FFF0 and $FFF1.

Another purpose of port A is to provide access to some of these timer functions. For example, pins PA0 to PA2 can be used to measure the edge-to-edge time durations of incoming pulses. The M68HC11 contains circuitry for edge detection, and for each input the edge polarity that is to be detected is programmable. Also, for each input a unique interrupt vector location is associated with edge detection. Thus, to measure the period of a pulse train input at PA0, for example, the counter state must be captured upon an edge detection. For PA0, counter capture is controlled by the IC3F flag in register TFLGI at location $1023. Registers at locations $101A and $101B receive the counter state. For PA0, edge detection interrupt is enabled with the IC3I flag in register TMSKI at location $1022. The vector for this interrupt is located at $FFEA and $FFEB. If the I bit in the CCR is reset, then an edge at PA0 will receive interrupt

© 2003 by CRC Press LLC

service, which should read the captured counter. Comparing counter states from successive edges of the same polarity can then be used to find the period.

Port D can serve as a general purpose 6-bit I/O port with address $1008. The direction of each bit is programmable through the DDRD register at location $1009. When serial communication is enabled, this port provides asynchronous serial input (R × D) at PD0 and serial output (T × D) at PD1. The baud rate is controlled by the contents of the BAUD register at location $102B. The five registers at locations $102B to $102F are all concerned with using and configuring asynchronous serial communication. From a programmer's viewpoint, serial input and output are accomplished by a parallel read from and parallel write to memory location $102F, respectively. Actually, two responsive registers at this address are distinguished by the R/$\overline{W}$ signal.

The other four pins of port D provide synchronous, high-speed serial communication. Pins PD3 and PD2 are used for transmitting and receiving serial data, respectively. Pin PD4 carries a clock signal to synchronize data transfer, and pin PD5 can be used to indicate the start of a data transfer. The three registers at locations $1028 to $102A are all concerned with using and configuring synchronous serial communication. To reduce package size, pin count, and communication paths, there are numerous devices that use serial I/O. Through port D, the M68HC11 can communicate with, for example, serial LED/LCD display drivers, serial data out A/D converters, serial in/out EEPROMs, or even another microprocessor.

Port E can serve as an 8-bit digital input port with address $100A. These inputs are also each connected to a sample and hold circuit and then to an eight-channel analog multiplexer, the output of which goes to a successive approximation A/D converter. The A/D converter produces an unsigned 8-bit number that is proportional to a DC voltage in the range of V_{RL} to V_{RH}. An analog input equal to V_{RL} (V_{RH}) yields an A/D conversion result of $00 ($FF). Each A/D conversion requires 32 E clock cycles. Flags in register ADTCL at location $1030 control A/D conversion. Four consecutive conversions of a single channel or one conversion of each of the lower four or the upper four channels can be obtained, depending on flags in the ADCTL register. A/D conversion results are available from registers at locations $1031 to $1034.

Without question, the M68HC11 is a composite machine with many options among its numerous features under software control. Features such as software security, failure detection and recovery, power-down/standby, and others have not been discussed.

In the single chip mode in Fig. 61.98, ports B and C and the control signals serve other purposes. Here, port B is an 8-bit output port with address $1004. Pin 6, which is the R/$\overline{W}$ signal in the expanded mode, can now be configured as an output strobe (STRB) that produces a pulse whenever a write to

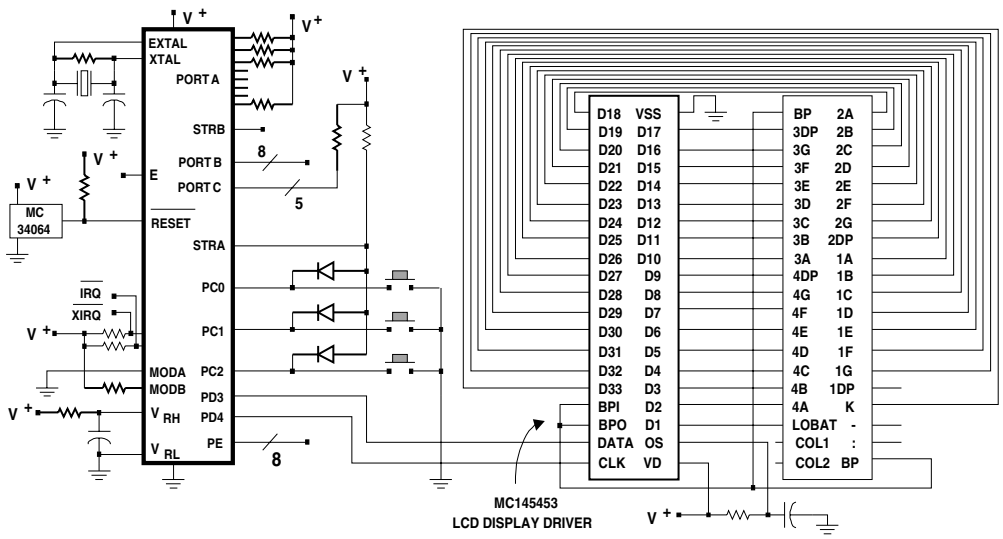

FIGURE 61.98 M68HC11 microcontroller used for a 3-button and 4-digit LCD display device.

© 2003 by CRC Press LLC

$1004 (port B) occurs. Port C is a general purpose I/O port with address $1003, and its data direction is controlled by the DDRC register at location $1007. The eight pins of port C also go to a register with address $1005. Pin 4, which is the AS signal in the expanded mode, is now an input strobe (STRA). An edge, the polarity of which is programmable, at this input will cause the data at the port C pins to be latched into the register PORTCL with address $1005. Full hand-shaking is implemented, because when data is latched into the PORTCL register, the flag STAF in status register PIOC at location $1002 becomes set, and after both the flag and PORTCL have been read, the flag becomes reset.

In a single-chip mode, one can have as many as 27(12) output bits and 11(26) input bits, depending on data direction control or fewer I/O bits if some of these pins are used for A/D, serial communication, or timer functions. Moreover, software must reside in the internal 8*K* byte ROM of the M68HC11A8 or the internal 12*K* byte ROM of the M68HC11E9. Like external ROM, this ROM is positioned at the top end of the memory space. It must receive its content at the time of manufacture. With some restrictions, it can be enabled or disabled by the ROMON flag of the CONFIG register at location $103F. This is a special 1-byte EEPROM so that it will retain its content through power-down and power-up cycles. The M68HC711E9 is an EPROM version of the M68HC11E9. The EPROM can be programmed/erased in the field for development in the single chip mode. There is also an OTP (one time programmable) version of the E9. Several other members of the M68HC11 family of microcontrollers have varying amounts of hardware resources.

Recently, the M68HC11 evolved into the M68HC12. In addition to more of the resources available in the M68HC11, the M68HC12 has two expanded modes of operation using either an 8-bit or a 16-bit data bus. Most noteworthy of this processor is its extensive and complex instruction set. In particular, there are instructions that make it convenient to implement fuzzy logic controllers, including fuzzification, inference engine, and defuzzification computing.

In contrast to the evolution of the M68HC11, the MSP430 microcontroller family from Texas Instruments has a very small instruction set, like a RISC machine, with instructions executing in single clock cycles. With its 14-bit A/D converter and fast multiply and accumulate instructions, it can be applied to do low frequency digital signal processing. Operating on 3 volts, this processor is particularly well suited for low voltage, low power consumption, and portable applications.

The M68HC12 and MSP430 microcontroller families are available with a variety of resources including ROM, RAM, EEPROM, parallel and serial I/O, A/D conversion, timers, and more within a package. An MSP430 can even include an LCD driver and flash memory. When packaged hardware resources can match application requirements, economical and compact hardware designs can be achieved.

Design Guidelines

Looking back at Fig. 61.67, we see that its simplicity is deceptive. Nonetheless, in view of Fig. 61.98 or even Fig. 61.84, Fig. 61.67 represents the typical embedded microprocessor application. To use a microprocessor requires an awareness of what may seem like an untold amount of information (facts). This should not and cannot be avoided. Time spent in the beginning learning the details will likely save time and expense that may have been spent later making revisions. Here, we have raised only a few issues to explore the possibilities.

As we look at different processors we find that while the programming model, instruction set, and hardware resources change, hardware design is concerned mostly with interfacing to achieve electrical, timing, and functional compatibility. Some important principles carry over from one microprocessor to another. It is a component that is fundamentally intended to provide trade-offs between hardware and software. This is a matter of degree, and will vary from one application to another. Much care must be taken to suitably allocate the hardware/software trade-offs. Software and hardware development tools such as software simulators, hardware in circuit emulators, logic analyzers, cross-assemblers and cross-compilers, real-time kernels, and others are necessary to be competitive in product development. Software will likely carry the greater burden to achieve a product that functions according to a desired mode of operation, and it will also incur the greater development cost.

61.5 Systolic Arrays

Kung Yao and Flavio Lorenzelli

Concurrency, Parallelism, Pipelining, and Systolic Array

Motivations and Definitions

Real-time high throughput rate processing constitutes one of the most demanding aspects of modern digital signal processing. In order to achieve the desired throughput rate, various forms of concurrent operations are needed. **Concurrency** denotes the ability of a processing system to perform more than one operation at a given time. Concurrency can be achieved through either parallelism or pipelining, or both. **Parallelism** addresses concurrency by replicating some desired processing functions many times. High throughput rate is achieved by having simultaneous operations performed by these functions on different parts of the program. On the other hand, **pipelining** tackles concurrency by breaking some demanding part of the task into many smaller simpler pieces, with many corresponding processing elements (PE), so that processing can be performed in a pipeline manner. This digital pipe is arranged so that it is capable of processing the instructions and data independent of the number of PEs in the pipe. Then, high throughput rate can be achieved by having fast PEs in the pipe. As we shall see, a systolic array can exploit both the parallelism and pipelining capability of some algorithms.

The term **systolic array** was coined by Kung and Leiserson [2] to denote one simple class of concurrent processors, in which processed data move in a regular and periodic manner similar to that of the systolic pumping action of the blood by the heart. The earlier definition of a systolic array by Kung [3] requires: (1) only a small class of PEs is in the array, with each element in a class performing identical operation; (2) all operations are performed in a synchronous manner independent of the processed data — the only control data broadcast to the PEs is the synchronous clock signal; and (3) the PEs have only nearest-neighbor communications. These regular structure and local communication properties of a systolic array are consistent with efficient modern VLSI designs. Later, various extensions of these assumptions were made: (1) Some of the PEs can perform a limited number of different functions, depending on the presence of some control data; (2) wavefront array allows PEs to start/end/control their own processing tasks, depending on the data; (3) PEs can have communications to few nearby neighbors; wraparound communications among PEs located at the edge of the array are allowed.

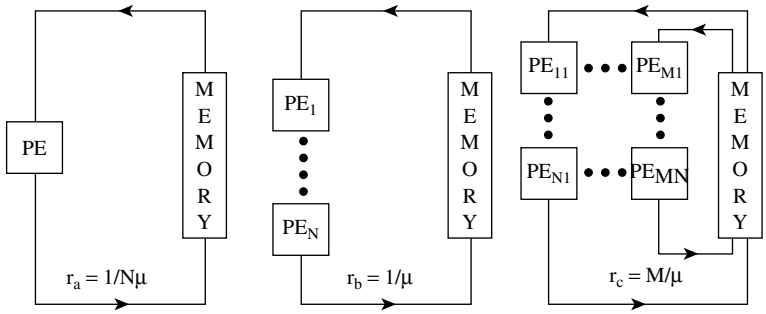

FIGURE 61.99 (a) A uniprocessor system; (b) a linear systolic array; (c) a rectangular systolic array.

Systolic arrays can be designed as linear arrays or two-dimensional rectangular or triangular arrays. In Fig. 61.99(a), consider a uniprocessor system requiring μ time unit to complete a basic operation. If some task requires N such repeated identical operations, the effective throughput rate of this system is given by $r_a = 1/N\mu$. In Fig. 61.99(b), consider a linear array consisting of a single pipe with N such PEs. Then the rate of this linear systolic array is given by $r_b = 1/\mu$. This demonstrates the pipelining aspects of the array. In Fig. 61.99(c), consider a rectangular array consisting of M pipes, with each pipe having N PEs. The rate of this rectangular systolic array is given by $r_c = M/\mu$. This demonstrates both the pipelining and parallelism of the array. While the three models in Fig. 61.99 are overly simple, nevertheless they demonstrate the fact that if a given task can be designed for systolic processing, different systolic arrays can yield significantly higher throughput rates as compared to a uniprocessor of a given capability. This is the most basic aspect of systolic processing in which a higher hardware complexity is traded for a higher throughput rate.

Systolic Arrays for Correlation

Consider the linear correlation of a data sequence $\{x_1, x_2, \ldots, x_M\}$ with a weight sequence $\{a_1, a_2, \ldots, a_N\}$ to yield an output sequence $\{y_1, y_2, \ldots, y_{M-N+1}\}$ given by $y_i = a_1x_i + a_2x_{i+1} + \ldots + a_Nx_{i+N-1} = \sum_{j=1}^{N} a_j x_{i+j-1}$, $i = 1, 2, \ldots M - N + 1$. For the case of $N = 3$ and $M > N$, we have

$$
\begin{aligned}
y_1 &= a_1x_1 + a_2x_2 + a_3x_3 \\
y_2 &= a_1x_2 + a_2x_3 + a_3x_4 \\
y_3 &= a_1x_3 + a_2x_4 + a_3x_5 \\
&\vdots
\end{aligned}
$$

Here, we show two of many possible systolic arrays that can implement the above correlation operations. Design B1 in Fig. 61.100(a) uses three identical PEs to perform the accumulation (multiply and add) operation. Here, the weights a_i are preloaded to the cells and stay throughout the computation. Partial results y_i move systolically from cell to cell. Starting at the third iteration, $y_1, y_2, \ldots$, are outputted from the rightmost cell at the rate of one output per iteration. For each iteration, a x_i is broadcast to all the cells, and a y_i, initialized to zero, enters the leftmost cell. The broadcasted data x_i is marked with an arrow ↓ in Table 61.12. Indeed, by comparison we see y_1, y_2, and y_3, outputted at iteration $T = 3$, 4, and 5, agree with those given from the correlation equations.

In design B2, shown in Fig.61.100(b), each input x_i is again broadcasted to each cell, each y_i stays at each cell to accumulate terms, while the weights a_i circulate around the cells in the array. A tag bit is associated with a_1 to reset the contents of the accumulator, while a tag bit is associated with a_3 to output the contents of the accumulator after the first two iterations. Data movements in design B2 are shown in Table 61.13. Note that resets occur at cell 1 at iteration 1, cell 2 at iteration 2, cell 3 at iteration 3, cell

$T = 1$	$\downarrow x_1 a_1$	$\downarrow x_1 a_2$	$\downarrow x_1 a_3$
$T = 2$	$\downarrow x_2 a_1$	$a_1 a_1 + \downarrow x_2 a_2$	$x_1 a_2 + \downarrow x_2 a_3$
$T = 3$	$\downarrow x_3 a_1$	$x_2 a_1 + \downarrow x_3 a_2$	$x_1 a_1 + x_2 a_2 + \downarrow x_3 a_3 \rightarrow y_1$
$T = 4$	$\downarrow x_4 a_1$	$x_3 a_1 + \downarrow x_4 a_2$	$x_2 a_1 + x_3 a_2 + \downarrow x_4 a_3 \rightarrow y_2$
$T = 5$	$\downarrow x_5 a_1$	$x_4 a_1 + \downarrow x_5 a_2$	$x_3 a_1 + x_4 a_2 + \downarrow x_5 a_3 \rightarrow y_3$

TABLE 61.13 Data Movement in Design B2

Iteration	Cell 1	Cell 2	Cell 3
$T = 1$	$0 + a_1 \downarrow x_1$	$a_3 \downarrow x_1$	$a_2 \downarrow x_1$
$T = 2$	$a_1 x_1 + a_2 \downarrow x_2$	$0 + a_1 \downarrow x_2$	$a_2 x_1 + a_3 \downarrow x_2$
$T = 3$	$a_1 x_1 + a_2 x_2 + a_3 \downarrow x_3 \rightarrow y_1$	$a_1 x_2 + a_2 \downarrow x_3$	$0 + a_1 \downarrow x_3$
$T = 4$	$0 + a_1 \downarrow x_4$	$a_1 x_2 + a_2 x_3 + a_3 \downarrow x_4 \rightarrow y_2$	$a_1 x_3 + a_2 \downarrow x_4$
$T = 5$	$a_1 x_4 + a_2 \downarrow x_5$	$0 + a_1 \downarrow x_5$	$a_1 x_3 + a_2 x_4 + a_3 \downarrow x_5 \rightarrow y_3$

4 at iteration 4, etc. Similarly, output y_1 occurs from cell 1 at iteration 3, y_2 from cell 2 at iteration 4, y_3 from cell 3 at iteration 5, etc.

Systolic Array Design Techniques

Systolic array designs, as shown above for the correlation case, can be obtained by ad hoc approaches. More formal procedures for the systematic design of systolic arrays have been proposed by Moldovan [7], Quinton [9], Kung [5], Rao [10], Darte and Delosme [1] and others. All those more formal procedures are collectively referred to as dependence graph mapping techniques for systolic array design.

In this approach, an algorithm must be formulated in the **single assignment algorithm** form. Each variable has a unique value during the evaluation of the algorithm. Those variables with multiple values can be converted to single values by vectorizing the variables through the introduction of new indices.

© 2003 by CRC Press LLC

As an example, consider the matrix multiplication of $C = AB$, where $A = [a_{ik}]$ is $N_1 \times N_3$, $B = [b_{kj}]$ is $N_3 \times N_2$, and $C = [c_{ij}]$ is $N_1 \times N_2$. A conventional formulation of this algorithm contains the expression, $c_{ij} = c_{ij} + a_{ik}\, b_{kj}$ for $i = 1$ to N_1, $j = 1$ to N_2, and $k = 1$ to N_3. We note, c_{ij} has multiple values for $k = 1, \ldots, N_3$. We can modify it to have single values by replacing it by the variable c_{ijk}. The previous equation for c_{ij} then becomes $c_{ijk} = c_{ij(k-1)} + a_{ik}\, b_{kj}$, $c_{ij0} = 0$, c_{ijN_3}, $i = 1, \ldots, N_1$, $j = 1, \ldots, N_2$, $k = 1, \ldots, N_3$.

All algorithm variables are assumed to be indexed variables with V variable names, denoted by the generic names of V_m, $1 \le m \le V$. In the above matrix–matrix multiplication problem $V = 3$, and we can take $X_1 = c$, $X_2 = a$, and $X_3 = b$. For each variable name, the domain of the index vectors is a subset in an S-dimensional space. This subset is called the algorithm's **index space** and S is its dimension. For most iterative signal processing problems, time is usually one of the index space coordinates. For the preceding matrix–multiplication problem, we need to propagate a_{ik} across the j variables as well as b_{kj} over the i variables in order to perform the basic multiplication operation. These and a_{ik} and b_{kj} are propagating variables because they involve no computations, but need to be made available at various stages of the computation. In the matrix–matrix problem, clearly $S = 3$ and the index space is $\mathbf{S}_0 = \{(i, j, k): 1 \le \mathrm{i} \le N_1, 1 \le j \le N_2, 1 \le k \le N_3,\}$. Furthermore, the initializations of the new variables are given by $a(i, 0, k) = a_{ik}$, $b(0, j, k) = b_{jk}$, $c(i, j, 0) = 0$, $c(i, j, N_3) = c_{ij}$, and the algorithm is finally given by $a(i, j, k) = a(i, j, -1, k)$, $b(i, j, k) = \mathrm{a}(i-1, j, k)$, $\mathrm{c}(i, j, k) = c(i, j, k-1) + a(i, j, j)b(i, j, k)$, for $(i, j, k) \in \mathbf{S}_0$.

In general, a point (or node) in the index space is called an **index point**. Thus, $X_m(I)$ is the variable X_m defined at the index point I. A dependence graph mapping is a representation of a single assignment algorithm, where the dependencies among the variables are represented by directed arcs among the nodes. A basic property of the class of algorithms of interest is that of **shift-invariance**.

An algorithm is shift-invariant if the dependence graph is regular. That is, $X(I)$ depends on $Y(J)$, then $X(I + K)$ depends on $Y(J + K)$ for all I, J, and K in the index space. Three well-known shift-invariance algorithms include:

1. Uniform recurrence equations (URE): $X_1(I) = F_1(X_1(I - D_1), \ldots, X_V(I - D_V))$, $X_\mathrm{i}(I) = X_i(I - D_i)$, $2 \le i \le V$. Computation occurs only in $F_1(\cdot)$ and propagations in all the other variables, Clearly, the final form of the above matrix–matrix multiplication algorithm is a URE algorithm with $V = 3$, $F_1(\cdot) = c(i, j, k)$, with $X_1(\cdot) = c(\cdot)$, $X_2(\cdot) = a(\cdot)$, $X_3(\cdot) = b(\cdot)$, $I = (i, \mathrm{i}, k)$, $D_1 = [0, 0, 1]^T$, $D_2 = [0, 1, 0]^T$, and $D_3 = [1, 0, 0]^T$.
2. Generalized uniform recurrence equations (GURE): $X_m(I) = F_m(X_{m_1}(I - D_{m_1}), \ldots, X_{m_{k(m)}}(I - D_{m_{k(m)}}))$, $1 \le m \le V$, where $m_1, \ldots, m_{k(m)}$, belongs to $\{1, \ldots, m\}$. In GURE we can have computations in all V functions of $F_m(\cdot)$. The number of independent variables $m_{k(m)}$ depends on each m. The shift index dependence, $I - D_{m_i}$, is fixed for each X_{m_i}.
3. Regular iterative algorithm (RIA): $X_m(I) = F_m(X_{m_1}(I - D_{m_1, m}), \ldots, X_{m_{k(m)}}(I - D_{m_{k(m)}m}))$, $1 \le m \le \mathrm{V}$. Here, the shift index dependency, $I - D_{m_i, m}$, is not fixed but is a function of m_i and m.

Each processor of the systolic array is assumed to have all the necessary computational modules to compute $F_m(.)$. For URE, we need only one such module, but for GURE and RIA, we need V modules. The time required for the computation of $F_m(\cdot)$ is denoted by τ_m, and the minimum time between such computations is denoted by h_m. In most cases, we can set τ_m and h_m to unity. The design of a processor array to perform the algorithm requires spatial and temporal assignments. Each $X_m(I)$ must be assigned to a processor at each integral time slot. The processor **allocation function**, $A(I)$ assigns all variables with the index I to the processors in the array. The **scheduling function**, $S_m(I)$, assigns the start of the computation for the variable $X_m(I)$. The simplest form of scheduling and processor allocations are based on the projection of the high multidimensional dependence graph onto the lower dimensional processor array. Variables represented by nodes in the dependence graph are mapped to processors which perform the computations. The directed arcs of the dependence graphs are transformed to physical communication links in the processor array.

The essence of the allocation function $\mathrm{A}(\cdot)$ is thus to return for every index value $\mathrm{I} \in \mathbf{S}_0$ a vector which indicates the processor in charge of the computation represented by a point in a lower dimensional space. Analogously, the scheduling function $S_m(\cdot)$ provides the relative start of the execution for the computation

© 2003 by CRC Press LLC

indexed by I. These two functions cannot be chosen independently because two computations assigned to the same processor cannot be scheduled for the same time (**compatibility constraint**). Additional details on this constraint are given later. While in principle $A(\cdot)$ and $S_m(\cdot)$ can be any function, we shall consider only **affine functions**, in the sense that $A(I) = , A^{\mathrm{T}}I$, $S_m(I) = \lambda^T i + \gamma_m$, where A is a suitable matrix, λ a vector, and γ_m an integral constant.

The dependence graph of an algorithm can be interpreted as a *lattice* embedded in a multidimensional integral space (i.e., a proper bounded subset of $\mathbf{Z}^s$, where $\mathbf{Z}$ is the set of relative integers), enclosed in a convex polyhedron. We assume the lattice to be "dense" in the sense that all the integral points in it correspond to actual computations. The whole procedure of mapping an algorithm onto a systolic-type processor consists of two conceptually different but interdependent operations of using a space transformation and a time transformation. The former actually *projects* the dependence graph onto a lower dimensional structure which then can be mapped one-to-one onto the physical array, while the latter gives the start of the execution of each computation.

For simplicity, consider the projection of the S-dimensional space onto an $(S - 1)$ dimensional processor space. The more general problem of projecting the dependence graph onto an $(S - p)$-dimensional space ($p \geq 1$) can be expressed using a similar but more involved notation and is omitted here. Instead of considering allocation functions, we refer to the *projection vector* u, which is orthogonal to the processor space onto which we project. Assume that we have chosen both the projection and the scheduling vectors (u and λ, respectively). For normalization purposes, they are chosen to be coprime vectors, such that the greatest common divisor of their components is 1, and their first nonzero element is positive.

Two sets of constraints must be satisfied by u and λ. Assume nodes I and J are located along a direction parallel to the projection vector u such that $J = I + \alpha u$, $\alpha \in \mathbf{Z}$. Then, the computations associated with the two nodes will be projected onto the same processor. Consequently, compatibility constraint requires that they be performed at different times. Analytically, this is equivalent to $|\lambda^{\mathrm{T}} u| \; \lambda \; max_{m=1,\ldots,V} h_m$, which for $h_m = 1$ simplifies to $|\lambda^{\mathrm{T}} u| > 0$. Thus, for this case λ and u cannot be perpendicular. Furthermore, the quantity $c \triangleq |\lambda^{\mathrm{T}} u|$ represents the number of time slots between successive calculations scheduled on the same processor. $1/c$ is sometimes called the **efficiency** of the processors because the larger the c, the more time the processors can idle. One common approach is to select the projection vector and the scheduling vector so as to achieve the highest efficiency, with c being as close to 1 as possible.

Consider the case in which the variable $X_m(I)$ depends on $X_n(I - D_{nm})$. The **precedence constraint** implies the calculation of $X_n(I - D_{nm})$ must be scheduled so as to be completed before the start of the calculation of $X_m(I)$. Analytically, the precedence constraint is equivalent to $\lambda^{\mathrm{T}} D_{nm} + \gamma_m - \gamma_n \geq \tau_n = 1$, for all $1 \leq m \leq v$ and for all dependences D_{nm}. If the γ constants are chosen to be all equal, the precedence constraint becomes $\lambda^{\mathrm{T}} D_{nm} \geq 1 \forall m = 1, \ldots, V$.

Assume the precedence and compatability constraints are satisfied and λ and u are coprime vectors. Then it is possible to extend both vectors to two unimodular matrices. A matrix with integral entries is called **unimodular** when its determinant is equal to ± 1. This implies that they admit integral inverses. The unimodular extension of coprime vectors is not unique. We will choose U and Λ to be the unimodular extended matrices that have u and λ, respectively, as their first columns. It is possible to show that the columns of any S-dimensional unimodular matrix can constitute a basis for the space Z^S. Moreover, if we denote $\sigma_1, ..., \sigma_s$ to be the columns of $\sum = U^{-\mathrm{T}}$, then we have $\sigma_1^{\mathrm{T}} u = 1$ and $\sigma_1^{\mathrm{T}} u = 0$ for all $i = 2, \ldots, S$. Therefore, $\{\sigma_2, \ldots, \sigma_s\}$ will be a basis of the processor space of the resulting logic array. Similarly, the first column of T (the inverse of Λ^T) t_1, represents the direction in which time increases by one step; i.e., it is the vector defining the hyperplane of the points computed at the same time. The other columns of T (denoted by $t_2, \ldots, t_s$) are a basis of such a hyperplane.

If we denote by $\sum_+ = [\sigma_2, \ldots, \sigma_s]$ the matrix basis of the processor space, the allocation function and the scheduling function have the form $A(I) = \sum_+^{\mathrm{T}} I$, $S_m(I) = \lambda^{\mathrm{T}} I + \gamma_m$, $m = 1, \ldots, V$. With these elements we can have the complete description of the final array. The processors are labeled by $A(I) = \sum_+^{\mathrm{T}} I$ as I ranges over the index space. The dependences D_{nm} are mapped onto communication links $\sum_+^{\mathrm{T}} D_{nm}$ and the delay registers on such links must be in number equal to $\lambda^{\mathrm{T}} D_{nm} + \gamma_m - \gamma_n - \tau_n = \lambda^{\mathrm{T}} D_{nm} - 1$.

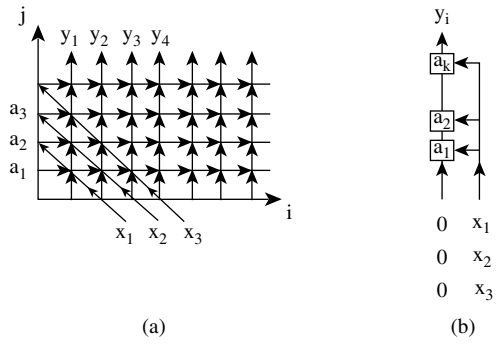

FIGURE 61.101 (a) Two-dimensional dependence graph; (b) one-dimensional dependence graph.

Reconsider the systolic correlation problem using the weights $\{a_1, \ldots, a_k\}$ and the data $\{x_1, \ldots, x_n\}$, as discussed earlier. Recall the correlation is given by $y_i = a_1 x_i + a_2 x_{i+1} + \ldots + a_k x_{i+k-1}$, $1 \le i \le n + 1 - k$. A recurrence equation formulation of this equation is given by $y(i, j) = y(i, j - 1) + w(i, j)x(i, j)$, $y(i, 0) = 0$, $y_i = y(i, k)$; $w(i, j) = w(i - 1, j)$, $w(1, j) = a_j$; and $x(i, j) = x(i+1, j - 1)$, $x(i, 0) = x_{i-1}$, all with $1 \le i \le n + 1 - k$, $1 \le j \le k$. A dependence graphical representation of these equations is shown in Fig. 61.101(a).

A URE reformulation of the recurrence equations yields $X_1(I) = y(i, j) = F_1(X_1(I - D_1), X_2(U - D_2), X_3(I - D_3))$, $X_2(I) = w(i, j) = X_2(I - D_2)$, $X_3(I) = x(i, j) = X_3(I - D_3)$, with the index point $I = [i, j]^T$ and displacement vectors $D_1 = [0, 1]^T$, $D_2 = [1, 0]^T$, and $D_3 = [-1, 1]^T$. In particular, consider the URE representation of the B1 design based on the choice of $u = [1, 0]^T$, $\sum_+ = [0, 1]^T$, $\lambda = [1, 1]^T$, $\gamma_m = 0$, $m = 1, 2$, and 3, and $\tau_n = h_n = 1$, $n = 1, 2$, and 3. Then, the two-dimensional graph of Fig. 61.101(a) is projected onto the one-dimensional graph of Fig. 61.101(b). Specifically, for any index $I = [i, j]^T$, the processor allocation function yields $A(I) = \sum_+^T I = j$, $i \le j \le k$, which is a valid projection from two-dimensions to one. On the other hand, the index point for each input data x_1 (with variable name of X_3) is given by $I = [i, l - i + 1]^T$, $l = 1, \ldots, n$. Then the scheduling function $S_3(I)$ is given by $S_3(I) = \lambda^T I = [1, 1]\ [i, l - i + 1]^T = i + l - i + 1 = l + 1$, $l = 1, \ldots, n$. This indicates each x_1 for the previously given I must be available at all the processors at time $l + 1$. Thus, there is no propagation and this means all the x_1 must be broadcasted to all the processors. However, the simplistic definition of a systolic design does not allow broadcasting. Indeed, the precedence constraint is *not* satisfied with D_3. That is, $\lambda^T D_3 = [1,1][-1, 1]^T = 0 \not\ge \tau_n = 1$. Of course, other choices of λ and u generate other forms of systolic array architecture for correlation. For more complicated signal processing tasks such as QR decomposition, recursive least-squares estimation, singular value decomposition, Kalman filtering, etc., the design of efficient systolic array architectures are generally difficult. The dependence graph mapping technique provides a systematic approach to such designs by providing the proper selections of these λ and u vectors.

Digital Filters

The application of digital filtering has spread tremendously in recent years to numerous fields, such as signal processing, digital communications, image processing, and radar processing. It is well known that the sampling rate, which is closely related to the system clock, must be higher than the Nyquist frequency of the signals of interest. It follows that in order to perform real-time filtering operations when high frequency signals are involved, high-speed computing hardware is necessary.

Pipelining techniques have been widely used to increase the throughput of synchronous hardware implementations of a transfer function of a particular algorithm. Most algorithms can be described in a number of different ways, and each of these descriptions can be mapped onto a set of different concurrent architectures. Different descriptions may lead to realizations with entirely different properties, and can have a dramatic impact on the ultimate performance of the hardware implementation. Pipelining can also be used for other than throughput increase. For a fixed sample rate, a pipelined circuit is characterized by a lower power consumption. This is due to the fact that in a pipelined system capacitances can be

© 2003 by CRC Press LLC

charged and discharged with a lower power supply. Because the dissipated power depends quadratically on the voltage supply, the power consumption can be reduced accordingly.

An increase in the speed of the algorithm also can be achieved by using *parallelism*. By replicating a portion of the hardware architecture, similar or identical operations can be performed by two or more concurrent circuits, and an intelligent use of this hardware redundancy can result in a net throughput increase, at the expense of area. Note that VLSI technologies favor the design in which individual sections of the layout are replicated numerous times. A regular and modular design can be achieved at relatively low costs. For a fixed sample rate, parallelism can be exploited for a low power design due to the reduced speed requirements on each separate portion of the circuit.

Much work has been done in the field of systolic synthesis of finite and infinite impulse response (FIR/IIR) filters, as can be seen from the literature references. In the following subsection, we consider possible strategies that can be used to increase the throughput of the concurrent architectures of the FIR and IIR filters.

Finite Impulse Response Filters

Finite impulse response (FIR) filters have been largely employed because of certain desirable properties. In particular, they are always stable, and causal FIR filters can posses linear phase. A large number of algorithms have been devised for the efficient implementation of FIR filters, which minimize the number of multipliers, the round-off noise, or the coefficient sensitivity. The generic expression that relates the output $y(n)$ at time n to the inputs $x(n\text{-}i)$ at times $(n\text{-}i)$ $i = 0,1, \ldots, q$ is given by

$$y(n) = \sum_{i=0}^{q} a_i x(n-i)$$

where the $\{a_i\}_{i=0}^{q}$ are the FIR filter coefficients. Here, we consider only issues of pipelining and parallelism.

The pipeline rate, or throughput, of implemented nonrecursive algorithms such as FIR filters can be increased without changing the overall transfer function of the algorithms by means of a relatively simple modification of the internal structure of the algorithm. In particular, one set of latches and storage buffers can be inserted across any feed-forward cutset of the data flow graph. Figure 61.102(b), illustrates the

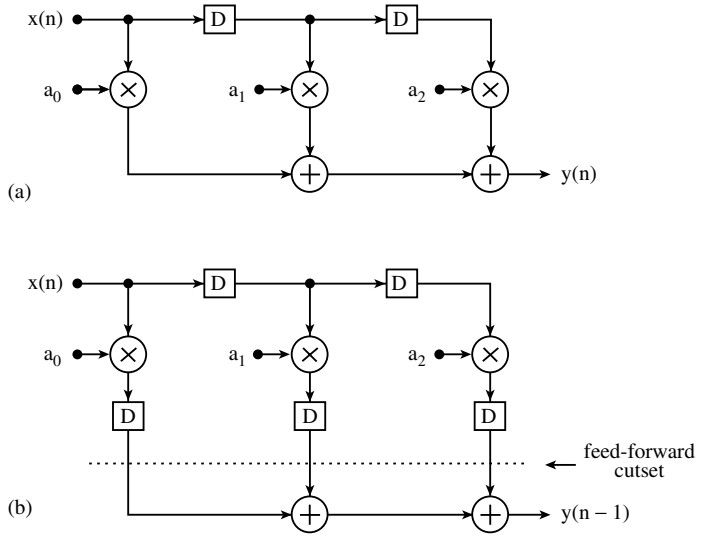

FIGURE 61.102 A three-tap FIR filter. (a) With no pipelining, the throughput is limited by the rate of one multiplication and two additions. (b) With pipelined circuit, the throughput is increased to the rate of one multiplication or two additions.

© 2003 by CRC Press LLC

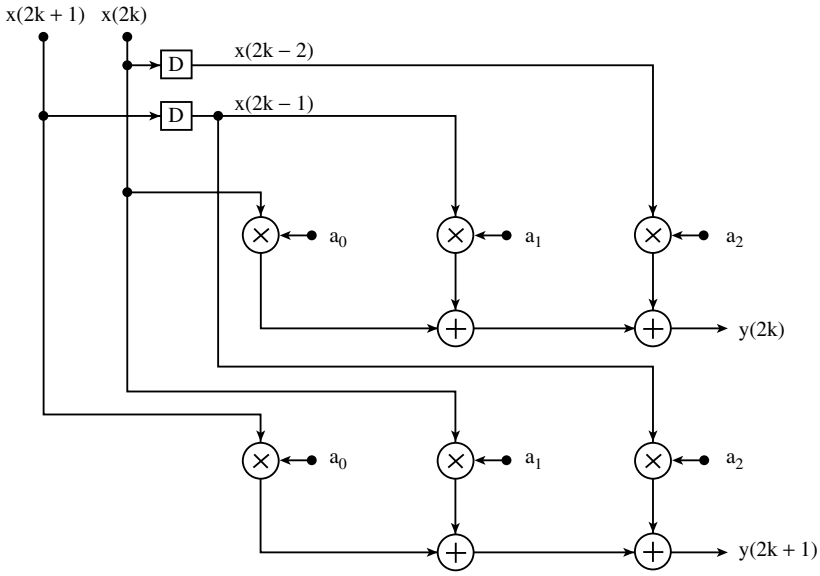

FIGURE 61.103 Three-tap FIR filter whose hardware has been duplicated to achieve double throughput rate.

increase of throughout achieved by pipelining in a second-order three-tap FIR filter. The sample rate of the circuit of Fig. 61.102(a) is limited by the throughput of one multiplication *and* two additions. After placing the latches at the locations shown in Fig. 61.102(b), the throughput can be increased to the rate of one multiplication *or* two additions. Pipelining can be used to increase the sample rate in all the cases in which no feedback loops are present. The drawbacks of pipelining are an increased latency and a larger number of latches and buffers.

Parallelism can be used to increase the speed of an FIR filter. Consider Fig. 61.103, in which the three-tap FIR filter of Fig. 61.102 was duplicated. Because at each time instant two input samples are processed and two samples are output, the effective throughput rate is exactly doubled.

As can be seen from Fig. 61.103. parallelism leads to speed increase at a considerable hardware cost. For many practical implementations, parallelism and pipelining can be used concomitantly, when either method alone would be insufficient or limited by technology such as I–O, clock rate, etc.

Infinite Impulse Response Filters

These are recursive filters in the sense that their output is function of current inputs as well as past outputs. The general I–O relationship is expressed by

$$y(n) = \sum_{j=1}^{p} a_i y(n-j) + \sum_{i=o}^{q} b_i x(n-i) \tag{61.22}$$

where the $\{a_j\}_{j=1}^{p}$ are the coefficients associated to the recursive part, and the $\{b_i\}_{i=0}^{q}$ are the coefficients associated to the nonrecursive portion of the filter. The associated transfer function is written as the following z-transform

$$H(z) = \frac{\sum_{i=o}^{q} b_i z^{-i}}{1 - \sum_{j=1}^{p} a_j z^{z-j}}$$

© 2003 by CRC Press LLC

For stability reasons, it is required that all the poles (i.e., the zeroes of the denominator of $H(z)$) be inside the unit circle in the z-plane.

Consider a circuit in which L loops are present each with latency τ_k, $k = 1, \ldots, L$. The number of latches present in each loop is equal to v_k, $k = 1, \ldots, L$. Then the throughput period cannot be shorter than

$$T_{\max} \equiv \max_{k=1,\ldots,L} \left\lceil \frac{\tau_k}{v_k} \right\rceil$$

The pipeline can be increased by increasing the number of latches internal to the feedback loops. The computational latency associated with the internal feedback prevents one from introducing pipeline simply by inserting latches on feedforward cutsets. In fact, inserting latches in the loop would change the overall transfer function. This difficulty can be overcome by recasting the algorithm into an equivalent formulation from an I–O point of view. The transformations applied to the algorithm, prior to the mapping, have the purpose of creating additional concurrency, thereby increasing the achievable throughput rate. Without ever changing the algorithm's transfer function, additional delays are introduced inside the recursive loop. These delays are subsequently used for pipelining. In the sequel, we briefly describe two types of look-ahead techniques that generate the desired algorithmic transformations, namely the clustered and the scattered look-ahead techniques proposed by Loomis and Sinha [18] and Parhi and Messerschmitt [19], respectively. Look-ahead techniques are based on successive iterations of the basic recursion, in order to generate the desired level of concurrency. The implementation is then based on the iterated version of the algorithm.

***Clustered Look-Ahead*:** In a pth order recursive system, the output at time n is a function of the past output samples $y(n\text{-}1)$, $y(n-2)$, …, $y(n-p)$. In the clustered look-ahead technique, the recursion is iterated m times so that the current output is a function of the cluster of p consecutive samples $y(n-m)$, $y(n-m-1)$, …, $y(n-m-p)$. The original order-p recursive filter is emulated by a $(p+m)$th filter, where m canceling poles and zeroes have been added. In this way the m delays generated inside the feedback loop can be used to pipeline by m stages.

By iterating 61.22 m times, we can derive the following I–O relationship

$$y(n) = \sum_{j=1}^{p-1} \left[\sum_{k=j+1}^{p} a_k r_{j+m-k} \right] y(n-j-m) + \sum_{j=0}^{m-1} \sum_{k=0}^{q} b_k x(n-k-j)$$

where the coefficients $\{r_i\}$ can be precomputed off-line, and are such are such that $r_i = \sum_{k=1}^{p} a_k r_{i-k}$, $i > 0$, $r_0 = 1$, and $r_i = 0$, $i = -(p-1), \ldots, -1$. This implementation requires $(p+m)$ multiplications for the nonrecursive part, and p for the recursive part, for a total of $(2\,p+m)$, which grows linearly with m. The transfer function is equal to

$$H(z) = \frac{\displaystyle\sum_{j=0}^{m-1} \sum_{k=0}^{q} b_k z^{-k-j}}{1 - \displaystyle\sum_{j=1}^{p-1} \left[\sum_{k=j+1}^{p} a_k r_{j+m-k} \right] z^{-j-m}}$$

The clustered look-ahead technique does not guarantee that the resulting filter is stable because it may introduce poles outside the unit circle.

Consider the following simple example with a stable transfer function:

$$H(z) = \frac{1}{1 - 1.3z^{-1} + 0.35z^{-2}}$$

© 2003 by CRC Press LLC

with poles at $z = 0.7$ and $z = 0.5$. The two-stage equivalent filter can be obtained by introducing the canceling pole-zero pair at $z = -1.3$, as follows:

$$H(z) = \frac{1+1.3z^{-1}}{\left(1-1.3z^{-1}+0.35z^{-2}\right)\left(1+1.3z^{-1}\right)} = \frac{1+0.9z^{-1}}{1-1.34z^{-2}+0.455z^{-3}}$$

Because a pole is found at $z = -1.3$, this transfer function is clearly unstable.

***Scattered Look-Ahead*:** In the scattered look-ahead technique, the current output sample $y(n)$, is expressed in terms of the (scattered) p past outputs $y(n - m)$, $y(n - 2m)$, …, $y(n - mp)$. The original order-p filter is now emulated by an order-mp filter. For each pole of the original filter, $(m - 1)$ canceling pole-zero pairs are introduced at the same distance from the origin as the original pole. Thus, stability is always assured. The price we must pay is higher complexity, on the order of mp. To best describe the technique, it is convenient to write the transfer function $H(z)$ as a ratio of polynomials, i.e., $H(z) = N(z)/D(z)$. The transformation can be written as follows:

$$H(z) = \frac{N(z)}{D(z)} = \frac{N(z)\prod_{k=1}^{m-1} D\left(ze^{j(2\pi k/m)}\right)}{\prod_{k=0}^{m-1} D\left(ze^{j(2\pi k/m)}\right)}$$

Note that the transformed denominator is now a function of z^{-m}.

Consider the example of the previous section. For the scattered look-ahead technique, it is necessary to introduce pole-zero pairs at $z = 0.7\, e^{\pm j(2\pi/3)}$ and $z = 0.5\, e^{\pm j(2\pi/3)}$. The transformed denominator equals $1 - 0.125z^{-3}$.

The complexity of the nonrecursive part of the transformed filter is $(pm + 1)$ multiplications, while the recursive part requires p multiplications, for a total of $(pm + p + 1)$ pipelined multiplications. Although the complexity is still linear in m, it is much higher than in the clustered look-ahead technique for a large value of p.

Parhi and Messerschmitt [19] presented a technique to reduce the complexity of the nonrecursive portion down to $O(p \log_2 m)$, applicable when m is a power of 2. This technique can be described as follows. Assume that the original recursive portion of the given IIR filter is given by

$$H(z) = \frac{1}{1-\sum_{j=1}^{p} a_j^{(1)} z^{-j}}$$

An equivalent two-stage implementation of the same filter can be obtained by multiplying numerator and denominator by the polynomial $(1 - \sum_{j=1}^{p} (-1)^j a_j^{(1)} z^{-j})$, which is given by

$$H(z) = \frac{1-\sum_{j=1}^{p} (-1)^j a_j^{(1)} z^{-j}}{1-\sum_{j=1}^{p} a_j^{(2)} z^{-j}}$$

where the set of coefficient $\{a_j^{(2)}\}_{j=1}^{p}$ is obtained from the original set $\{a_j^{(1)}\}_{j=1}^{p}$ by algebraic manipulation. By repeating this process $\log_2 m$ times one can obtain an m-stage pipelined implementation, equivalent to the original filter. In this way the hardware complexity only grows logarithmically with the number of pipelining stages.

© 2003 by CRC Press LLC

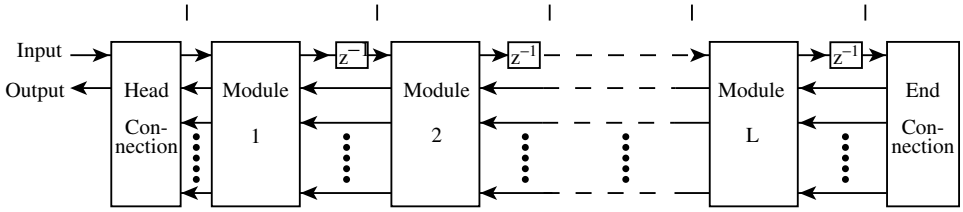

FIGURE 61.104 A general structure of bidirectional IIR filters.

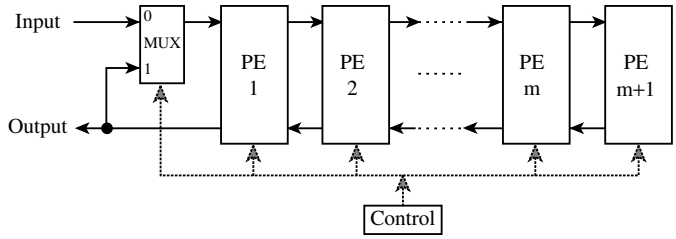

FIGURE 61.105 The overlapped subfilter scheme for IIR filtering.

***Bidirectional Systolic Arrays for Infinite Impulse Response Filtering*:** Lei and Yao [16] showed that many IIR filter structures can be considered as special cases of a general class of systolizable filters, as shown in Fig. 61.104. These filters can be pipelined by rescaling the time so that $z' = z^{1/2}$, , and by applying a cutset transformation. This time rescaling causes the hardware factorization to reduce to merely 50%, which is quite inefficient. Lei and Yao [17] later proposed two techniques to improve the efficiency of these bidirectional IIR filters.

In the first method ("overlapped subfilter scheme"), one makes use of the possibility to factor the numerator and the denominator of the given transfer function. For instance, if

$$H(z) = \frac{N(z)}{D(z)} = \underbrace{\frac{N_a(z)}{D_a(z)}}_{H_a(z)} \cdot \underbrace{\frac{N_b(z)}{D_b(z)}}_{H_b(z)}$$

where $a + b = p$, $a - b = 0$, 1, or 2, and p is the number of modules of the original transfer function. Then the two subfilters, $H_a(z)$ and $H_b(z)$, can be realized on the same systolic array of $a + 1$ modules, as in Fig. 61.105. A multiplexer at the input of the array chooses the incoming data at even time instants, and the data from the output of the first module at odd time instants. The modules alternately perform operations associated to $H_a(z)$ and $H_b(z)$ in such away as to interleave the operations and have an overall 100% efficiency.

In the second technique ("systolic ring scheme") the number of modules is about half of the order of the original transfer function. The modules of the new structure are arranged as a systolic ring, as in Fig. 61.106. For example, a five-module ring can be used to implement a ten-module IIR filter: module i performs the operations associated to modules i and $(5 + i)$ of the original array, for $i = 1, \ldots, 5$. Note that in the original structure every other module is idle. The resulting ring is therefore 100% efficient.

Systolic Word and Bit-Level Designs

Previous discussions on systolic array designs have taken place at the word level. This is to say that the smallest data or control item exchanged between pairs of processors is constituted by a *word* representable by B bits. Each processor in a word-level system has the capability of performing word-level operations. Some may be as complex as floating point multiplications or others as simple as square root operations,

© 2003 by CRC Press LLC

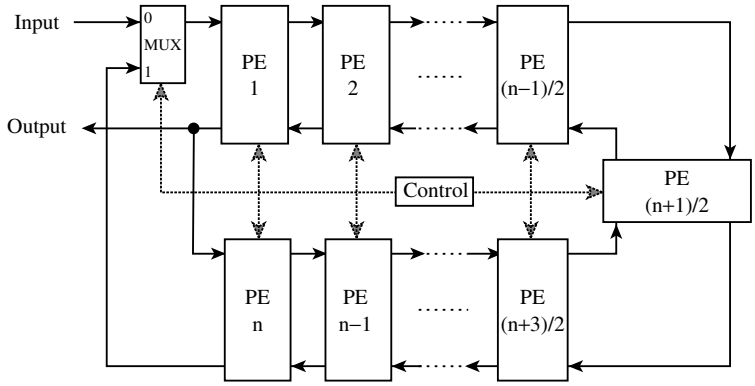

FIGURE 61.106 The systolic ring scheme for IIR filtering.

etc. The systolic array approach can be applied at various different levels beyond the word level, according to what is sometimes referred to as **granularity** of the algorithm description. Systolic arrays and associated dependence graphs can, in fact, be defined at high levels of description, in which each individual processor can, in principle, be a whole mainframe computer or even a separate parallel processor array. The communication between processors thus takes the form of complex protocols and entire data sequences. According to the same principle, the algorithm description can also be done at the lowest level of operation, namely, at the bit level, at which each processor is a simple latched logic gate, capable of performing a logic binary operation. The exchanged data and control also take the form of binary digits. The different approaches due to the different granularity of description have different merits and can be advantageously used in various circumstances or at different steps of the design.

These considerations bring to one possible design strategy, namely, the **hierarchical systolic design**. In this approach the complete systolic design is broken down to a sequence of hierarchical steps, each of which define the algorithm at different levels of granularity. At first, the higher level of description is adopted, the relative dependence graph is drawn, and, after suitable projection and scheduling, a high-level systolic architecture is defined. Subsequently, each high-level processor is described in terms of finer scale operations. Dependence graph and systolic architecture corresponding to these operations are produced and embedded in the higher level structure previously obtained. The process can continue down to the desired level of granularity. The simplest form of hierarchical design implies two steps. The first step involves the design of the word-level architecture. Second, the operations performed by each work-level processor are described at bit level. The corresponding bit-level arrays are then nested into the word-level array, after ensuring that data flows at both levels are fully compatible.

The hierarchical approach has the merits of reducing the complexity of each step of the design. The dependence graphs involved usually have reduced dimensionality (thus, are more manageable), and the procedure is essentially recursive. The drawback of a hierarchical design is that it implicitly introduces somewhat arbitrary boundaries between operations, thereby reducing the set of resulting architectures. An approach that leaves all options open is to consider the algorithm at bit level from the outset. This approach has led to new insights and novel architectures. The price to pay is that the designer must deal with dependence graphs of higher dimensionality. As an example, the dependence graph of the inner product between two N-vectors, $c = \sum_{i=0}^{N-1} a_i b_i$ is two dimensional. If the same inner product is written at bit level, i.e., $c_k = \sum_{i=0}^{N-1} \sum_{j=0}^{B-1} a_{i,j} b_{i,k-j}$ + carries, $k = 0, \ldots, B-1$, then it produces a three-dimensional dependence graph.

Examples of the two design procedures applied to the convolution problem are considered below. First, consider the factors that can make bit-level design advantageous:

- **Regularity.** Most bit-level arrays are highly regular. Only relatively simple cells need be designed and tested. The communication pattern is simple and regular. Neighbor-to-neighbor connections allow high packing density and low transmission delays.

© 2003 by CRC Press LLC

- **High pipeline rate.** Because the individual cells have reduced computation time (on the order of the propagation delay through a few gates), the overall throughput can be made very high.
- **Inexpensive fault tolerance.** The use of bypass circuitry can be made without wasting too much of the silicon area.

It must be borne in mind that bit level arrays realistically cannot be operated in wavefront array mode because the interprocessor hand-shaking protocols would be too expensive as compared to the data exchange. A good clock signal distribution is therefore needed to synchronize the array operations. In systolic arrays, unlike synchronous architectures of a different sort, only the incremental clock skew must be minimized by suitably designing the clock signal distribution lines. This problem may become particularly delicate in bit-level arrays, where the number of processors involved is very high.

Bit-Level Design of a Serial Convolver

Bit-level systolic design was first proposed by McCanny and McWhirter [29]. Subsequently, they and others have applied this technique to various algorithms. As a simple example, consider the bit-level design of a serial convolver. The word-level output of an N point convolver can be written as $y_k = \sum_{i=0}^{N-1} a_i x_{k-i}$, $k = 0, 1, \ldots$, where $\{a_i\}_{i=0}^{N-1}$ is a given set of coefficients and x_i, $i = 0,1, \ldots$, is a sequence of input data. Coefficients and data values are assumed to be B-bit words. The word-level dependence graph is shown in Fig. 61.107, together with one possible systolic realization. In this case, the coefficients are permanently stored in each individual cell. Input and output values are propagated in opposite directions. In each processing element, the corresponding coefficient is multiplied by the incoming data value. This product is added to the partial output value and the accumulated result is propagated forward. Each cell performs the simple multiply and add operation expressed by $y_{k,i+1} \leftarrow y_{k,i} + a_i\, x_{k-i}$, $y_k = y_{k,N}$.

According to the hierarchical approach, one must now proceed to determine the dependence graph corresponding to the bit-level description of the multiply-and-add operation. The complete dependence graph can be subsequently obtained by embedding the finer scale graph into the higher level graph. If both a_i and x_i are B-bit binary numbers, then the jth bit of y_{ki}, can be computed according to $y_{k,i,j} = y_{k,i,j} + s_{i,k,j}, s_{i,k,j} \equiv \sum_{l=0}^{B-1} a_{i,l} x_{k-i,j-l}$ + carries, where $a_{i,l}$ and $x_{i,l}$, $l = 0, \ldots, B-1$, represent the lth bit of a_i and x_i. The dependence graph corresponding to this operation is given in Fig. 61.108, where subscripts only

indicate the bit position, and $B = 3$. Note that this graph is quite similar to the graph corresponding to a convolver, apart from the carry bits, which are taken care of by the insertion of an additional row of cells.

The combined dependence graph, obtained from the word dependence graph of Fig. 61.107, in which each cell is replaced by the bit-level dependence graph of Fig. 61.108, is given in Fig. 61.109.

The data flows are fully compatible at both word and bit levels. At this point, a full two-dimensional bit-level systolic array can be obtained from the final dependence graph by simply replacing each node with latched full adder cells. Different linear systolic implementations can be obtained by projecting the combined dependence graph along various directions. One possibility is again to keep the coefficients residents in individual cells, and have input data bits and accumulated results propagate in opposite directions. The schematic representation of the systolic array with these features is drawn in Fig. 61.109. Judgment about the merits of different projections involves desired data movement, I–O considerations, throughput rate, latency time, efficiency factor (ratio of idle time to busy time per cell), etc.

As discussed previously, the convolution operation can be described at bit level from the very beginning. In this case the expression for the jth bit of the kth output can be expressed as follows:

© 2003 by CRC Press LLC

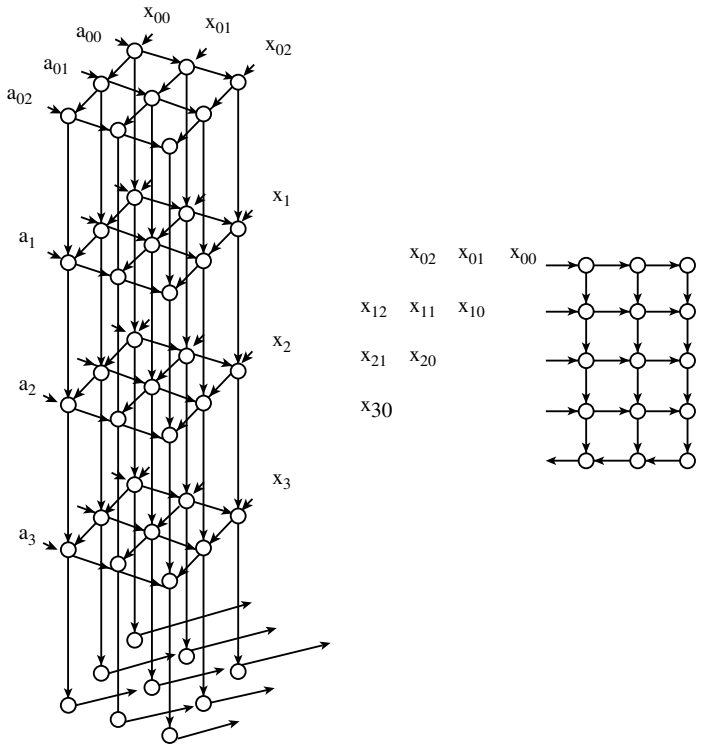

FIGURE 61.110 General three-dimensional bit-level dependence graph for convolution.

$$y_{k,j} = \sum_{i=0}^{N-1} \sum_{l=0}^{B-1} a_{i,l} x_{k-i,j-1} + \text{carries} \tag{61.23}$$

By using this expression as a starting point, one is capable of generating a number of feasible systolic realizations potentially much larger than what is attainable from the two-step hierarchical approach. The reason for this can be simply understood by nothing that in this formulation no arbitrary precedence relationship is imposed between the two summations on i and l, whereas earlier we required that the summation on l would always *precede* the summation on i. The result is a fairly complicated three-dimensional dependence graph of size $N \times B \times$ number of inputs, as shown in Fig. 61.110. Observe that the bottom level of the dependence graph corresponds to the summation over l in (61.23). In the same figure a schematic two-dimensional bit-level systolic realization of the algorithm is given, in which the coefficient bits are held in place. Projections along different directions have different characteristics and may be considered preferable in different situations. The choice ultimately must be made according to given design constraints or to efficiency requirements.

The concept of bit-level design, as considered here, can be applied to a large variety of algorithms. Indeed, it has generated a number of architectures, including FIR/IIR filters, arrays for inner product computation, median filtering, image processing, eigenvalue problems, Viterbi decoding, etc.

Recursive Least-Squares Estimation

Least-Squares Estimation

The least-squares (LS) technique constitutes one of the most basic components of all modern signal processing algorithms dealing with linear algebraic and optimization of deterministic and random signals and systems. Specifically, some of the most computationally intensive parts of modern spectral analysis,

© 2003 by CRC Press LLC

beam formation, direction finding, adaptive array, image restoration, robotics, data compression, parameter estimation, and Kalman filtering all depend crucially on LS processing.

Regardless of specific application, an LS estimation problem can be formulated as $Ax \approx y$, where the $m \times n$ data matrix A and the $m \times 1$ data vector y are known, and we seek the $n \times 1$ desired solution x. In certain signal processing problems, rows of A are composed of sequential blocks of lengths n taken from a one-dimensional sequence of observed data. In other n-sensor multichannel estimation problems, each column of A denotes the sequential outputs of a given sensor. In all cases, the desired solution x provides the weights on the linear combinations of the columns of A to optimally approximate the observed vector y in the LS sense. When $m = n$ and A is nonsingular, then an exact solution for x exists. The Gaussian elimination method provides an efficient approach for determining this exact solution. However, for most signal processing problems, such as when there are more observations than sensors, and thus $m > n$, then no exact solution exists. The optimum LS solution $\hat{x}$ is defined by $\|A\hat{x} - y\| = \min_x \|Ax - y\|$. The classical approach in LS solution is given by $\hat{x} = A^+ y$, where A^+ is the pseudo-inverse of A defined by $A^+ = (A^T A)^{-1} A^T$. The classical LS approach is not desirable from the complexity, finite precision sensitivity, and processing architecture points of views. This is due to the need for a matrix inversion, the increase of numercial instability from "squaring of the condition number" in performing the $A^T A$ operation, and the block nature of the operation in preventing a systolic update processing and architecture for real-time applications.

The QR decomposition (QRD) approach provides a numerically stable technique for LS solution that avoids the objections associated with the classical approach. Consider a real-valued $m \times n$ matrix A with $m \geq n$ and all the columns are linearly independent (i.e., rank $A = n$). Then, from the QRD, we can find a $m \times m$ orthogonal matrix Q such that $QA = \bar{R}$. The $m \times n$ matrix $\bar{R} = [R^T, 0^T]^T$ is such that R is an $n \times n$ upper triangular matrix (with nonzero diagonal elements) and 0 is an all-zero $(m - n) \times n$ matrix. This upper triangularity of R is used crucially in the following LS solution problem.

Because the l_2 norm of any vector is invariant with respect to an orthogonal transformation, an application of the QRD to the LS problem yields $\|Ax - y\|^2 = \|Q(Ax - y)\|^2 = \|\bar{R}x - f\|^2$, where f is a $m \times 1$ matrix given by $f = Qy = [u^T, v^T]^T$. Denote $e = Ax - y$ as the *residual* of the LS problem. Then, the previous LS problem is equivalent to $\|e\|^2 = \|Ax - y\|^2 = \|[Rx, 0x]^T - [u^T - v^T]^T\|^2 = \|Rx - u\|^2 + \|v\|^2$. Because R is a nonsingular upper triangular square matrix, the back substitution procedure of the Gaussian elimination method can be used to solve for the exact solution $\hat{x}$ of $R\hat{x} = u$. Finally, the LS problem reduces to $\min_x \|Ax - y\|^2 = \|A\hat{x} - y\|^2 = \|\bar{R}\hat{x} - f\|^2 = \|R\hat{x} - u\|^2, + \|v\|^2 = \|v\|^2$. For the LS problem, any QRD technique such as the Gram-Schmidt method, the modified-Gram–Schmidt (MGS) method, the Givens transformation, and the Householder transformation is equally valid for finding the matrix R and the vector v. For a systolic implementation, the Givens transformation yields the simplest architecture, but the MGS and Householder transformation techniques are also possible with slight advantages under certain finite precision conditions.

Recursive Least-Squares Estimation

The complexity involved in the computation of the optimum residual $\hat{e}$ and the optimum LS solution vector $\hat{x}$ can become arbitrarily large as the number of samples in the column vectors of A and y increases. In practice, we must limit m to some finite number greater than the number of columns n. Two general approaches in addressing this problem are available. In the **sliding window** approach, we periodically incorporate the latest observed set of data (i.e., *updating*) and possibly remove an older set of data (i.e., *downdating*). In the **forgetting factor** approach, a fixed scaling constant with a magnitude between 0 and 1 is multiplied against the R matrix and thus exponentially forget older data. In either approach, we find the optimum LS solution weight vector $\hat{x}$ in a recursive least-squares manner. As the statistics of the signal change over each window, these $\hat{x}$ vectors change *adaptively* with time. This observation motivates the development of a recursive least-squares solution implemented via the QRD approach. For simplicity, we consider only the updating aspects of the sliding window recursive least-squares problem.

Let m denote the present time of the sliding window of size m. Consider the $m \times n$ matrix $A(m)$, the $m \times 1$ column vector $y(m)$, the $n \times 1$ solution weight column vector $x(m)$, and the $m \times 1$ residual column

© 2003 by CRC Press LLC

vector $e(m)$ expressed in terms of their values at time $m-1$ as $A(m) = [\alpha(1), \ldots, \alpha(m)]^T = [A(m-1)^T, \alpha(m)]^T$, $y(m) = [y_1, \ldots, y_m]^T$ $[y(m-1)^T, y^T m]^T$, $x(m) = [x_1(m), \ldots, x_n(m)]^T$, and $e(m)$ $A(m) \times (m) - y(m) = [e_1(m), \ldots, e_n(m)^T$. By applying the orthogonal matrix $Q(m) = [Q_1(m)^T, Q_2(m)^T]^T$ of the QRD of the $m \times n$ matrix $A(m)$, we obtain $Q(m)$ $A(m) = [R(m)^T, 0^T]^T = R_0(m)$ and $Q(m)y(m) = [Q_1(m)^T, Q_2(m)^T]^T$ $y(m) = [u(m)^T, v(m)^T]^T$. The square of the l_2 norm of the residual e is then given by $\in(m) = \|e(m)\|^2 = \|A(m)x(m) - y(m)\|^2 = \|Q(m)(A(m)x(m) - y(m))\|^2 = \|R(m)x(m) - u(m)\|^2 + \|v(m)\|^2$. The residual is minimized by using the back substitution method to find the optimum LS solution $\hat{x}(m)$ satisfying $R(m)\hat{x}(m) = u(m) = [u_1(m),\ldots,u_n(m)]^T$. It is clear that the optimum residual $\hat{e}(m)$ is available after the optimum LS solution $\hat{x}(m)$ is available as seen from $\hat{e}(m) = A(m)\hat{x}(m) - y(m)$. It is interesting to note that it is not necessary to first obtain $\hat{x}(m)$ explicitly and then solve for $\hat{e}(m)$ as shown earlier. It is possible to use a property of the orthogonal matrix $Q(m)$ in the QRD of A and the vector $y(m)$, to obtain $\hat{e}(m)$ explicitly. Specifically, note $\hat{e}(m) = A(m)\,\hat{x}(m) - y(m) = Q_1(m)^T\,R(m)\,\hat{x}(m) - y(m) = [Q_1(m)^T\,Q_1(m) - I_m]y(m) = -Q_2(m)^T\,Q_2(m)y(m) = -Q_2(m)^T v(m)$. This property is used explicitly in the following systolic solution of the last component of the optimum residual.

Recursive QR Decomposition

Consider the recursive solution of the QRD. First, assume the decomposition at step m–1 has been completed as given by $Q(m-1)A(m-1) = [R(m-1)^T, 0^T]^T$ by using a $(m-1) \times (m-1)$ orthogonal matrix. Next, define a new $m \times m$ orthogonal transformation $T(m) = [Q(m) - 1), 0; 0,1]$. By applying $T(m)$ on the new $m \times n$ data $A(m)$, which consists of the previously available $A(m-1)$ and the newly available row vector $\alpha(m)^T$ we have

$$T(m)A(m) = \begin{bmatrix} Q(m-1) & 0 \\ 0 & 1 \end{bmatrix}\begin{bmatrix} A(m-1) \\ \alpha(m)^T \end{bmatrix} = \begin{bmatrix} Q(m-1)\,A(m-1) \\ \alpha(m)^T \end{bmatrix}$$

$$= \begin{bmatrix} R(m-1) \\ 0 \\ \alpha(m)^T \end{bmatrix} = R_1(m)$$

While $R(m$–$1)$ is an $n \times n$ upper triangular matrix, $R_1(m)$does not have the same form as the desired $R_0(m) = [R(m)^T, 0^T]^T$ where $R(m)$ is upper triangular.

Givens Orthogonal Transformation

Next, we want to transform $R_1(m)$ to the correct $R_0(m)$ form by an orthogonal transformation $G(m)$. While any orthogonal transformation is possible, we will use the Givens transformation approach due to its simplistic systolic array implementation. Specifically, denote $G(m) = G_n(m)G_{n-1}(m) \ldots G_1(m)$, where $G(m)$ as well as each $G_i(m)$, $i = 1, \ldots n$, are all $m \times m$ orthogonal matrices. Define

$$G_i(m) = \begin{array}{c} \\ 1 \\ \\ i \\ \\ m \end{array}\begin{array}{c} \begin{array}{ccccc} 1 & & i & & m \end{array} \\ \begin{bmatrix} 1 & & 0 & & 0 \\ & 1 & & & \\ & & & & \\ 0 & & c_i(m) & & s_i(m) \\ & & & 1 & \\ 0 & & -s_i(m) & & c_i(m) \end{bmatrix} \end{array}, \quad i = 1, \ldots, n$$

as a $m \times m$ identity matrix, except that the (i, i) and (m, m) elements are specified as $c_i(m) = \cos\theta_i(m)$, where $\theta_i(m)$ represents the rotation angle at the ith iteration, the (i, m) element as $s_i(m) = \sin\theta_i(m)$, and the (m, i) element as $-S_i(m)$. By cascading all the $G_i(m)$, $G(m)$ can be reexpressed as

© 2003 by CRC Press LLC

$$G(m)=\begin{bmatrix} k(m) & 0 & d(m) \\ 0 & I_{m-n-1} & 0 \\ h^{\mathrm{T}}(m) & 0 & \gamma(m) \end{bmatrix}$$

where $k(m)$ is $n \times n$, $d(m)$ and $h(m)$ are $n \times 1$, and $\gamma(m)$ is 1×1. In general $k(m)$, $d(m)$, and $h(m)$ are quite involved functions of $c_i(m)$ and $s_i(m)$, but $\gamma(m)$ is given simply as $\gamma(m) = \prod_{i=1}^{n} c_i(m)$ and will be used in the evaluation of the optimum residual.

Use $G(m)$ to obtain $G(m)T(m)A(m) = G(m)R_1(m)$. In order to show the desired property of the n orthogonal transformation operations of $G(m)$, first consider

$$G_1(m)R_1(m)=\begin{bmatrix} c_1(m) & & & & s_1(m) \\ & 1 & & & \\ & & 1 & & \\ & & & 1 & \\ s_1(m) & & & & c_1(m) \end{bmatrix}\begin{bmatrix} x & x & \cdots & x \\ 0 & x & \cdots & x \\ & & \cdots & x \\ 0 & 0 & \cdots & x \\ x & x & \cdots & x \end{bmatrix}$$

$$=\begin{bmatrix} x & x & \cdots & x \\ 0 & x & \cdots & x \\ & & \cdots & x \\ 0 & 0 & \cdots & x \\ 0 & x & \cdots & x \end{bmatrix}$$

In the preceding expression, an x denotes some nonzero valued element. The purpose of $G_1(m)$ operating on $R_1(m)$ is to obtain a zero at the $(m, 1)$ position without changing the $(m-2) \times n$ submatrix from the second to the $(m-1)$st rows of the r.h.s. of the expression. In general, at the ith iteration, we have

$$G_i(m)\begin{bmatrix} x & x & . & . & . & x \\ & x & . & . & . & x \\ & & & & & x \\ & & & \vdots & & \\ 0 & 0 & . & . & . & 0 \\ 0 & 0 & 0 & x & x & x \end{bmatrix}_{i-1}=\begin{bmatrix} x & x & . & . & . & x \\ & x & . & . & . & x \\ & & & & & x \\ & & & \vdots & & \\ 0 & 0 & . & . & . & 0 \\ 0 & 0 & 0 & 0 & x & x \end{bmatrix}_{i}$$

The preceding zeroing operation can be explained by noting that the Givens matrix G_i(m) operates as a $(m-2) \times (m-2)$ identity matrix on all the rows on the right of it except the ith and the mth rows. The crucial operations at the ith iteration on these two rows can be represented as

$$\begin{bmatrix} c & s \\ -s & c \end{bmatrix}\begin{bmatrix} 0 & \cdots & 0 & r_i & r_{i+1} & \cdots & r_n \\ 0 & \cdots & 0 & a_i & a_{i+1} & \cdots & a_n \end{bmatrix}$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad i$$

© 2003 by CRC Press LLC

$$= \begin{bmatrix} 0 & \cdots & 0 & r_i^T & r_{i+1}^T & \cdots & r_n^T \\ 0 & \cdots & 0 & 0 & a_{i+1}^T & \cdots & a_n^T \end{bmatrix}$$
$$i$$

For simplicity of notation, we suppress the dependencies of i and m on c and s. Specifically, we want to force $a_i^T = 0$ as given by $0 = a_i^T = -sr_i + ca_i$. In conjunction with $c^2 + s^2 = 1$, this requires $c^2 = r_i^2/(a_i^2 + r_i^2)$ and $s^2 = a_i^2/(a_i^2/r_i^2)$. Then $r_i^T = cr_i + sa_i = \sqrt{(a_i^2 + r_i^2)}$, $c = r_i/r_i^T$, and $s = a_i/r_i^T$. This shows from the individual results of $G_1(m)$, $G_2(m)$, …, $G_n(m)$, the overall results yield $Q(m)\ A(m) = G(m)\ \bar{R}(m) = [R(m)^T, 0^T]^T = R_0(m)$, with $Q(m) = G(m)T(m)$.

Recursive Optimal Residual and LS Solutions

Consider the recursive solution of the last component of the optimum residual $\hat{e}(m) = [\hat{e}_1(m), \ldots, \hat{e}_m(m)]^T = -Q_2(m)^T\ v(m) = -Q_2(m)^T\ [v_1(m), \ldots, v_m(m)^T]$. Because $Q_2(m) = [Q_2(m-1), 0; h(m)^T\ Q_1(m-1), \gamma(m)]$, then $\hat{e}(m) = [\hat{e}_1(m), \ldots, \hat{e}_m(m)]^T = Q_2(m) = -[Q_2^T(m-1), Q_1^T(m-1)h(m); 0, \gamma(m)]\ [v_1(m), \ldots, v_m(m)]$. Thus, the last component of the optimum residual is given by $\hat{e}(m) = -\gamma(m)v_m(m) = -\prod_{i=1}^{n} c_i(m)v_m(m)$, which depends on all the products of the cosine parameters $c_i(m)$ in the Givens QR transformation, and $v_m(m)$ is just the last component of $v(m)$, which is the result of $Q(m)$ operating on $y(m)$.

As considered earlier, the LS solution $\hat{x}$ satisfies the triangular system of equations. After the QR operation on the extended matrix $[A(m), Y(m)]$, all the $r_{ij}, j \geq i = 1, \ldots, n$ and $u_i, i = 1, \ldots, n$ are available. Thus, $\{\hat{x}_1, \ldots, \hat{x}_n\}$ can be obtained by using the back substitution method of $\hat{x}_i = (u_i - \sum_{j-i+1}^{n} r_{ij}\ \hat{x}_j/r_{ij})$, $i = n, n-1, \ldots, 1$. Specifically, if $n = 1$, then $\hat{x}_1 = u_1/r_{11}$. If $n = 2$, then $\hat{x}_2 = u_2/r_{22}$ and $\hat{x}_1 = u_1 - r_{12}\ \hat{x}_2/r_{11} = u_1/r_{11} - u_2 r_{12}/r_{11}r_{22}$. If $n = 3$, then $\hat{x}_3 = u_3/r_{33}$, $\hat{x}_2 = u_2 - r_{23}\ x_3/r_{22} = u_2/r_{22} - r_{23}u_3/r_{22}r_{23}$, and $\hat{x}_1 = u_1 - r_{12}\ \hat{x}_2 - r_{13}\ \hat{x}_3/r_{11} = u_1/r_{11} - r_{12}u_2/r_{11}r_{22} + u_3[-r_{13}/r_{11}r_{33} + r_{12}r_{23}/r_{11}r_{22}r_{33}]$.

Systolic Array Implementation for QR Decomposition and LS solution

The recursive QRD considered above can be implemented on a two-dimensional triangular systolic array based on the usage of four kinds of processing cells. Figure 61.111(a) shows the boundary cell for the generation of the sine and cosine parameters, s and c, needed in the Givens rotations. Figure 61.111(b) shows the internal cell for the proper updating of the QRD transformations. Figure 61.111(c) shows the single output cell needed in the generation of the last component of the optimal residual $\hat{e}_m(m)$ as well as the optimal LS solution $\hat{x}(m)$. Figure 61.111(d) shows the delay cell which performs a unit time delay for proper time skewing in the systolic processing of the data.

Figure 61.112 shows a triangular systolic array capable of performing the recursive QRD for the optimal recursive residual estimation and the recursive least-squares solution by utilizing the basic processing cells in Fig. 61.111. In particular, the associated LS problem uses an augmented matrix [A,y] consisting of the $m \times n$ observed data matrix A and the m × 1 observed vector y. The number or processing cells in the triangular array consists of n boundary cells, $n(n+1)/2$ internal cells, one output cell, and n delay cells.

The input to the array in Fig. 61.112 uses the augmented matrix

$$[A, Y] = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} & y_1 \\ a_{21} & a_{22} & \cdots & a_{2n} & y_2 \\ & & \vdots & & \\ a_{m1} & a_{m2} & \cdots & a_{mn} & y_m \end{bmatrix}$$

skewed in a manner such that each successive column from left to right is delayed by a unit time as given by

© 2003 by CRC Press LLC

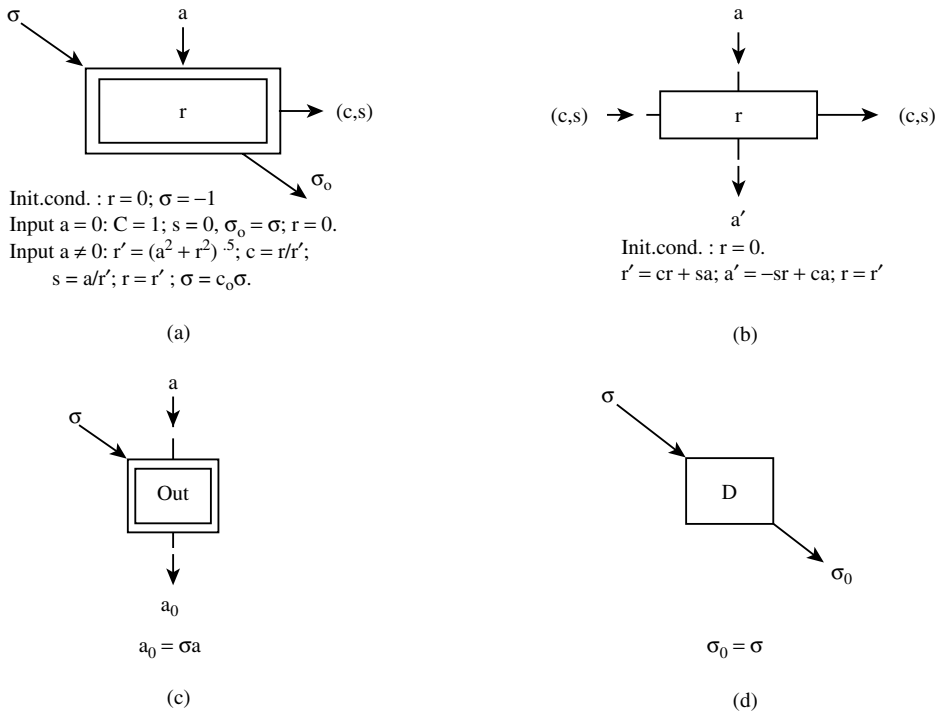

FIGURE 61.111 (a) Boundary cell; (b) internal cell; (c) output cell; (d) delay cell.

$$\begin{bmatrix}
a_{11} & 0 & & \cdots & 0 & 0 & k=1 \\
a_{21} & a_{12} & 0 & \cdots & 0 & 0 & 2 \\
a_{31} & a_{22} & a_{13} & \cdots & 0 & 0 & 3 \\
 & & & \vdots & & & \vdots \\
a_{n1} & a_{(n-1)2} & & & a_{1n} & 0 & n \\
a_{(n+1)1} & a_{n2} & & & a_{2n} & y_1 & n+1 \\
 & & & \vdots & & & \vdots \\
a_{m1} & a_{(m-1)2} & & & a_{(m-n+1)n} & y_{m-n} & m \\
 & & & \vdots & & & \vdots \\
0 & & & & a_{mn} & y_{m-1} & m+n-1 \\
0 & & & & 0 & y_m & m+n
\end{bmatrix}$$

We see that at time k, input data consists of the kth row of the matrix, and moves down with increasing time. However, in Fig. 61.112, purely for drawing purpose in relation to the position of the array, the relevant rows of data are drawn as moving up with increasing k.

Consider some of the iterative operations of the QRD for the augmented matrix [A, y] for the systolic array in Fig. 61.112. At time $k = 1$, a_{11} enters BC 1 and results in $c = 0$, $s = 1$, and $r_{11} = a_{11}$. All other cells are inactive. At $k = 2$, a_{21} enters BC 1, with the results $c = a_{11}\sqrt{(a_{11}^2 + a_{21}^2)}$, $s = a_{21}\sqrt{(a_{11}^2 + a_{21}^2)}$, $r_{11} = \sqrt{a_{11}^2 + a_{21}^2}$. This r_{11} corresponds to that of r_i^T, while the preceding c and s correspond to the c and s in the

© 2003 by CRC Press LLC

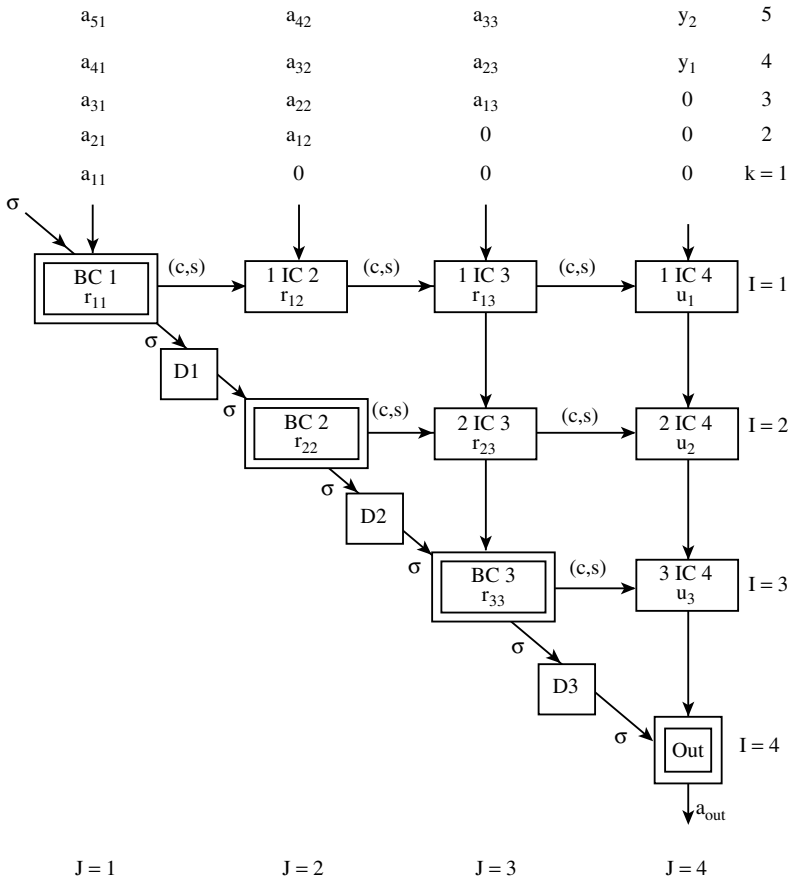

FIGURE 61.112 Triangular systolic array implementation of an $n = 3$, QRD-recursive, least-squares solver.

Givens transformation. Indeed, the new a_i^T is zero and does not need to be saved in the array. Still, at $k = 2$, a_{12} enters 1 IC 2 and outputs $a^T = 0$ and $r_{12} = a_{12}$. At $k = 3$, a_{13} enters BC 1, and the Givens rotation operation continues where the new r_i is given by the previously processed r_i^T and a_i is now given by a_{13}. Meanwhile, a_{22} enters at 1 IC 2. It outputs $a^T = -a_{21}a_{12}/\sqrt{(a_{11}^2 + a_{21}^2)} + -a_{22}a_{21}/\sqrt{(a_{11}^2 + a_{21}^2)}$, which corresponds to that of a_{i+1}^T, and $r_{12} = a_{11}a_{12}/\sqrt{(a_{11}^2 + a_{21}^2)} + -a_{21}a_{22}/\sqrt{(a_{11}^2 + a_{21}^2)}$, which corresponds to that of r_{i+1}^T. In general, the top (i.e., $I = 1$) row of the processing cells performs Givens rotation by using the first row to operate on the second, third, …, mth rows (each row with $n + 1$ elements), such that the {21,31, …, $m1$} locations in the augmented matrix are all zeroed. The next row ($I = 2$) of cells uses the second row to operate on the third, …, mth rows (each row with n elements), such that locations at {32, 42, …, $m2$} are zeroed. Finally, at row $I = n$, by using the nth row to operate on the $(n + 1)$st, …, mth rows, elements at locations $\{(n + 1)n, (n + 2)n, \ldots, mn\}$ are zeroed. We also note that the desired cosine values in $\gamma(m)$ are being accumulated by c along the diagonal of the array. Delay cells $\{D_1, D_2, \ldots, D_n\}$ are used to provide the proper timing along the diagonal.

The cell BC 1 (at $I = J = 1$) terminates in the QR operation at time $k = m$, while the cell at $I = 1$ and $J = 2$ terminates at $k = m + 1$. In general, the processing cell at location (I, J) terminates at $k = I + J + m - 2$. In particular, the last operation in the QRD on the augmented matrix is performed by the cell at $I = n$ and $J = n + 1$ at time $k = 2n + m - 1$. Then, the last component of the optimum residual $e_m(m)$ exits the output cell at time $k = 2n + m$.

After the completion of the QRD obtains the upper triangular system of equation, we can "freeze" the r_{IJ} values in the array to solve for the optimum LS solution $\hat{x}$ by the back substitution method. Specifically,

© 2003 by CRC Press LLC

we can append $[I_n, 0]$, where I_n is a $n \times n$ identity matrix and 0 is an $n \times 1$ vector of all zeroes, to the bottom of the augmented matrix [A, y]. Of course, this matrix is skewed as before when used as input to the array. In particular, immediately after the completion of the QR operation at BC 1, we can input the unit value at time $k = m + 1$. This is stage 1 of the back substitution method. Due to skewing, a unit value appears at the $I = 1$ and $J = 2$ cell at stage 3. Finally, at stage $(2n - 1)$, which is time $k = m + 2n - 1$, the last unit value appears at the $I = n$ and $J = 1$ cell. For our example of $n = 3$, this happens at stage 5. The desired LS solution $\hat{x}_1$ appears at stage $(2n + 1)$ (ie., stage 7 for $n = 3$), which is time $k = 2n + m + 1$, while the last solution $\hat{x}_n$ appears at stage $3n$ (i.e., stage 9 for $n = 3$), which is time $k = 3n + m$. The values of $\{\hat{x}_1, \hat{x}_2, \hat{x}_3\}$ at the output of the systolic array are identical to those given by the back substitution method solution of the LS problem.

Kalman Filtering

Kalman filtering (KF) was developed in the late 1950s as a natural extension of the classical Wiener filtering. It has profound influence on the theoretical and practical aspects of estimation and filtering. It is used almost universally for tracking and guidance of aircraft, satellites, GPS, and missiles as well as many system estimation and identification problems. KF is not one unique method, but is a generic name for a class of state estimators based on noisy measurements. KF can be implemented as a specific algorithm on a general-purpose mainframe/mini/microcomputer operating in a batch mode, or it can be implemented on dedicated system using either DSP, ASIC, or custom VLSI processors in a real-time operating mode.

Classically, an analog or a digital filter is often viewed in the frequency domain having some low-pass, bandpass, high-pass, etc. properties. A KF is different from the classical filter in that it may have multiple inputs and multiple outputs with possibly nonstationary and time-varying characteristics performing optimum states estimation based on the unbiased minimum variance estimation criterion.

In the following discussions, we first introduce the basic concepts of KF, followed by various algorithmic variations of KF. Each version has different algorithmic and hardware complexity and implementational implications. Because there are myriad of KF variations, we then consider two simple systolic versions of KF.

Basic Kalman Filtering

The KF model consists of a discrete-time linear dynamical system equation and a measurement equation. A linear discrete-time dynamical system with $n \times 1$ state vector $x(k + 1)$, at time $k + 1$, is given by $x(k + 1) = A(k)x(k) + B(k)u(k) + w(k)$, where $x(k)$ is the $n \times 1$ state vector at time k, $A(k)$ is an $n \times n$ system coefficient matrix, $B(k)$ is an $n \times p$ control matrix, $u(k)$ is a $p \times 1$ deterministic vector, which for some problems may be zero for all k, and $w(k)$ is an $n \times 1$ zero-mean system noise vector with a covariance matrix $W(k)$. The input to the KF is the $m \times 1$ measurement (also called observation) vector $y(k)$, modeled by $y(k) = C(k)x(k) + v(k)$, where $C(k)$ is an $m \times n$ measurement coefficient matrix, and $v(k)$ is a $m \times 1$ zero-mean measurement noise vector with an $m \times m$ positive-definite covariance matrix $V(k)$. The requirement of the positive-definite condition on $V(k)$ is to guarantee the Cholesky (square root) factorization of $V(k)$ for certain KF algorithms. In general, we will have $m \leq n$ (i.e., the measurement vector dimension is less than or equal to that of the state vector dimension). It is also assumed that $w(k)$ is uncorrelated to $v(k)$. That is, $E\{w(i)v(j)^T\} = 0$. We also assume each noise sequence is white in the sense $E\{w(i)w(j)^T\} = E\{v(i)v(j)^T\} = 0$, for all $i \neq j$.

The KF provides a recursive linear estimation of $x(k)$ under the minimum variance criterion based on the observation of the measurement $y(k)$. Let $\hat{x}(k)$ denote the optimum filter state estimate of $x(k)$ given measurements up to and including $y(k)$, while $x_+(k)$ denotes the optimum predicted state estimate of $x(k)$ given measurement up to and including $y(k - 1)$. Then the $n \times n$ **optimum estimation error covariance matrix** is given by $P(k) = E\{(x(k) - \hat{x}(k))(x(k) - \hat{x}(k))^T\}$, while the **minimum estimation error variance** is given by $J(k) = \text{Trace}\ \{P(k) = E\{(x(k) - \hat{x}(k))^T\ (x(k) - \hat{x}(k))\}$. The $n \times n$ **optimum prediction error covariance matrix** is given by $P_+(k) = E\{x(k) - x_+(k))(x(k) - x_+(k))^T\}$.

© 2003 by CRC Press LLC

The original KF recursively updates the optimum error covariance and the optimum state estimate vector by using two sets of update equations. Thus, it is often called the **covariance KF**. The **time update equations** for $k = 1, 2, \ldots$, are given by $x_+(k) = A(k-1)\hat{x}(k-1) + B(k-1)u(k-1)$ and $P_+(k) = A(k-1)P(k-1)A^{\mathrm{T}}(k-1) + W(k-1)$. The $n \times n$ **Kalman gain matrix** $K(k)$ is given by $K(k) = P_+(k)C^{\mathrm{T}}(k)[C(k)P_+(k)C^{\mathrm{T}}(k) + V(k)]^{-1}$. The **measurement update equations** are given by $\hat{x}(k) = x_+(k) + K(k)(y(k) - C(k)x_+(k))$ and $P(k) = P_+(k) - K(k)P_+(k)$. The first equation shows the update relationship of $\hat{x}(k)$ to the predicted state estimate $x_+(k)$, for $x(k)$ based on $\{\cdots, y(k-2), y(k-2), y(k-1)\}$, when the latest observed value $y(k)$ is available. The second equation shows the update relationship between $P(k)$ and $P_+(k)$. Both equations depend on the $K(k)$, which depends on the measurement coefficient matrix $C(k)$and the statistical property of the measurement noise, covariance matrix $V(k)$. Furthermore, $K(k)$ involves an $m \times m$ matrix inversion.

Other Forms of Kalman Filtering

The basic KF algorithm considered above is called the covariance form of KF because the algorithm propagates the prediction and estimation error covariance matrices $P_+(k)$ and $P(k)$. Many versions of the KF are possible, characterized partially by the nature of the propagation of these matrices. Ideally, under infinite precision computations, no difference in results is observed among different versions of the KF. However, the computational complexity and the systolic implementation of different versions of the KF are certainly different. Under finite precision computations, especially for small numbers of bits under fixed point arithmetics, the differences among different versions can be significant. In the following discussions we may omit the deterministic control vector $u(k)$ because it is usually not needed in many problems. In the following chol (.) qr(.), and triu (.) stand for Cholesky factor, QR decomposition, and triangular factor, respectively.

1. **Information Filter.** The inverse of the estimation error covariance matrix $P(k)$ is called the information matrix and is denoted by $PI(k)$. A KF can be obtained by propagating the information matrix and other relevant terms. Specifically, the information filter algorithm is given by time updates for $k = 1, 2, \ldots$, of $L(k) = A^{-\mathrm{T}}(k-1)PI(k-1)A^{-1}(k-1) \times [W^{-1}(k-1) + A^{-\mathrm{T}}(k-1)PI(k-1)A^{-\mathrm{T}}(k-1)]^{-1}$, $d_+(k) = (I - L(k)A^{-\mathrm{T}}(k-1)PI(k-1)A^{-1}(k-1)$. The measurements updates are given by $d(k) = d_+(k) + C^{\mathrm{T}}(k)V^{-1}(k)y(k)PI(k) = PI_+(k) + C^{\mathrm{T}}(k)V^{-1}(k)C(k)$.
2. **Square-Root Covariance Filter (SRCF).** In this form of the KF, we propagate the square root of $P(k)$. In this manner, we need to use a lower dynamic range in the computations and obtain a more stable solution under finite precision computations. We assume all three relevant covariance matrices are positive-definite and have the factorized form of $P(k) = S^{\mathrm{T}}(k)S(k)$, $W(k) = S_W^{\mathrm{T}}(k)S_W(k)$, $V(k) = S^{\mathrm{T}}(k)S_v(k)$. In particular, $S(k) = \mathrm{chol}(P(k))$, $S_W(k) = \mathrm{chol}(W(k))$, $S_V(k) = \mathrm{chol}(V(k))$, are the upper triangular Cholesky factorizations of $P(k)$, $W(k)$, and $V(k)$, respectively. The time updates for $k = 1, 2, \ldots$, are given by $x_+(k) = A(k-1)\,\hat{x}\,(k-1)$, $U(k) = \mathrm{triu}(\mathrm{qr}([S(k-1)A^{\mathrm{T}}(k-1); S_W(k-1)]))$, $P_{+s}(k) = U(k)(1{:}n;\ 1{:}n)$. The measurement updates are given by $P_+(k) = P_{+s}^{\mathrm{T}}(k)P_{+s}(k)$,/,$K(k) = P_+(k)C^+(k)[C(k)P_+(k)C^+(k)+V(k)]^{-1}$, $\hat{x}(k) + K(k)(y(k) - C(k)x_+(k))$,$Z(k) = \mathrm{triu}(qr([S_v(k),\ 0_{mn}; P_{+s}(k)C^+(k),\ P_{+s}(k)]))$ and $S(k) = \mathrm{Z}(k)(m+1{:}\ m+n,\ m+1{:}\ m+n)$.
3. **Square-Root Information Filter (SRIF).** In the SRIF form of the KF, we propagate the square root of the information matrix. Just as in the SRCF approach, as compared to the conventional covariance form of the KF, the SRIF approach, as compared to the SRIF approach, needs to use a lower dynamic range in the computations and obtain a more stable solution under finite precision computations. First, we denote $SI(k) = (\mathrm{chol}\ (P(k)))^{-1}$, $SI_W(k) = (\mathrm{chol}(W(k)))^{-1}$, and $SI_V(k) = (\mathrm{chol}(V(k)))^{-1}$. The time updates for $k = 1, 2, \ldots$, are given by $U(k) = \mathrm{triu}(\mathrm{qr}([SI_W(k-1),\ 0_{n\times n}, 0_{n\times 1}; SI(k-1)A^{-1}(k-1),\ SI(k-1)A^{-1}(k-1),\ b(k-1)]))$, $P_{+S}(K) = U(k)(n+1{:}2n,\ n+1{:}2n)$ and $b_+(k) = U(k)(n+1{:}\ 2n, 2n+1)$. The measurement updates are given by $\mathrm{Z}(k) = \mathrm{triu}(\mathrm{qr}([P_{+S}(k),b_+(k); SI_V(k)C(k),\ SI_V(k)y(k)]))SI(k) = Z(k)(1{:}n,\ 1{:}n)$, and $b(k) = Z(k)(1{:}\ n,\ n+1)$. At any iteration, $\hat{x}(k)$ and $P(k)$ are related to $b(k)$ and $SI(k)$ by $\hat{x}(k) = SI(k)b(k)$ and $P(k) = (SI^{\mathrm{T}}(k)SI(k))^{-1}$.

Systolic Matrix Implementation of the KF Predictor

The covariance KF for the optimum state estimate $\hat{x}(k)$ includes the KF predictor $x_+(k)$ In particular, if we are only interested in $x_+(k)$ a relatively simple algorithm for $k = 1, 2, \ldots$, is given by $K(k) = P_+(k)C^{\mathrm{T}}(k)[C(k)P_+(k)C^{\mathrm{T}}(k) + V(k)]^{-1}$, $x_+(k+1) = A(k)\,x_+(k) + A(k)\,K(k)\,[y(k) - C(k)x_+\,(k)]$ and $P_+(k+1) = A(k)\,P_+(k)A^{\mathrm{T}}(k) - A(k)K(k)C(k)P_+(k)A^{\mathrm{T}}(k) + W(k)$. To start this KF prediction algorithm, we use $\hat{x}(0)$ and $P(0)$ to obtain $x_+(1) = A(0)\hat{x}(0)$ and $P_+(1) = A(0)P(0)A^{\mathrm{T}}(0) + W(0)$. The above operations involve matrix inverse; matrix-matrix and matrix-vector multiplications; and matrix and vector additions. Fortunately, the matrix inversion of $\alpha = C(k)P_+(k)C^{\mathrm{T}}(k) + V(k)$ can be approximated by the iteration of $\beta(i+1) = \beta(i)[2I - \alpha\beta(i)$, $i = 1, \ldots, I$. Here, $\beta(i)$ is the ith iteration estimate of the inverse of the matrix α. While the preceding equation is not valid for arbitrary α and $\beta(i)$, for KF applications, we can use $I = 4$ because a good initial estimate $\beta(1)$ of the desired inverse is available from the previous step in the KF. Clearly, with the use of the above equation for the matrix inversion, all the operations needed in the KF predictor can be implemented on an orthogonal array using systolic matrix operations of the form $D = B \times A + C$, as shown in Fig. 61.113.

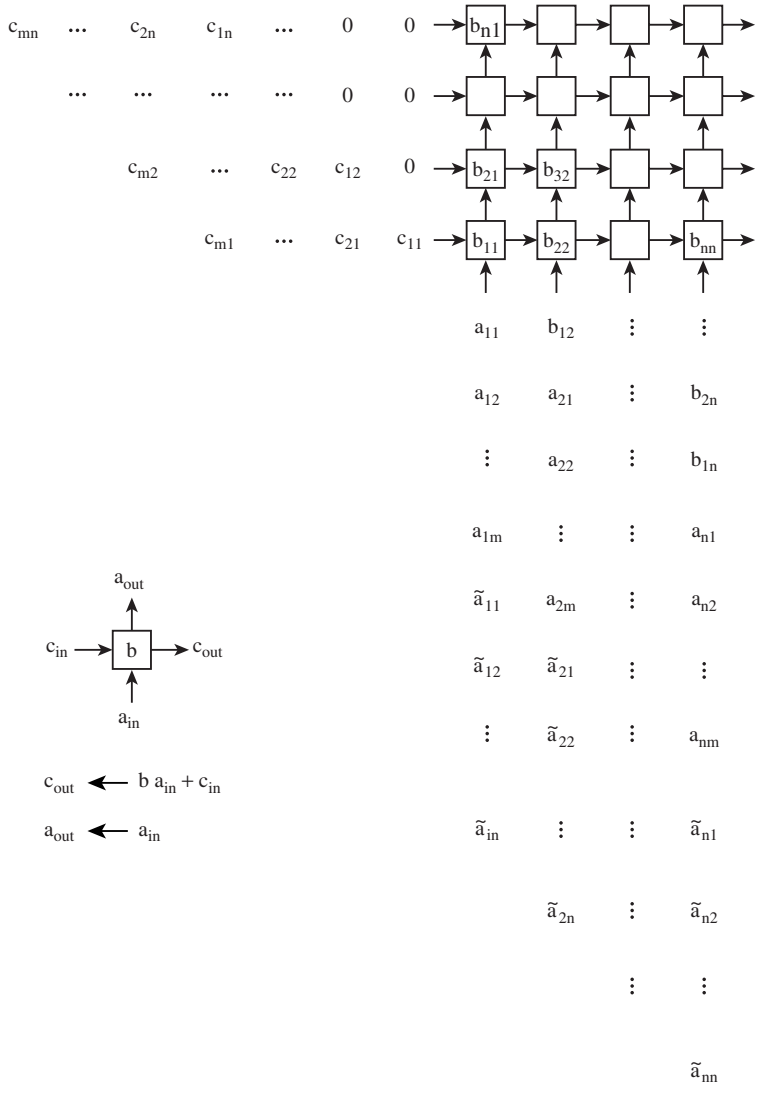

FIGURE 61.113 Systolic matrix multiplication and addition of $B \times A + C$.

TABLE 61.14 Systolic Matrix Operations of a KF Predictor

Step	B	A	C	D	Time
1	$P_+(k)$	$C^T(k)$	0	$P_+(k)\ C^T(k)$	$n+m$
2	$P_+(k)$	$A^T(k)$	0	$P_+(k)\ A^T(k)$	n
3	$C(k)$	$P_+(k)\ C^T(k)$	$V(k)$	$C(k)P_+(k)\ C^T(k)+V(k)=\alpha$	$2m$
4	α	$-\beta(i)$	$2I$	$2I-\alpha\beta(i)$	$2Im$
5	$\beta(i)$	$2I-\alpha\beta(i)$	0	$\beta(i+1)$	$2Im$
6	$P_+(k)\ C^T(k)$	β	0	$K(k)$	$n+m$
7	$A(k)$	$K(k)$	0	$A(k)K(k)$	$n+m$
8	$A(k)$	$x_+(k)$	0	$A(k)x_+(k)$	1
9	$-C(k)$	$x_+(k)$	$y(k)$	$y(k)-C(k)x_+(k)$	$m+1$
10	$A(k)K)(k)$	$-C(k)$	$A(k)$	$A(k)-A(k)K(k)C(k)$	$2n$
11	$A(k)K(k)$	$y(k)-C(k)x_+(k)$	$A(k)x_+(k)$	$x_+(k+1)$	1
12	n–3				
13	$A(k)-A(k)K(k)C(k)$	$P_+(k)\ A^T(k)$	$W(k)$	$P_+(k)$	$2n$

The recursive algorithm of the KF predictor is decomposed as a sequence of matrix multiplications, as shown in Table 61.14. In step 1 the $n \times n$ matrix $P_+(k)$ and the $m \times n$ matrix $C^T(k)$ are denoted as B and A, respectively. The rows of B (starting from the n, $n-1$, …,1 row) are skewed and inputted to the n x n array starting at time 1. By time n (as shown in Fig. 61.113), all the elements of the first column of B (i.e., b_{n1}, …, b_{11}) are in the first column of the array. At time $n+1$, …, $2n-1$, elements of the second to nth columns of B are inputted to the array and remain there until the completion of the BA matrix multiplication. At time $n+1$, a_{11} enters (1,1) cell and starts the BA process. At time $n+m$, a_{1m} enters the (1,1) cell. Of course, additional times are needed for other elements in the second to the nth rows of A to enter the array. Further processing and propagation times are needed before all the elements of $D = BA = P_+(k)C^T(k)$ are outputted. However, in step 2, because B remains as $P_+(k)$, we do not need to input it again, but only append $A(k)$ (denote as $\tilde{A}$ in Fig. 61.113) in the usual skewed manner after the previous A = $C^T(k)$. Thus, at time $n+m+1$, $\tilde{a}_{11}$ enters the (1, 1) cell. By time $n+m+n$, $\tilde{a}_{1n}$ enters the (1, 1) cell. Thus, step 1 takes $n+m$ time units, while step 2 takes only n time units. In step 3 m time units are needed to load $C(k)$ and m time units are needed to input $P_+(k)C^T(k)$, resulting in $2m$ time units. Steps 4 and 5 perform one iteration of the inverse approximation. In general, $I = 4$ iterations is adequate, and $16m$ time units are needed. Thus far, all the matrices and vectors are fed continuously into the array with no delay. However, in order to initiate step 13, the $(n, 1)$ component of $(A(k) - A(k)K(k)C(k)$ is needed, but not available. Thus, at the end of step 11, an additional $(n-3)$ time units of delay must be provided to access this component. From Table 61.14, a total of $9n + 22m$ time units is needed to perform one complete KF prediction iteration.

Systolic KF Based on the Faddeev Algorithm

A form of KF based on mixed prediction error covariance $P_+(k)$ and information matrix $PI\ (k) = P^{-1}(k)$ updates can be obtained from the covariance KF algorithm. For $k = 1, 2, \ldots$, we have $x_+(k) = A(k-1)\hat{x}(k-1) + B(k-1)$, $P_+(k) = A(k-1)PI^{-1}(k-1)A^T(k-1) + W(k-1)$, $PI(k) = P_+^{-1}(k) + C^T(k)V^{-1}(k)C(k)K(k) = PI^{-1}(k)C^T(k)V^{-1}(k)$ and $\hat{x}(k) = x_+(k) + K(k)(y(k) - C(k)x_+(k))$. The algorithm starts with the given $\hat{x}(0)$ and $P(0)$, as usual. Because this algorithm requires the repeated use of matrix inversions for $(PI(k-1))$, $(P_+(k))^{-1}$, $(V(k))^{-1}$ as well as $P(k) = (PI(k))^{-1}$, the following **Faddeev algorithm** is suited for this approach.

Consider an n x n matrix A, an n x m matrix B, a p x n matrix C, and a p x m matrix D arranged in the form of a compound matrix $[A\ B; -C\ D]$. Consider a p x n matrix W multiplying $[A\ B]$ and added to $[-C\ D]$, resulting in $[A\ B; -C + WAD + WB]$. Assume W is chosen such that $-C + WA = 0$, or $W = CA^{-1}$. Then, we set $D + WB = D + CA^{-1}B$.

In particular, by picking $\{A, B, C, D\}$ appropriately, the basic matrix operations needed above can be obtained using the Faddeev algorithm. Some examples are given by

© 2003 by CRC Press LLC

$$\begin{matrix} A & I \\ -I & 0 \end{matrix} \Rightarrow D + WB = A^{-1}$$

$$\begin{matrix} I & B \\ -C & 0 \end{matrix} \Rightarrow D + W\ B = CB$$

$$\begin{matrix} I & B \\ -C & D \end{matrix} \Rightarrow D + WB = D + CB$$

$$\begin{matrix} A & B \\ -I & 0 \end{matrix} \Rightarrow D + WB = A^{-1}B$$

A modified form of the previous Faddeev algorithm first triangularizes A with an orthogonal transformation Q, which is more desirable from the finite precision point of view. Then, the nullification of the lower left portion can be performed easily using the Gaussian elimination procedure. Specifically, applying a QRD, $Q[A\ B] = [R\ QB]$. Then, applying the appropriate W yields

$$\begin{bmatrix} R & QB \\ -C + WQA & D + WQB \end{bmatrix} = \begin{bmatrix} R & QB \\ 0 & D + CA^{-1}B \end{bmatrix} \tag{61.24}$$

The preceding mixed prediction error covariance and information matrix KF algorithm can be reformulated as a sequence of Faddeev algorithm operations, as given in Table 61.15. The times needed to perform steps 2, 3, 4, and 6 are clearly just the sum of the lengths of the two matrices in the corresponding steps. Step 1 requires only n times unit to input the second row of matrices because $\hat{x}(k-1)$ is already located in the array from the previous iteration (step 8 output) and one time unit to output $x_+(k)$. Due to the form of $[-I\ 0]$ in step 4, $C(k)$ of step 5 can be inputted before the completion of $P_+^{-1}(k)$ in step 4. Thus, only n time units are needed in step 5. Similarly, $x_+(k)$ of step 7 can be inputted in step 6. Thus, we need

TABLE 61.15 Faddeev Algorithm Solution to KF

Step	Compound Matrix	$D + WB$	Time
1	$\begin{matrix} I & \hat{x}(k-1) \\ -A(k-1) & B(k-1)u(k-1) \end{matrix}$	$x_+(k)$	$n+1$
2	$\begin{matrix} P^{-1}(k-1) & A^{\mathrm{T}}(k-1) \\ -A(k-1) & W(k-1) \end{matrix}$	$P_+(k)$	$2n$
3	$\begin{matrix} V(k-1) & I \\ -C^{\mathrm{T}}(k) & 0 \end{matrix}$	$C^{\mathrm{T}}(k)V^{-1}(k-1)$	$m+n$
4	$\begin{matrix} P_+(k) & \mathrm{I} \\ -I & 0 \end{matrix}$	$p_+^{-1}(k)$	$2n$
5	$\begin{matrix} I & C(k) \\ -C^{\mathrm{T}}(k)V^{-1}(k) & P_+^{-1}(k) \end{matrix}$	$P^{-1}(k)$	n
6	$\begin{matrix} P^{-1}(k) & C^{\mathrm{T}}(k+1)V^{-1}(k) \\ -I & 0 \end{matrix}$	$K(k)$	$2n$
7	$\begin{matrix} I & x_+(k) \\ C(k) & y(k) \end{matrix}$	$y(k) - C(k)_{x_+}(k)$	$m+1$
8	$\begin{matrix} I & y(k) - C(k)x_+(k) \\ -K(k) & x_+(k) \end{matrix}$	$\hat{x}(k)$	$m+1$

© 2003 by CRC Press LLC

only $m + 1$ time units to input $[C(k)\ y(k)]$ and complete its operations. In step 8 only $m + 1$ time units are needed as in step 1. Thus, a total of $9n + 3m + 3$ time units are needed for the Faddeev algorithm approach to the KF.

Other Forms of Systolic KF and Conclusions

While the operations of a KF can be expressed in many ways, only some of these algorithms are suited for systolic array implementations. For a KF problem with a state vector of dimension n and a measurement vector of dimension m, we have shown the systolic matrix-matrix multiplication implementation of the predictor form of the KF needs $9n + 22m$ time steps for each iteration. A form of KF based on mixed update of prediction error covariance and information matrices is developed based on the Faddeev algorithm using matrix-matrix systolic array implementation. It has a total of $9n + 3m + 3$ time steps per iteration. A modified form of the SRIF algorithm can be implemented as a systolic array consisting of an upper rectangular array of $n(n + 1)/2$ internal cells, and a lower n-dimensional triangular array of n boundary cells, and $(n - 1)^2/2$ internal cells, plus a row of n internal cells, and $(n - 1)$ delay cells. It has a total of n-boundary cells, $((n-1)^2 + 2n^2 + 2n)/2$ internal cells, and $(n-1)$ delay cells. Its throughput rate is $3n$ time steps per iteration. A modified form of the SRCF algorithm utilizing the Faddeev algorithm results in a modified SRCF form of a KF consisting of a trapezodial section, a linear section, and a triangular section systolic array. The total of these three sections needs $(n + m)$ boundary cells, n linear cells, and $((m - 1)^2 + 2nm + (n - 1)^2)/2$ internal cells. Its throughput rate is $3n + m + 1$ time steps per iteration. The operations of both of these systolic KF are quite involved and detailed discussions are omitted here. In practice, in order to compare different systolic KFs, one needs to concern oneself not only with the hardware complexity and the throughput rate, but other factors involving the number of bits needed finite precision computations, data movement in the array, and I–O requirements as well.

Eigenvalue and Singular Value Decompositions

Results from linear algebra and matrix analysis have led to many powerful techniques for the solution of wide range of practical engineering and signal processing problems. Although known for many years, these mathematical tools have been considered too computationally demanding to be of any practical use, especially when the speed of calculation is an issue. Due to the lack of computational power, engineers had to content themselves with suboptimal methodologies of simpler implementation. Only recently, due to the advent of parallel/systolic computing algorithms, architectures, and technologies, have engineers employed these more sophisticated mathematical techniques. Among these techniques are the so-called eigenvalue decomposition (EVD) and the singular value decomposition (SVD). As an application of these methods, we consider the important problem of spatial filtering.

Motivation–Spatial Filtering Problem

Consider a linear array consisting of L sensors uniformly spaced with an adjacent distance d. A number M, $M < L$, of narrowband signals of center frequency f_0, impinging on the array. These signals arrive from M different spatial direction angles $\theta_1, \ldots, \theta_M$, relative to some reference direction. Each sensor is provided with a variable weight. The weighted sensor outputs are then collected and summed. The goal is to compute the set of weights to enhance the estimation of the desired signals arriving from directions $\theta_1, \ldots, \theta_M$.

In one class of beamformation problems, one sensor (sometimes referred to as main sensor) receives the desired signal perturbed by interference and noise. The remaining $L - 1$ sensors (auxiliary sensors) are mounted and aimed in such a way as to collect only the (uncorrelated) interference and noise components. In this scenario the main sensor gain is to be kept at a fixed value, while the auxiliary weights are adjusted in such a way as to cancel out as much perturbation as possible. Obviously, the only difference of this latter cast is that one of the weights (the one corresponding to the main sensor) is kept at a constant value of unity.

Let the output of the ith sensor, $i = 1, \ldots, L$, at discrete time $n = 0, 1, \ldots$, be given by

© 2003 by CRC Press LLC

$$\bar{x}_i(n) = \Re\left\{\left[x_i(n) + v_i(n)\right]e^{j(2\pi f_0 n)}\right\} \qquad x_i(n) = a_i(n)\sum_{k=1}^{M} S_k(n)e^{j2\pi(i-1)d\sin\theta_k/\lambda}$$

where $a_i(n)$ is the antenna gain at time n, S_k is the complex amplitude of the kth signal, inclusive of the initial phase, and λ is the signal wavelength. The vectors $x_i(n)$ and $v_i(n)$ are analytic signal representations. The noise $v_i(n)$ is assumed to be uncorrelated white and Gaussian, of power σ_N^2. In order to avoid the ill effects of spatial aliasing, let us also assume that $d \le \lambda/2$. The outputs of the sensor array for times $n = 0, 1, \ldots, N$, can be collected in matrix form as follows:

$$\underbrace{X}_{N\times L} = \underbrace{S}_{N\times M} = \underbrace{A}_{M\times L} + \underbrace{V}_{N\times L}$$

The matrix A is referred to as the **steering matrix**. In the case in which $a_i(n) = 1$ for all i, the matrix A is Vandermonde and full rank, and its kth row can be expressed as $A(\theta) = (1, e^{j2\pi d\sin\theta/\lambda}, \ldots, e^{j2\pi(L-I)d\sin\theta_k/\lambda})$.

The data correlation matrix, $R_X = \mathrm{E}\{X^{\mathrm{H}}X\}$, where $E(\cdot)$ is the ensemble average operator, is equal to $R_X = A^H R_s A + \sigma_N^2 I$, $R_s = \mathrm{E}\{S^{\mathrm{H}}S\}$. We note:

1. The matrix R_s has rank M by definition as does the matrix $A^{\mathrm{H}}R_s A$.
2. The rows of A are in the range space of R_X.
3. The value σ_N^2 is an eigenvalue of R_X with multiplicity $L - M$, given the det $(R_X - \sigma_N^2 I) = 0$, and the rank of $A^{\mathrm{H}}R_s A$ is M.

The eigenvalue decomposition of R_X can therefore be written as $R_X = V_S\Lambda_S V_S^{\mathrm{H}} + \sigma_N^2 V_N V_N^{\mathrm{H}}$, where V_S is $L \times M$, V_N is L x $(L - M)$, $V_S^{\mathrm{H}}V_S = I$ and $V_N^{\mathrm{H}}V_N = 1$, and $V_S^{\mathrm{H}}V_N = 0$. Moreover, we have that $AV_N = 0$. Let $A(\theta)$ be a generic steering vector, defined as $A(\theta) \equiv (1, e^{j2\pi d\sin\theta/\lambda}, \ldots, e^{j2\pi(L-I)d\sin\theta/\lambda})$. Then, the function $\mathcal{S}(\theta) = 1/|A(\theta)V_N|^2$ has M poles at the angles $\theta = \theta_k k = 1, \ldots, M$. Alternatively, any linear combination, w, of the columns of V_N is such that $\mathrm{E}\{||Xw||_2\} = \min_z \mathrm{E}\{||Xz||_2\} = \sigma_N$. In other words, the signals impinging from angular directions $\theta_1, \ldots, \theta_M$ are totally canceled out in the system output.

The desired weighting vector for our spatial filtering problem can consequently be expressed as $w = V_N p$, $p = [p_1, \ldots, p_{L-M}]^{\mathrm{T}}$, for any nonzero vector p. From the above discussion, we see that the solution to the original spatial filtering problem can be obtained from the eigenvalue decomposition of the correlation matrix $\mathrm{R}_X = \mathrm{E}\{X^{\mathrm{H}}X\}$. In practice the sample correlation matrix $\hat{R}_X$ is used instead, where the ensemble average is replaced by a suitable temporal average.

The computation of the covariance matrix implies the computation of the matrix product $X^H X$. Some small elements in X are then squared and the magnitude of the resulting element can become comparable or smaller than the machine precision. Rounding errors can often impair and severely degrade the computed solution. In these cases it is better to calculate the desired quantities (correlation eigenvalues and eigenvectors) directly from the data matrix X using the SVD technique as considered next.

Eigenvalue Decomposition of a Symmetric Matrix

Consider an $L \times L$ real symmetric matrix $A = A^T$. In the previous spatial filtering example, $A = R_X$. Let

$$G(i, j, \theta) = \begin{array}{c} \\ i \\ \\ \\ j \\ \\ \end{array}\begin{array}{c} \begin{array}{ccccc} i & & & j & \end{array} \\ \begin{pmatrix} I_{i-1} & & & & \\ & c & & s & \\ & & I_{j-i-1} & & \\ & -s & & c & \\ & & & & I_{L-j} \end{pmatrix} \end{array}$$

© 2003 by CRC Press LLC

be an **orthogonal Givens rotation matrix**, where $c = \cos\theta$ and $s = \sin\theta$. Pre- or postmultiplication of A by G leaves A unchanged, except for rows (columns) i and j, which are replaced by a linear combination of old rows (columns) i and j. A **Jacobi rotation** is obtained by simultaneous pre- and postmultiplication of a matrix by a Givens rotation matrix, as given by $G(i, j, \theta)^{\mathrm{T}} AG(i, j, \theta)$, where θ is usually chosen in order to zero out the (i, j) and (j, i) entries of A.

The matrix A can be driven toward diagonal form by iteratively applying Jacobi rotations, as given by $A_0 \leftarrow A$, $A_{k+1} \leftarrow G_k^{\mathrm{T}} A G_k$, where G_k is a Givens rotation matrix. A **sweep** is obtained by applying $L(L-1)/2$ Jacobi rotations, each nullifying a different pair of off-diagonal elements, according to a prespecified order. Given the matrix $A_k = (a_{pq}^{(k)})$ at the kth iteration, and a pair of indices (i, j), the value of $\tan\theta$ can be obtained from the following equations:

$$u = \frac{a_{jj}^{(k)} - a_{ii}^{(k)}}{2a_{ij}^{(k)}} \quad \tan\theta = \frac{sign(u)}{|u| + \sqrt{1+u^2}} \tag{61.25}$$

It is possible to demonstrate that each Jacobi rotation reduces the matrix off-norm. The matrix A_k indeed tends to diagonal form and for all practical purposes it reaches it after $\mathbb{O}(\log L)$ sweeps.

The matrix V of eigenvectors is obtained by applying the same rotations to a matrix initialized to the identity, as follows: $V_0 \leftarrow I$, $V_{k+1} \leftarrow V_k G_k$. A two-dimensional systolic array implementation of the previous algorithm is shown in Fig. 61.114, for the case $L = 8$. At the beginning of iteration k, processor P_{ij} contains elements

$$\begin{pmatrix} a_{2i-1,2j-1}^{(k)} & a_{2i-1,2j}^{(k)} \\ a_{2i,2j-1}^{(k)} & a_{2i,2j}^{(k)} \end{pmatrix} \qquad i, j = 1, 2, \ldots, L/2 ,$$

The diagonal processors compute the rotation parameters and apply the rotation to the four entries they store. Subsequently, they propagate the rotation parameters horizontally and vertically to their neighbors, which, upon receiving them, apply the corresponding rotation to their stored entries. After the rotation is applied, each processor swaps its entries with its four neighbors along the diagonal connections. The correct data movement at the edges of the array is also shown in Fig. 61.114. A correct scheduling of operations requires that each processor be idle for two out of three time steps, which translates into an *efficiency* of 33%. Each sweep takes $3(L-1)$ time steps, and the number of sweeps can be chosen on the order of $\log L$.

Singular Value Decomposition of a Rectangular Matrix via the Hestenes Algorithm

Consider an $N \times L$ real matrix A, $N \geq L$. Its SVD can be written as follows:

$$\underset{N\times L}{\underset{\sim}{A}} = \underset{N\times L}{\underset{\sim}{U}} \; \underset{L\times L}{\underset{\sim}{\sum}} \; \underset{L\times L}{\underset{\sim}{V^{\mathrm{T}}}}$$

where U and V have orthonormal columns. The matrix $\sum = \mathrm{diag}(\sigma_1, ..., \sigma_L)$ is the diagonal matrix of singular values, where $\sigma_1 \geq \sigma_2 \geq \ldots \geq \sigma_L \geq 0$. Consider the following recursion $A_0 \leftarrow A$, $A_{k+1} \leftarrow A_k G_k$, where the Givens rotations are chosen not to zero out entries of A_k, but to orthogonalize pairs of its columns. A sweep is now defined as a sequence of Givens rotations that orthogonalize all $\binom{L}{2}$ pairs of columns exactly once. Observe the similarity with the algorithm described previously for the calculation of eigenvalues and eigenvectors. If $G(i, j, \theta)$ is the Givens rotation which orthogonalizes columns i and j of A, then $G(i, j, \theta)^{\mathrm{T}} MG(i, j, \theta)$ is the Jacobi rotation that zeroes out the entries (i, j) and (j, i) of $M = A^{\mathrm{T}}A$. A sweep (as defined here) of rotations applied to the rectangular matrix A corresponds exactly to a sweep (as defined earlier) of rotations applied to the symmetric matrix M.

At any time step, the original matrix A can be expressed as follows:

$$A = A_k V_k^{\mathrm{T}} \quad V_k = \prod_{i=1}^{k} G_k$$

where V_k has orthonormal columns for any k (by definition of Givens rotations). After a number of sweeps (on the order of log L) the matrix A_k approaches a matrix, W, of orthogonal columns, $A_k \rightarrow W$, $V_k \rightarrow V$. If σ_i is the norm of the ith column of W, $i = 1, \ldots, L$, then we have $W = U$ diag $(\sigma_1, \ldots, \sigma_L)$, $A = U \sum V^{\mathrm{T}}$.

This SVD approach based on the Hestenes algorithm can be realized on a Brent-Luk [58] linear systolic array, as shown in Fig. 61.115, for the case $L = 8$. Each processor stores a pair of columns; in particular, the procedure starts by storing columns $2k - 1$ and $2k$ in processor P_k. Each processor computes the rotation parameters which orthogonalize the pair of columns.

Let x and z be the two stored columns. Let ξ and ζ be their norms, and η be their inner product. Then the value of $\tan\theta$ from

$$u = \frac{\zeta - \xi}{2\eta} \qquad \tan\theta = \frac{\mathrm{sign}(u)}{|u| + \sqrt{1+u^2}}$$

After applying the computed rotation, each processor swaps its pair of columns with the two neighboring processors along the connections shown in Fig. 61.115. The column indices stored in each processor at the different steps of a single sweep are given in Table 61.16. Note that all the $\binom{L}{2}$ pairs of indices are generated by using the Brent–Luk scheme. The stopping criteria can be set in advance. A possible criterion is by inspecting the magnitude of the rotating angles. When they are all in absolute value below a given threshold, then the algorithm can stop. More commonly, a predetermined number of sweeps is chosen ahead of time. Observation shows that a number of sweeps on the order of log L is sufficient for convergence.

Singular Value Decomposition of a Rectangular Nonsymmetric Matrix via the Jacobi Algorithm

The SVD algorithm described in the previous section has the drawback of a somewhat complicated updating procedure. In many signal processing applications, continuous updating of the matrix decomposition as new samples are appended to the data matrix is required. Such problems occur in spectral analysis, direction-of-arrival estimation, beam forming, etc. An efficient updating procedure for the SVD of rectangular matrices of growing row size is given by the algorithm described in this section, based on the succession of two basic operations: a QR updating step, followed by a rediagonalization operation. This algorithm is otherwise known as a version of the Kogbetliantz algorithm for triangular matrices.

Given the $m \times L$ data matrix at time m, $A_m = [a_1, \ldots, a_m]^T$, where a_i, $i = 1, \ldots, m$ are the rows of A_m, one defines the exponentially weighted matrix $B_m(\beta) A_m$, where $B_m(\beta)$ is the diagonal forgetting matrix $B_m(\beta) \equiv diag(\beta^{m-1}, \beta^{m-2}, \ldots, \beta, 1)$, and $0 < \beta \leq 1$ is the forgetting factor. The updating problem is to determine the SVD of the updated weighted matrix $B_{m+1}(\beta) A_{m+1}$, given the SVD at time m,

$$B_m(\beta) A_m = U_m \sum_m V_m$$

Often only the singular values and right singular vectors are of interest. This is fortunate because the left singular matrix grows in size as time increases, while the sizes of $\sum_m$ and V_m remain unchanged.

The algorithm can be summarized as follows. Given the matrices V_m and $\sum_m$ and the new data sample x_{m+1},

$$\Sigma'_m \leftarrow \begin{pmatrix} \beta \Sigma_m \\ x_{m+1} V_m \end{pmatrix} V'_m \leftarrow V_m,$$

the QR updating step

$$\begin{pmatrix} \Sigma'_m \\ 0 \end{pmatrix} \leftarrow Q_{m+1} \Sigma'_m$$

the rediagonalization using permuted Jacobi rotations

for $k = 1, \ldots, 1$,
  for $i = 1, \ldots, n-1$, $j = i + 1$,

$$\Sigma'_m \leftarrow \prod_{ij} G(i, j, \theta) \Sigma'_m G(i, j, \phi)^T \prod_{ij},$$

$$V'_m \leftarrow V'_m G(i, j, \phi)^T \prod_{ij}.$$

end

© 2003 by CRC Press LLC

end

$\Sigma_{m+1} \leftarrow \Sigma'_m$,

$V_{m+1} \leftarrow V'_m$.

In the preceding algorithm, the parameter l determines both the number of computations between subsequent updates and the estimation accuracy at the end of each update step. When l is chosen equal to the problem order L, then one complete sweep is performed. In practice, the l parameter can be chosen as high as ~$10L$ (usually for block computations or slow updates) and as small as 1 (for very high updating rates, with understandable degradation of estimation accuracy). The matrices Σ_m and Σ'_m are upper triangular at all times. This is ensured by the application of the permuted left and right Givens rotations in the rediagonalization step. After the application of any Jacobi rotation, the rotated rows and columns are subsequently permuted. This expedient not only preserves the upper triangularity of the Σ-matrices, but also makes it possible for the rotations to be generated on the diagonal and propagated along physically adjacent pairs of rows and columns. All these features make this algorithm a very attractive candidate for a systolic implementation.

A schematic diagram of the systolic array proposed by Moonen et al. [63] is shown in Fig. 61.116, where the triangular array stores the matrices Σ_m and Σ'_m, for all m, and the square array stores the V-matrix. The incoming data samples, x_{m+1}, are input into the V-array, where the vector-by-matrix multiplication $x_{m+1}\ V_m$ is performed. The output is subsequently fed into the triangular array. As it propagates through the array, the QR updating step is carried on: left rotations are generated in the diagonal elements of the array and propagated through the corresponding rows of the Σ-matrix. One does not need to wait for the completion of the QR step to start performing the Jacobi rotations associated with the diagonalization step. It is known that the two operations (QR update and diagonalization) can be interleaved without compromising the final result. The parameters relative to the left rotations are, as before, propagated along the rows of the triangular matrix, while the right rotation parameters move along the columns of Σ_m, and are passed on to the V-array. Due to the continual modification of the matrix V_m caused by these right rotations, and because of the use of finite precision arithmetic, the computed right singular matrix may deviate from orthogonality. It is also known that in a realistic environment the norm of $V_m V_m^{\mathrm{T}} - I$ grows linearly with m. Reorthogonalization procedures must therefore be included in the overall scheme. A complicated reorthogonalization procedure based on left rotations, which interleaves with the other operations, was described in Moonen et al. [63]. An improved reorthogonalization algorithm was proposed by Vanpoucke and Moonen [66], where the matrix V_m is stored in parametrized form, thereby guaranteeing orthogonality at all times. The resulting triangular array and its modes of operation were also described.

Bang-Sup Song

Introduction

Digital-to-analog converters (DACs), referred to as decoders in communications terms, are devices by which digital processors communicate with the analog world. Although DACs are used as key elements in analog-to-digital converters (ADCs), they find numerous applications as stand-alone devices from CRT display systems and voice/music synthesizers to automatic test systems, waveform generators, digitally controlled attenuators, process control actuators, and digital transmitters in modern digital communications systems.

The basic function of the DAC is the conversion of input digital numbers into analog waveforms. An N-bit DAC provides a discrete analog output level, either voltage or current, for every level of 2^N digital words, $\{D_i; i = 0, 1,2, \ldots, 2^N - 1\}$, that is applied to the input. Therefore, an ideal voltage DAC generates 2^N discrete analog output voltages for digital inputs varying from 000…00 to 111…11 as illustrated in Fig. 62.1 for the four-bit example. The output has a one-to-one correspondence with the input

$$V_{\text{out}}(D_i) = V_{\text{ref}}\left(\frac{b_N}{2} + \frac{b_{N-1}}{2^2} + \cdots + \frac{b_2}{2^{N-1}} + \frac{b_1}{2^N}\right) \tag{62.1}$$

where V_{ref} is a reference voltage setting the output range of the DAC and $b_N\, b_{N-1},\ldots,b_1$ is the binary representation of the input digital word D_i. In the unipolar case, as shown, the reference point is 0 when the digital input D_0 is 000…00, but in bipolar or differential DACs, the reference point is the midpoint of the full scale when the digital input is 100…00, and the range is defined from $-V_{\text{ref}}/2$ to $V_{\text{ref}}/2$. Although purely current-output DACs are possible, voltage-output DACs are common in most applications.

Signal-to-Noise Ratio and Dynamic Range

The resolution is a term used to describe a minimum voltage or current that a DAC can resolve. The fundamental limit of a DAC is the quantization noise due to the finite resolution of the DAC. IF the input digital word is N bits long, the minimum step that a DAC can resolve is $V_{\text{ref}}/2^N$. If output voltages

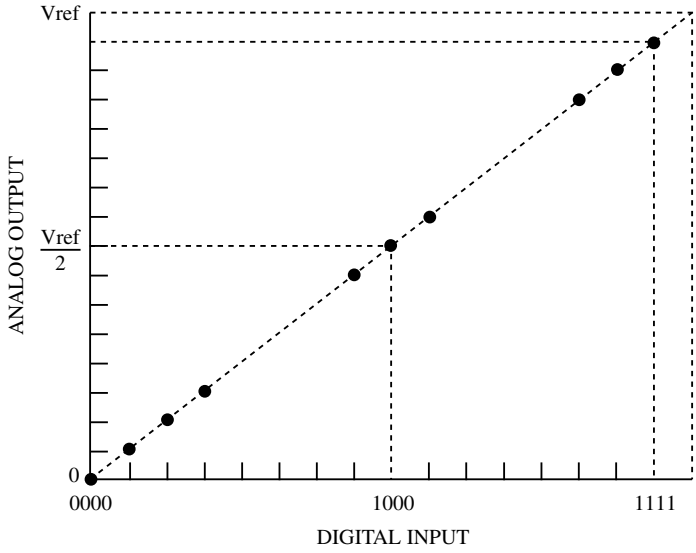

FIGURE 62.1 Transfer characteristics of a unipolar DAC.

are reproduced with this minimum step of uncertainty, an ideal DAC should have a maximum signal-to-noise ratio (SNR) of

$$\text{SNR} = \frac{3}{2}2^{2N} \approx 6N + 1.8(\text{dB}) \tag{62.2}$$

where SNR is defined as the power ratio of the maximum signal to the inband uncorrelated noise. For example, an ideal 16-bit DAC has an SNR of about 97.8 dB. The spectrum of the quantization noise is evenly distributed up to the Nyquist bandwidth (half the sampling frequency). Therefore, this inband quantization noise decreases by 3 dB when the oversampling ratio is doubled. This implies that when oversampled, the SNR within the signal band can be made lower than the quantization noise limited by (62.2).

The resolution of a DAC is usually characterized in terms of SNR, but the SNR accounts only for the uncorrelated noise. The real noise performance is better represented by TSNR, which is the ratio of the signal power to the total inband noise, including harmonic distortion. Also, a slightly different term is often used in place of the SNR. The useful signal range or dynamic range is defined as the power ratio of the maximum signal to the minimum signal. The minimum signal is defined as the smallest input, for which the TSNR is 0 dB, while the maximum signal is the full-scale input. Therefore, the SNR of nonideal DACs can be lower than the ideal dynamic range because the noise floor can be higher with a large signal present. In practice, DACs are limited not only by the quantization noise, but also by nonideal factors such as noises from circuit components, power supply coupling, noisy substrate, timing jitter, insufficient settling, and nonlinearity.

Basic Converter Design Issues

The performance of a DAC can be specified in terms of its linearity, monotonicity, and conversion speed. In most conventional DACs, except for the oversampling DACs the linearity and monotonicity are limited by how accurately the reference voltage/current is divided using passive/active components.

Linearity

Differential Nonlinearity. The output range of an N–bit DAC is equally divided into 2^N small units, as shown in Fig. 62.1, and one least significant bit (LSB) change in the input digital word makes the analog

© 2003 by CRC Press LLC

output voltage change by $V_{ref}/2^N$. The differential nonlinearity (DNL) is a measure of the deviation of the actual DAC output voltage step from this ideal voltage step for 1 LSB. The DNL is defined as

$$\text{DNL} = \frac{V_{out}(D_{i+1}) - V_{out}(D_i) - V_{ref}/2^N}{V_{ref}/2^N}, \quad \text{for } i = 0,1,\ldots,2^N - 2\ (\text{LSB}) \tag{62.3}$$

and the largest positive and negative numbers are usually quoted to specify the static performance of a DAC.

Integral Nonlinearity. The overall linearity of a DAC can be specified in terms of the integral nonlinearity (INL), which is a measure of deviation of the actual DAC output voltage from the ideal straight line drawn between two endpoints, 0 and V_{ref}. Because the ideal output is $i \times V_{ref}/2^N$ for any digital input D_i, the INL is defined as

$$\text{INL} = \frac{V_{out}(D_i) - i \times V_{ref}/2^N}{V_{ref}/2^N}, \quad \text{for } i = 0,1,\ldots,2^N - 1\ (\text{LSB}) \tag{62.4}$$

and the largest positive and negative numbers are usually quoted to specify the static performance of a DAC.

However, several definitions of INL may result depending on how two endpoints are defined. In some DAC architectures the two endpoints are not exactly 0 and V_{ref}. The nonideal reference point causes an offset error, while the nonideal full-scale range gives rise to a gain error. In most DAC applications, these offset and gain errors resulting from the nonideal endpoints do not matter, and the integral linearity can be better defined in a relative measure using a straight line linearity concept rather than the end point linearity in the absolute measure. The straight line can be defined as two endpoints of the actual DAC output voltages or as a theoretical straight line adjusted to best fit the actual DAC output characteristics. The former definition is sometimes called endpoint linearity, while the latter is called best straight line linearity.

Monotonicity

The DAC output should increase over its full range as the digital input word to the DAC increases. That is, the negative DNL should be < -1 LSB for a DAC to be monotonic. Monotonicity is critical in most applications, in particular, in digital control applications. The source of nonmonotonicity is an inaccuracy in binary weighting of a DAC. For example, the most significant bit (MSB) has a weight of one half of the full range. If the MSB weight is smaller than the ideal value, the analog output change can be smaller than the ideal step $V_{ref}/2^N$ when the input digital word changes from 0111…11 to 1000…00 at the midpoint of the DAC range. If this decrease in the output is > 1 LSB, the DAC becomes nonmonotonic. The similar nonmonotonicity can take place when switching the second or lower MSB bits in binary-weighted multi-bit DACs.

Monotonicity is inherently guaranteed if an N–bit DAC is made of 2^N elements for thermometer decoding. However, it is impractical to implement high-resolution DACs using 2^N elements because the number of elements grows exponentially as N increases. Therefore, to guarantee monotonicity in practical applications, DACs have been implemented using either a segmented DAC or an integrator-type DAC. Oversampling interpolative DACs also achieve monotonicity using a pulse-density modulated bitstream converted into analog voltages by a lossy integrator or by a low-pass filter.

Segmented Digital-to-Analog Converters. Applying a two-step conversion concept, a DAC can be made in two levels using coarse and fine DACs. The fine DAC divides one coarse MSB segment into fine LSBs. If one fixed MSB segment is subdivided to generate LSBs, matching among MSB segments creates a nonmonotonicity problem. However, if the next MSB segment is subdivided instead of the fixed segment, the segmented DAC can maintain monotonicity regardless of the MSB matching. This is called **next-segment approach**. Unless the next segment approach is used to make a segmented DAC with a total $M + N$ bits, the MSB DAC should have a resolution of $M + N$ bits for monotonicity, while the LSB DAC

© 2003 by CRC Press LLC

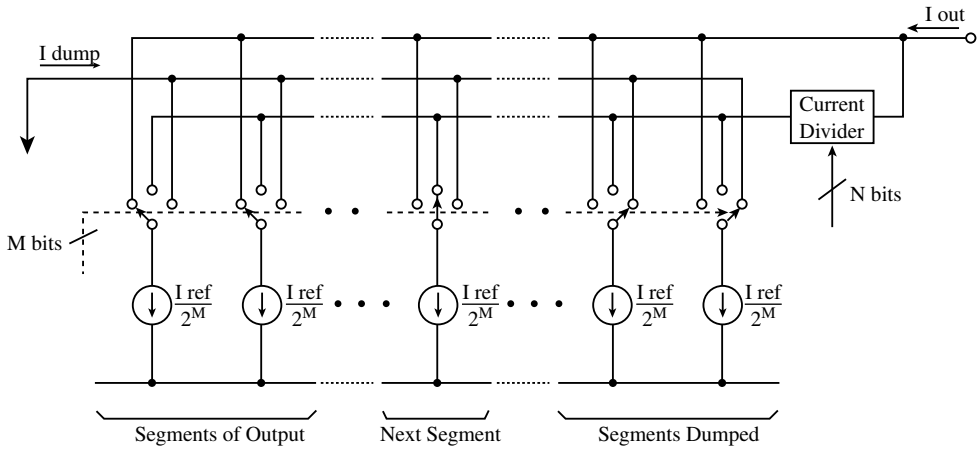

FIGURE 62.2 Segmented DAC for monotonicity.

requires an *N*–bit resolution. Using the next-segment approach, an MSB DAC made of 2^M identical elements guarantees monotonicity, although INL is still limited by the MSB matching.

To implement a segmented DAC using two resistor-string DACs, voltage buffers are needed to drive the LSB DAC without loading the MSB DAC. Although the resistor-string MSB DAC is monotonic, overall monotonicity is not guaranteed due to the offsets of the voltage buffers. The use of a capacitor-array LSB DAC eliminates a need for voltage buffers. The most widely used segmented DAC is a current-ratioed DAC, whose MSB DAC is made of identical elements for the next-segment approach, but the LSB DAC is a current divider. A binary-weighted current divider can be used as an LSB DAC, as shown in Fig. 62.2. For monotonicity, the MSB *M*–bits are selected by a thermometer code, but one of the MSB current sources corresponding to the next segment of the thermometer code is divided by a current divider for fine LSBs.

Integrator-Type Digital-to-Analog Converters. As mentioned, monotonicity is guaranteed only in a thermometer-coded DAC. The thermometer coding of a DAC output can be implemented either by repeating identical DAC elements many times or by repeatedly using the same element. The former requires more hardware, but the latter more time. In the continuous time integrator-type DAC the integrator output is a linear ramp and the time to stop integrating can be controlled by the digital codes. Therefore, monotonicity can be maintained. Similarly, the discrete time integrator can integrate a constant amount of charge repeatedly and the number of integrations can be controlled by the digital codes. The integration approach can give high accuracy, but its disadvantage is its slow speed limiting its applications.

Although it is different in concept, oversampling interpolative DACs modulate the digital code in to a bitstream, and its pulse density represents the DAC output. Due to the incremental nature of the pulse density modulation, oversampling DACs are monotonic. A DAC for the pulse-density modulated bit-stream is a lossy integrator. The integrator integrates a constant charge if the pulse is high, while it subtracts the same charge if the pulse is low. In principle, it is equivalent to the discrete time integrator DAC, but the output is represented by the average charge on the integrator.

Conversion Speed

The output of a DAC is a sampled-and-held step waveform held constant during a word clock period. Any deviation from the ideal step waveform causes an error in the DAC output. Highspeed DACs usually have a current output, but even current-output DACs are either terminated with a 50 to 75 Ω low-impedance load or buffered by a wideband transresistance amplifier. Therefore, the speed of a DAC is limited either by the RC time constant of the output node or by the bandwidth of the output buffer amplifier. Figure 62.3 illustrates two step responses of a DAC when it settles with a time constant of τ

© 2003 by CRC Press LLC

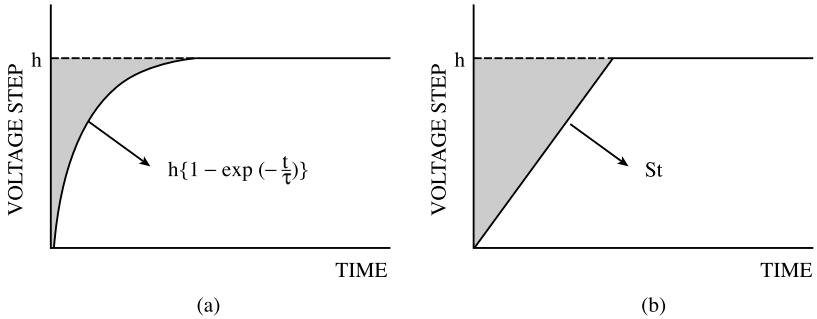

FIGURE 62.3 Errors in step response: (a) settling, and (b) slewing.

and when it slews with a slew rate of S, respectively. The transient errors given by the shaded areas of Fig. 62.3 are $h\tau$ and $h^2/2S$, respectively. This implies that a single time-constant settling of the former case only generates a linear error in the output, which does not effect the DAC linearity, but the slew-limited settling of the buffer generates a nonlinear error. Even in the single-time constant case (the former), the code-dependant time constant in settling can introduce a nonlinearity error because the settling error is a function of the time constant τ. This is true for a resistor-string DAC, which exhibits a code-dependent settling time because the output resistance of the DAC depends on the digital input.

The slew rate limit of the buffer is a significant source of nonlinearity since the error is proportional to the square of the signal, as shown in Fig. 62.3(b). The height and the width of the error term change with the input. The worst-case harmonic distortion (HD) when generating a sinusoidal signal with a magnitude V_0 with a limited slew rate of S is [1].

$$\mathrm{HD}_k = 8\frac{\sin^2\dfrac{\omega T_c}{2}}{\pi k\left(k^2-4\right)}\times\frac{V_0}{ST_c}, \quad k = 1, 3, 5, 7, \ldots \tag{62.5}$$

where T_c is the clock period. For a given distortion level, the minimum slew rate is given. Any exponential system with a bandwidth of ω_o gives rise to signals with the maximum slew rate of $2\omega_0 V_0$. Therefore, by making $2\omega_0 V_0 > S_{\min}$, no slew rate is limited and the DAC system will exhibit no distortion.

Converter Architectures

Many circuit techniques are used to implement DACs, but a few popular techniques used widely today are of the parallel type, in which all bits change simultaneously upon applying an input code word. Serial DACs, on the other hand, produce an analog output only after receiving all digital input data in a sequential form. When DACs are used as stand-alone devices, their output transient behavior limited by glitch, slew rate, word clock jitter, settling, etc. are of paramount importance, but are used as subblocks of ADCs, digital-to-analog converters need only to settle within a given time interval. In stand-alone DAC applications, the digital input word made of N bits should be synchronously applied to the DAC with a precise timing accuracy. Thus, the input data latches are used to hold the digital input during the conversion. The output analog sample-and-hold, usually called deglitcher, is often used for the better transient performance of a DAC. The three most popular architectures in integrated circuits are DACs using a resistor string, ratioed current sources, and a capacitor array. The current-ratioed DAC finds the greatest application as a stand-alone DAC, while the resistor-string and capacitor-array DACs are used mainly as ADC subblocks.

Resistor-String Digital-to-Analog Converters

The simplest voltage divider is a resistor string. Reference levels can be generated by connecting 2^N identical resistors in series between V_{ref} and 0. Switches to connect the divided reference voltages to the

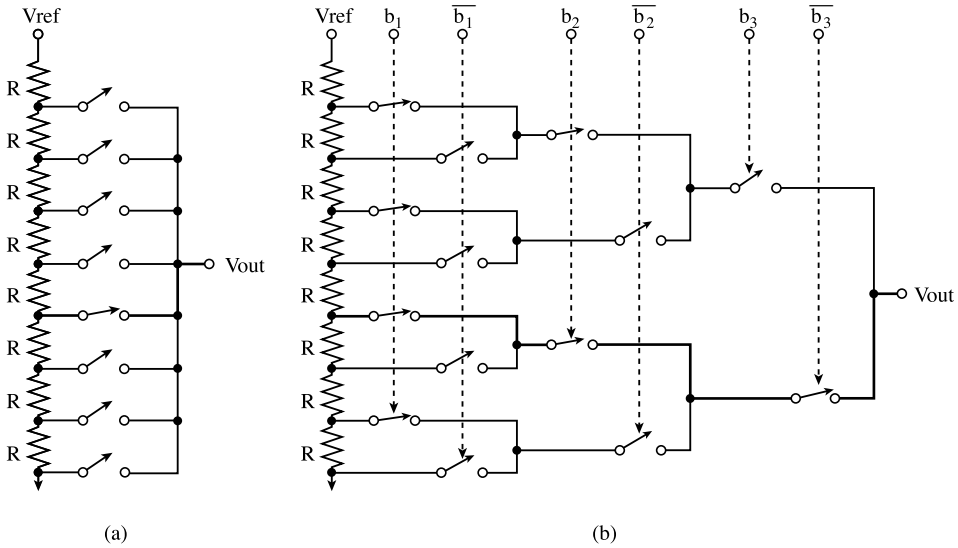

FIGURE 62.4 Resistor-string DAC: (a) with 1-out-of-2^N decoder, and (b) with a binary tree decoder.

TABLE 62.1 Resistor in IC Processes

Resistor Type	Sheet R (Ω/sq.)	Tolerance (%)	10–20 μm Matching (%)	T.C. (ppm/°C)
Diffusion	100–200	±20	±0.2–0.5	1500
Ion implantation	500–1k	±5	±0.1	200
Thin film	1k	±5	±0.1	10–100
Undoped poly	100–500	±20	±0.2	1500

output can be either a 1-out-of-2^N decoder or a binary tree decoder as shown in Fig. 62.4 for the 3-bit example. Because it requires a good switch, the stand-alone resistor-string DAC is easier to implement using CMOS. However, the lack of switches does not limit the application of the resistor string as a voltage reference divider subblock for ADCs in other process technologies.

Resistor strings are used widely as reference dividers, an integral part of the flash ADC. All resistor-string DACs are inherently monotonic and exhibit good differential linearity. However, they suffer from a poor integral linearity and also have the drawback that the output resistance depends on the digital input code. This causes a code-dependent settling time when charging the capacitive load of the output bus. The code-dependent settling time has no effect on the reference divider performance as an ADC subblock, but the performance is severely degraded as a stand-alone DAC. This nonuniform settling time problem can be alleviated by adding low-resistance parallel resistors and by compensating the MOS switch overdrive voltages.

In bipolar technology, the most common resistors are thin-film resistors made of tantalum, Ni-Cr, or Cr-SiO, which exhibit very low voltage and temperature coefficients. In CMOS either diffusion or undoped poly resistors are common. Four of the most frequently used resistors are listed in Table 62.1. Conventional trimming or adjustment techniques are impractical to be applied to all 2^N resistor elements. The following four methods are often used to improve the integral linearity of resistor-string DACs.

Layout Techniques. The use of large geometry devices and/or careful layout is effective in improving the matching marginally. Large geometry devices reduce the random edge effect, and the layout using a common centroid or geometric averaging can reduce the process gradient effect. However, typical matching of resistors in integrated circuits is still limited to an 8- to 10-bit level due to the mobility and resistor

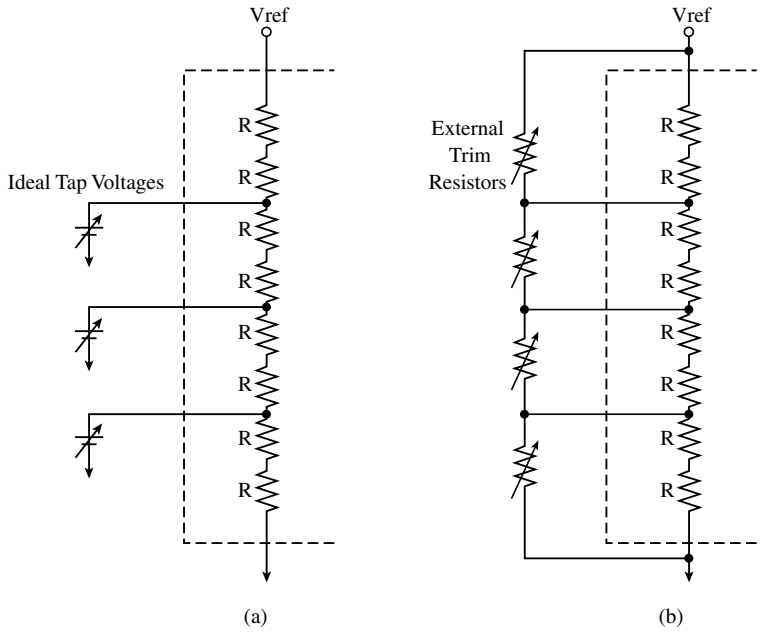

FIGURE 62.5 INL improvements: (a) by external voltage sources, and (b) by parallel resistors.

thickness variations. Differential resistor DACs with large feature sizes are reported to exhibit a higher matching accuracy of an 11- to 12-bit level.

Off-Chip Adjustment. It is possible to set tap points of a resistor-string to specified voltages by connecting external voltage sources to them, as shown in Fig. 62.5(a) for the 3-bit example. Simply put, the more taps adjusted, the better the integral linearity obtained. An additional benefit of this method is the reduced RC time constant due to the voltage sources at the taps. Instead of using voltage sources, the required voltages can be obtained using parallel trimming, resistors, as shown in Fig. 62.5(b). However, in addition to external components for trimming, fine adjustments and precision measurement instruments are needed to ensure that voltage levels are correct. Furthermore, due to mismatch in the temperature coefficients between the external components and the on-chip components, retrimming is often required when temperature changes.

Postprocess Trimming. The most widely used methods are laser trimming [2], Zener zapping [3], and other electrical trimming using PROM. The trimming method is the same as the parallel resistor trimming shown in Fig. 62.5(b) except for the fact that external trimming resistors are now integrated on the chip. While being trimmed, the resistor string is biased with a constant current. Individual segments are trimmed to have the same voltage drop. However, during normal conversion, the current source is replaced by a reference voltage source. The focused laser beam for trimming has a finite diameter, and the resistor to be trimmed occupies a large chip area. Both the laser trimming and the Zener zapping processes are irreversible. The long-term stability of trimmed resistors is a major concern, although the electrical and the PROM trimming (if PROM is replaced by EPROM) can be repeated. All trimming methods in this category are time consuming and require precision instruments.

On-Chip Buffers. The voltage at intermediate taps of the resistor string can be controlled by another resistor string through on-chip unity-gain buffers. This is actually an improved version of the off-chip method. The controlling resistors can be either laser trimmed or electronically controlled by switches. Laser-trimmed controlling resistors have the same problems mentioned earlier. The trimming network

© 2003 by CRC Press LLC

can be implemented to electronically control resistor values. In either case buffers with a high open-loop gain, a low output resistance, a large current driving capability, and a wide bandwidth for accurate and fast settling are required.

Current-Ratioed Digital-to-Analog Converters

The most popular stand-alone DACs in use today are current-ratioed DACs, of which the two types are a weighted-current DAC and an *R*-2*R* DAC.

Binary-Weighted Current Digital-to-Analog Converters. The weighted current DACs shown in Fig. 62.6 are made of an array of switched binary-weighted current sources and the current summing network. In bipolar technology binary weighting is achieved by ratioed transistors and emitter resistors with binary-related values of R, R/2, R/4, and so on, while in MOS technology, only ratioed transistors are used. One example is a video random access memory DAC in CMOS, which is made of simple PMOS differential pairs with binary-weighted tail currents. Digital-to-analog converters relying on active device matching can achieve an 8-bit level performance with a 0.2 to 0.5% matching accuracy using a 10 to 20 μm device feature size while degeneration with thin-film resistors gives a 10-bit level performance. The current sources are switched on or off by means of switching diodes or emitter-coupled differential pairs (source-coupled pairs in CMOS), as shown in Fig. 62.6. The output current summing is done by a wideband transresistance amplifier, but in high-speed DACs, the output current is used directly to drive a resistor load for a maximum speed but with a limited output swing. The weighted current design has the

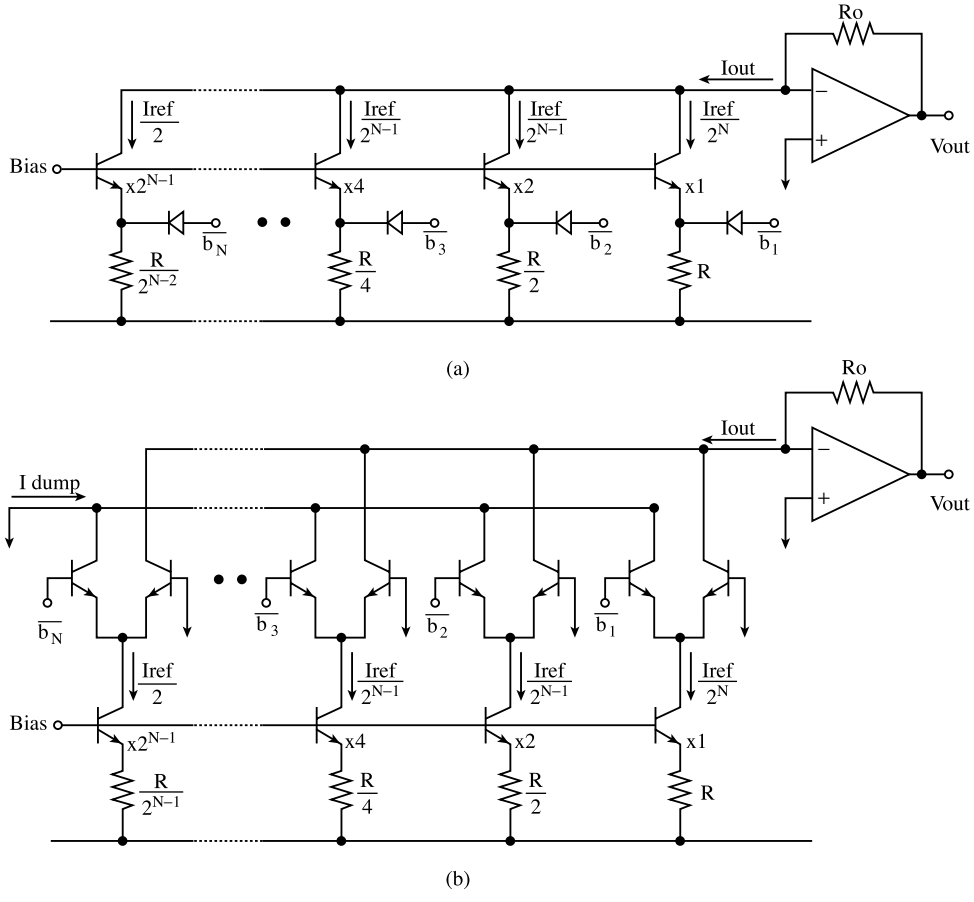

FIGURE 62.6 Binary-weighted current DAC: (a) diode switching, and (b) differential pair switching.

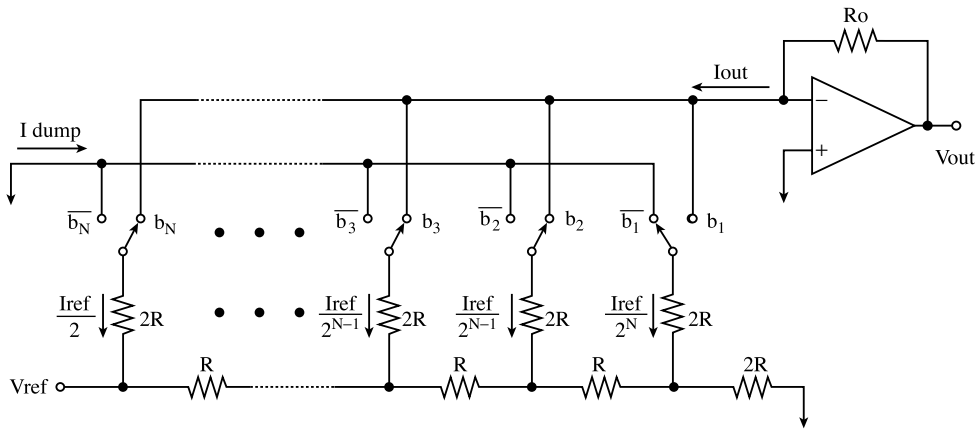

FIGURE 62.7 *R*-2*R* ladder DAC.

advantage of simplicity and high speed, but it is difficult to implement a high-resolution DAC because a wide range of emitter resistors and transistor sizes is used and very large resistors cause problems with both temperature stability and speed.

***R*-2*R* Ladder Digital-to-Analog Converters.** This large resistor ratio problem is alleviated by using a resistor divider known as an *R*-2*R* ladder, as shown in Fig. 62.7. The *R*-2*R* network consists of series resistors of value *R* and shunt resistors of value 2*R*. The top of each shunt resistor 2*R* has a single-pole double-throw electronic switch which connects the resistor either to ground or to the output current summing node. The operation of the *R*-2*R* ladder network is based on the binary division of current as it flows down the ladder. At any junction of series resistor *R*, the resistance looking to the right side is 2*R*. Therefore, the input resistance at any junction is *R*, and the current splits into two equal parts at the junction because it sees equal resistances in either direction. The result is binary-weighted currents flowing into each shunt resistor in the ladder. The digitally controlled switches direct the current to either ground or to the summing node. The advantage of the *R*-2*R* ladder method is that only two values of resistors are used, greatly simplifying the task of matching or trimming and temperature tracking. In addition, for high-speed applications relatively low resistor values can be used. Excellent results can be obtained using laser-trimmed thin-film resistor networks. Because the output of the *R*-2*R* DAC is the product of the reference voltage and the digital input word, the *R*-2*R* ladder DAC is often called a multiplying DAC (MDAC).

Both the weighted-current DAC and the *R*-2*R* DAC can be used as a current divider to make a sub-DAC. To make a segmented DAC for monotonicity based on the next-segment approach, as discussed earlier, the MSB should be made of thermometer-coded equal currents. Once the MSB is selected, the next segment should be divided further into LSBs as shown in Fig. 62.2. Integral nonlinearity can be improved by dynamically matching or by self-calibrating the MSB current sources as discussed later.

Capacitor-Array Digital-to-Analog Converter. Capacitors made of double-poly or poly-diffusion in MOS technology are considered one of the most accurate passive components comparable to thin-film resistors in bipolar process, both in the matching accuracy and voltage and temperature coefficients [4]. The only disadvantage in the capacitor-array DAC implementation is the use of a dynamic charge redistribution principle. A switched-capacitor counterpart of the resistor-string DAC is a parallel capacitor array of 2^N unit capacitors (C) with a common top plate. The capacitor-array DAC is not appropriate for stand-alone applications without a feedback amplifier virtually grounding the top plate and an output sample-and-hold or deglitcher. The operation of the capacitor-array DAC in Fig. 62.8 is based on the thermometer-coded DAC principle, and has a distinct advantage of monotonicity if the system is implemented properly. However, due to the complexity of handling the thermometer-coded capacitor array,

© 2003 by CRC Press LLC

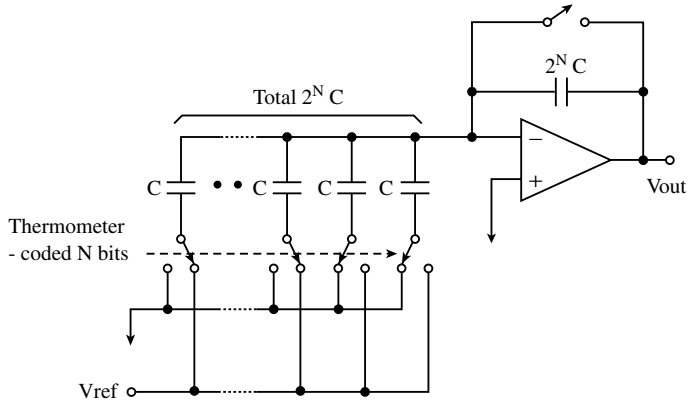

FIGURE 62.8 Thermometer-coded capacitor-array DAC.

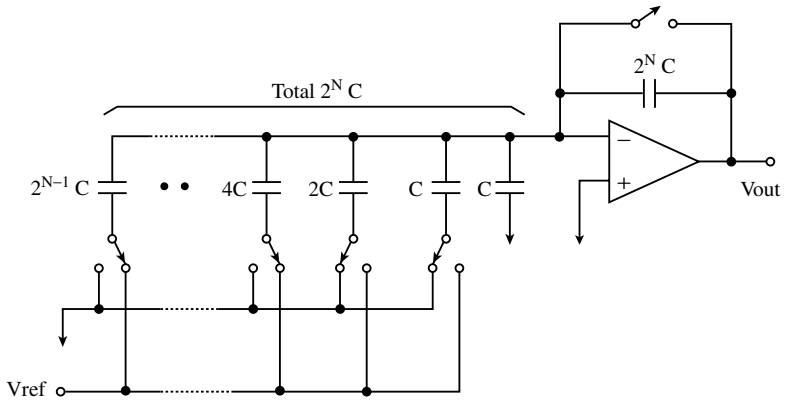

FIGURE 62.9 Binary-weighted capacitor-array DAC.

a binary-weighted capacitor array is often used, as shown in Fig. 62.9, by grouping unit capacitors in binary ratio values. A common centroid layout of the capacitor array is known to give a 10-bit level matching for this application when the unit capacitor size is over 12 μm × 12 μm. The matching accuracy of the capacitor in MOS technology depends on the geometry sizes of the capacitor width and length and the dielectric thickness.

As a stand-alone DAC, the top plate of the DAC is precharged either to the offset of the feedback amplifier or to the ground. One smallest capacitor is not necessary for this application. However, as a subblock of an ADC, the total capacitor should be 2^NC, as drawn in Fig. 62.9, and the top plate of the array is usually connected to the input nodes of comparators or high-gain operational amplifiers, depending on the ADC architectures. As a result, the top plate has a parasitic capacitance, but its effect on the DAC performance is negligible. The capacitor-array DAC requires two-phase nonoverlapping clocks for proper operation. Initially, all capacitors should be charged to ground. After initialization, depending on the digital input, the bottom plates are connected either to V_{ref} or to ground. Consider the case in which the top plate is floating without the feedback amplifier. If the charge at the top plate finishes its redistribution the top plate voltage neglecting the top plate parasitic effect becomes

$$V_o = \sum_{i=1}^{N} \frac{b_k}{2^i} V_{\text{ref}} \tag{62.6}$$

© 2003 by CRC Press LLC

where $b_N b_{N-1}$, …, $b_2 b_1$ is the input binary word. For example, switching the MSB capacitor bottom to V_{ref} changes the output voltage by

$$\frac{2^{N-1}C}{\sum_{i=1}^{N} C_i} V_{ref} = \frac{V_{ref}}{2} \tag{62.7}$$

where the capacitor C_i, for the ith bit is nominally scaled to $2^{i-1}C$. Therefore, the nonlinearity at the midpoint of the full range is limited by the ratio mismatch of the half sum of the capacitor array to the total sum of the array. Similarly, the nonlinearity at one fourth of the range is limited by the ratio of one fourth of the capacitor array to the total array, and so on.

One important application of the capacitor-array DAC is as a reference DAC for ADCs. As in the case of the *R*-2*R* MDAC, the capacitor-array DAC can be used as an MDAC to amplify residue voltages for multistep ADCs. As shown in Fig. 62.9, if the input is sampled on the bottom plates of capacitors instead of the ground, the voltage amplified is the amplified input voltage minus the DAC output. By varying the feedback capacitor size, the MDAC can be used as an interstage residue amplifier in multistep pipelined ADCs. For example, if the feedback capacitor is C and the digital input is the coarse *N*-bit decision of the sampled analog voltage, the amplifier output is a residue voltage amplified by 2^N for the subsequent LSB conversion.

R + *C* or *C* + *R* Combination Digital-to-Analog Converters

Both resistor-string and capacitor-array DACs need 2^N unit elements for *N*-bits, and the number grows exponentially. Splitting arrays into two, one for MSBs and the other for the LSBs, requires a buffer amplifier to interface between two arrays. Although a floating capacitor connects two capacitors arrays, the parasitic capacitance of the floating node is not well controlled. A more logical combination for high-resolution DAC is between resistor and capacitor DACs. This combination does not require any coupling capacitors or interface buffer amplifiers.

In the *R* + *C* combination, the MSB is set by the resistor string, and next segment of the resistor-string DAC supplies the reference voltage of the LSB capacitor DAC, as shown in Fig. 62.10. When the top plate is initialized, all capacitor bottom plates are connected to the lower voltage of the next segment of the resistor-string DAC. During the next clock phase, the bottom plates of capacitors are selectively connected to the higher voltage of the segment if the digital bit is ONE, but stays switched to the lower voltage if

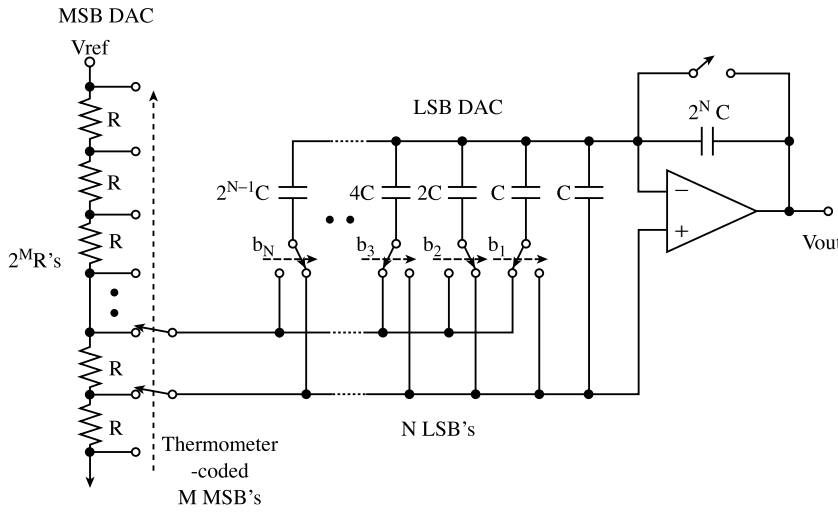

FIGURE 62.10 *R* + *C* combination DAC.

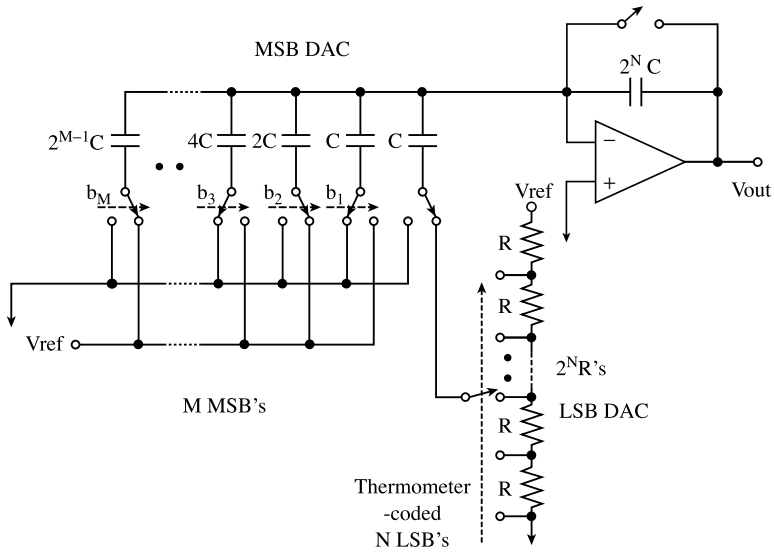

FIGURE 62.11 *C* + *R* combination DAC.

ZERO. This segmented DAC approach gives an inherent monotonicity as far as the LSB DAC is monotonic within its resolution. Although INL is poor, the fully differential implementation of this architecture benefits from the lack of the even-order nonlinearity, thereby achieving improved INL. On the other hand, in the *C* + *R* combination shown in Fig. 62.11, the operation of the capacitor DAC is the same. The MSB side reference voltage is fixed, but the reference voltage of the smallest capacitor is supplied by the LSB resistor-string DAC. This approach exhibits nonmonotonicity due to the capacitor DAC matching. Both combination DACs are seldom used as stand-alone DACs due to their limited speed, but are used frequently as subblocks of high-resolution ADCs.

Techniques for High-Resolution Digital-to-Analog Converters

Most DACs are made of passive or active components such as resistors, capacitors, or current sources, and their linearity relies on the matching accuracy of those components. Among frequently used DAC components, diffused resistors and transistors are in general known to exhibit an 8-bit level matching while thin-film resistors and capacitors are matched to a 10-bit level. Trimming or electronic calibration is needed in order to obtain a higher linearity than what is achievable with bare component matching. The traditional solutions to this have been the wafer-level trimming methods such as laser trimming and Zener zapping. Although many other promising trimming or matching techniques such as polysilicon fuse trimming, electrical trimming techniques using PROM, and large device matching by geometrical averaging have been proposed, conventional factory-set trimming or matching techniques give no flexibility of retrimming. How successfully these techniques can be applied to large-volume production of high-resolution DACs and how the factory-trimmed components will perform over the long term are still in question.

The future trend is toward more sophisticated and intelligent electronic solutions that overcome and complement some of the limitations of conventional trimming techniques. The methods recently developed are dynamic circuit techniques [5] for component matching, switched-capacitor integration [6], electronic calibration [7] of a DAC nonlinearity, and oversampling interpolation techniques [8] which trade speed with resolution. In particular, the oversampling interpolative DACs are used widely in stand-alone applications such as digital audio playback systems or digital communications due to their inherent monotonicity.

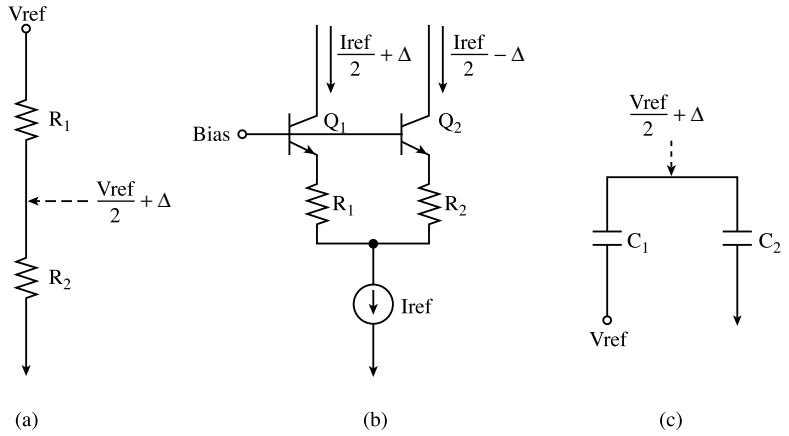

FIGURE 62.12 Divide-by-two elements: (a) resistor, (b) current, and (c) capacitor.

Dynamic Matching Techniques

In general, a dynamic element matching to improve the accuracy of the binary ratio is a time-averaging process. For simplicity, consider a simple voltage or current divide-by-two element, as shown in Fig. 62.12. Due to mismatches in the ratio of resistors, transistors, and capacitors, the divided voltage or current is not exactly $V_{ref}/2$ or $I_{ref}/2$, but their sum is V_{ref} or I_{ref}. The dynamic matching concept is to multiplex these two outputs with complementary errors of Δ and $-\Delta$ so that the errors Δ and $-\Delta$ can be averaged out over time while the average value of $V_{ref}/2$ or $I_{ref}/2$ remains. It is in effect equivalent to the suppressed carrier balanced modulation of the error component Δ. The high-frequency energy can be filtered out using a post low-pass filter. This technique relies on the accurate timing of the duty cycle. Any duty cycle error or timing jitter results in inaccurate matching. The residual matching inaccuracy becomes a second-order error proportional to the product of the original mismatch and the timing error.

The application of dynamic element matching to the binary-weighted current DAC is a straightforward switching of two complementary currents. Its application to the binary voltage divider using two identical resistors or capacitors requires exchanging of resistors or capacitors. This can be achieved easily by reversing the polarity of the reference voltage for the divide-by-two case. However, in the general case of N element matching the current division is inherently simpler in implementation than the voltage division. In general, to match the N independent elements, a switching network with N inputs and N outputs is required. The function of the switching network is to connect any input out of N inputs to one output with an average duty cycle of $1/N$. The simplest one is a barrel shifter rotating the I-O connections in a predetermined manner [5]. This barrel shifter generates a low-frequency modulated error when N becomes larger because the same pattern repeats every N clocks. A more sophisticated randomizer with the same average duty can distribute the mismatch error over the wider frequency range. The latter technique finds applications as a multi-bit DAC in the multibit noise-shaping sigma-delta data converter, whose linearity relies on the multi-bit DAC.

Voltage or Current Sampling. The voltage or current sampling concept is an electronic alternative to direct mechanical trimming. To sample voltage or current using a voltage or current sampler is equivalent to trimming individual voltage or current sources. The voltage sampler is usually called a sample-and-hold (S/H) circuit, while the current sampler is called a current copier. The voltage is usually sampled on the input capacitor of a buffer amplifier and the current is usually sampled on the input capacitor of a transconductance amplifier such as an MOS transistor gate. Therefore, both voltage and current sampling techniques are ultimately limited by their sampling accuracy.

© 2003 by CRC Press LLC

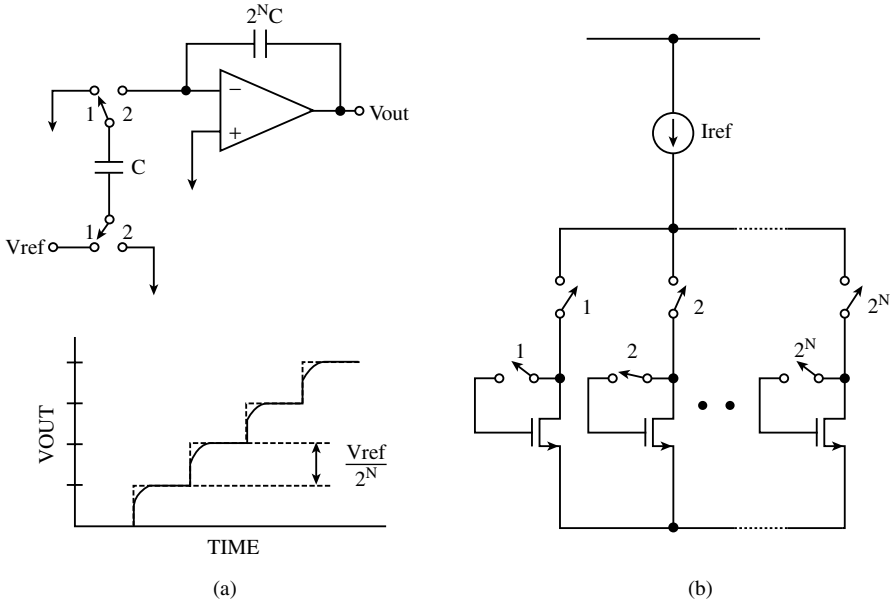

FIGURE 62.13 Voltage and current sampling concepts: (a) integrator, and (b) current copier.

The idea behind the voltage or current sampling DAC is to use one voltage or current element repeatedly. One example of the voltage sampling DAC is a discrete-time integrator-type DAC with many S/H amplifiers for sampling output voltages. The integrator integrates a constant charge repeatedly, and its output is sampled on a new S/H amplifier every time the integrator finishes an integration as shown in Fig. 62.13(a). This is equivalent to generating equally spaced reference voltages by stacking identical unit voltages [6]. The fundamental problem associated with this sampling voltage DAC approach is the accumulation of the sampling error and noise in generating larger voltages. Similarly, the current sampling DAC can sample a constant current on current sources made of MOS transistors, as shown in Fig. 62.13(b) [7]. Because one reference current is copied on other identical current samplers, the matching accuracy can be maintained as far as the sampling errors are kept constant. It is not practical to make a high-resolution DAC using voltage or current sampling alone. Therefore, this approach is limited to generating MSB DACs for the segmented DAC or for the subranging ADCs.

Electronic Calibration Techniques

Electronic calibration is a general term to describe various circuit techniques, which usually predistort the DAC transfer characteristic so that the DAC linearity can be improved. One such technique is a straightforward code mapping, and the other is a self-calibration. The code-mapping calibration is a very limited technique only for the factory because it requires a precision measurement setup and a large digital memory. The self-calibration is to incorporate all the calibration mechanisms and hardware on the DAC as a built-in function so that users can recalibrate whenever calibrations are needed. The self-calibration is based on an assumption that the segmented DAC linearity is limited by the MSB DAC so that only errors of MSBs may be measured, stored in memory, and recalled during normal operation. There are two ways of measuring the MSB errors. In one method individual-bit nonlinearities, usually appearing as component mismatch errors, are measured digitally [9], and a total error, which is called a code error, is computed from individual-bit errors depending on the output code during normal conversion. On the other hand, the other method measures and stores digital code errors directly and eliminates the digital code-error computation during normal operation [10]. The former requires less digital memory during normal conversion while the latter requires fewer digital computations.

© 2003 by CRC Press LLC

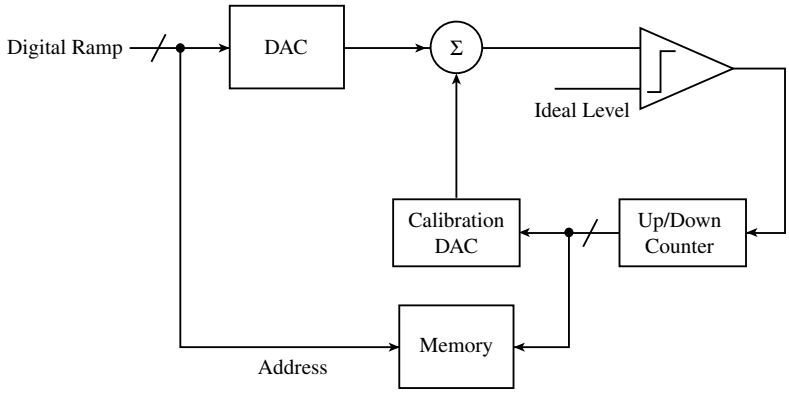

FIGURE 62.14 Code mapping with a calibration DAC.

Direct Code Mapping. The simplified code mapping of a DAC can be done with a calibration DAC, digital memory, and a precision instrument to measure the DAC output, as shown in Fig. 62.14. The idea is to measure the DAC error using a calibration DAC so that the DAC output corrected by the calibration DAC can produce an ideal DAC output. The input code of the calibration DAC is stored as a code error in digital memory addressed by the DAC input code. This code error is recalled to predistort the DAC output during normal operation. This technique needs a 2^N memory with a word length corresponding to the number of bits of the calibration DAC. This method can correct any kinds of DAC nonlinearities as long as the calibration DAC has an output range wide enough to cover the whole range of nonlinearity. However, the same method can be implemented without the use of a calibration DAC if the main DAC is monotonic with extra bits of resolution. In this case, the calibration is a simple code mapping, selecting correct input digital codes for correct DAC output voltages among redundant input digital codes.

Self-Calibration for Individual Capacitor Errors. The idea of measuring the individual bit errors using a calibration DAC is to quantize the difference Δ in the divide-by-two elements in Figure 62.12 because the ideal divide ration is 1/2. For example, the MSB should be half of the whole range of a DAC, the second MSB is half of the MSB, and so on. Unless buffer amplifiers are used, the ideal calibration DACs for *R* and *C* DACs are *C* and *R* DACs, respectively. The ratio error measurement cycle of two-bit *C* DAC is illustrated in Fig. 62.15. Errors can be quantized using a successive approximation method, but the up/down converter is shown here for simplicity. Initially, the top plate is charged to the comparator offset and the bottom plates of C_1 and C_2 sample 0 and V_{ref}. At the same time, the bottom plate of C_C samples

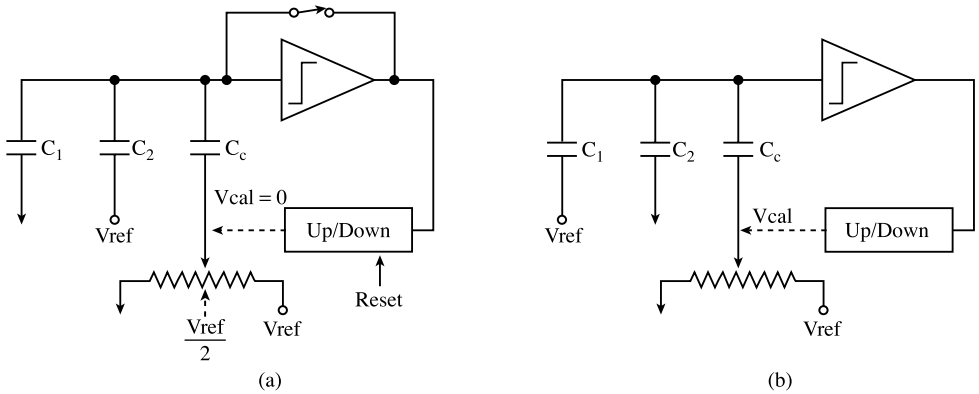

FIGURE 62.15 Capacitor ratio error measurement cycles: (a) initialization, and (b) error quantization.

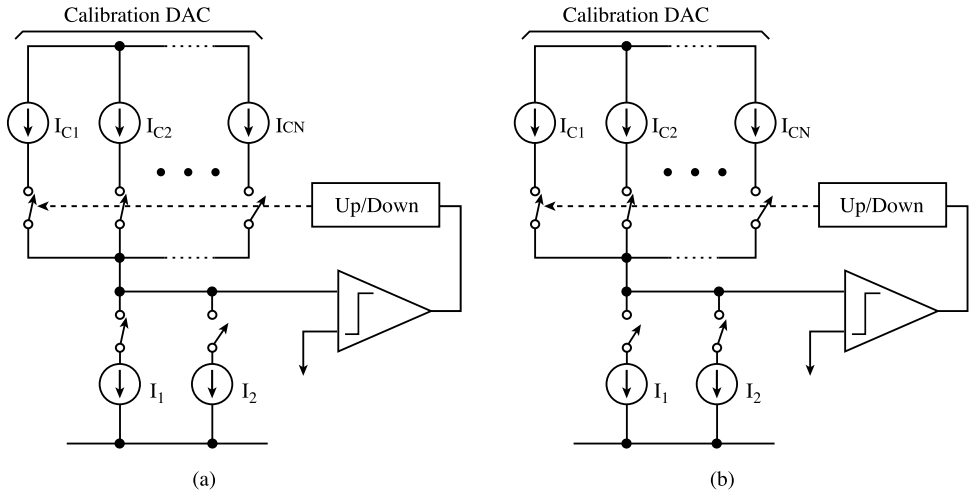

FIGURE 62.16 Current difference measurement cycles: (a) initialization, and (b) error quantization.

$V_{ref}/2$ and the up/down counter is reset to make $V_{cal} = 0$. In the next clock period the charge is redistributed by swapping 0 and V_{ref} on the bottom plates of C_1 and C_2. Then the top plate residual error V_x will be from the charge conservation

$$V_x = \frac{C_1}{C_1 + C_2 + C_C} V_{ref} - \frac{C_2}{C_1 + C_2 + C_C} V_{ref} = \frac{\Delta C}{2C + C_C} V_{ref} \tag{62.8}$$

If $V_{cal} = 0$, $C_1 = C + \Delta C/2$, and $C_2 = C - \Delta C/2$. This top plate residual voltage can be nulled out by changing the calibration DAC voltage V_{cal}. The measured calibration voltage is approximately

$$V_{cal} = -\frac{\Delta C}{C_C} V_{ref} \tag{62.9}$$

As the actual error V_x is half of the measured value when the V_{ref} is applied to C_1, the actual calibration DAC voltage to be subtracted during normal operation becomes $V_{cal}/2$. Similarly, the multi-bit calibration can start from the MSB measurement and move down to the LSB side [9].

The extension of this calibration technique to current DACs is straightforward. For example, two identical unipolar currents, I_1 and I_2, can be compared using a voltage comparator and a calibration DAC, as shown in Fig. 62.16. After I_1 is switched in, the calibration DAC finds an equilibrium as a null. Then the difference can be measured by interchanging I_1 and I_2 and finding a new equilibrium. Therefore, the current difference error is obtained as

$$I_{cal} = I_2 - I_1 \tag{62.10}$$

During normal operation, half of this value should be added to the DAC output using the same calibration DAC every time the current I_1 is switched to the DAC output. Similarly, the same amount is subtracted if I_2 is switched to the output.

Code-Error Calibration. The code-error calibration is based on the simple fact that the thermometer-coded MSBs of a DAC are made of segments of equal magnitude [10]. Any nonuniform segment will contribute to the overall nonlinearity of a DAC. The segment error between two adjacent input codes is measured by comparing the segment with the ideal segment. Starting from the reference point, 0 or $V_{ref}/2$, the same procedure is repeat until all the segment errors are measured. Therefore, the current

© 2003 by CRC Press LLC

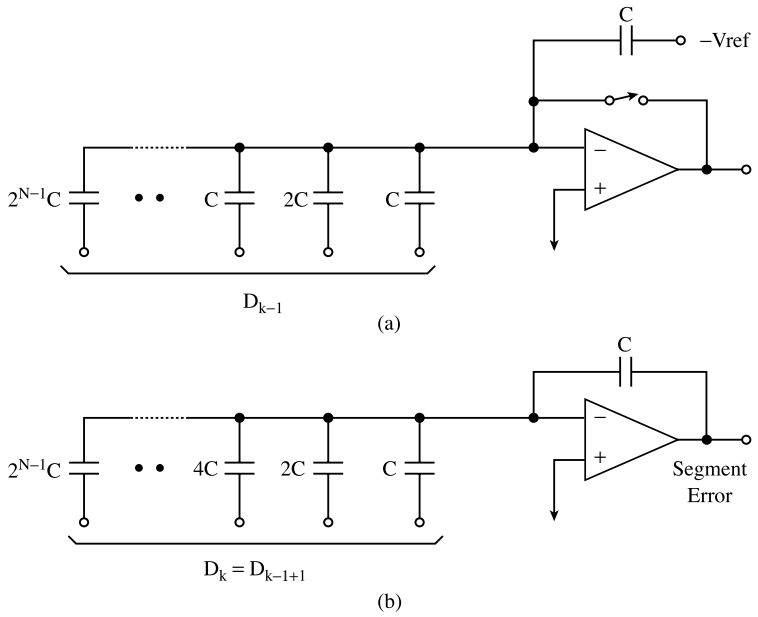

FIGURE 62.17 Code-error measurement cycle: (a) initialization, and (b) error quantization.

code error, Error(j), is obtained by adding the current segment error to the accumulated sum of all the previous segment errors:

$$\text{Error}(j) = \sum_{k=1}^{j} \text{Seg}(k) \tag{62.11}$$

where Seg(k) is the kth segment error from the reference point. These measured code errors are stored in memory addressed by digital codes so that they can be subtracted from uncalibrated raw digital outputs during normal conversion.

The segment error measurement of a current-ratioed DAC thermometer-coded MSBs is similar to the current difference measurement in Fig. 62.16. The only difference in measurement is the use of the reference segment current in place of one of the two currents to be compared. That is, each MSB current source is compared to the reference segment. For the capacitive DAC, the kth segment error can be measured in two cycles. After the output of the DAC is initialized to have a negative ideal segment voltage with the input digital code corresponding to $k-1$, the input code is increased by 1 as shown in Fig. 62.17. Applying digital codes to the capacitor-array DAC means connecting the bottom plates to either V_{ref} or ground depending on the corresponding digital bits. Then the kth segment error is generated at the output and can be measured digitally using subsequent ADC stages or using a calibration DAC as shown in Fig. 62.15.

Digital Truncation Errors. All calibration methods need extra bits of resolution in the error measurements because digital truncation errors are accumulated during code-error computations. For example, if the truncation errors are random, the additions of n digital numbers will increase the standard deviation of the added number by $n^{1/2}$. This accumulated truncation error affects both DNL and INL of the converter self-calibrated using measured errors of individual bits. On the other hand, if calibrated using measured segment errors, the DNL of the converter is always guaranteed to be within $\pm\frac{1}{2}$ LSB of a target resolution because all segment errors are measured with one extra bit of resolution, but the INL will still be affected by the digital truncation because code errors are obtained by accumulating segment errors. The effect of the digital truncation errors due to n repeated digital additions on the INL can be modeled using

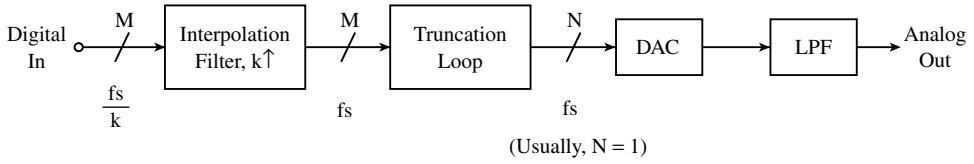

FIGURE 62.18 Interpolative oversampling DAC.

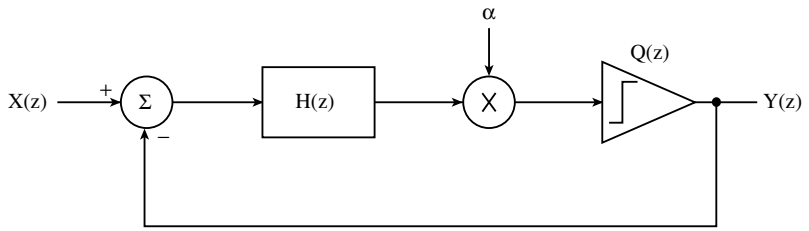

FIGURE 62.19 Delta-sigma modulation as a digital truncator.

uncorrelated and independent random variables, and the standard deviation of INL is calculated in LSB units as

$$\sigma_{\text{INL}} = \sqrt{\frac{(n-i)(i-1)}{12(n-1)}}(\text{LSB}) \quad \text{for } i = 1, 2, \ldots, n \tag{62.12}$$

For example, when $n = 16$, the maximum standard deviation of the INL at the midpoint is about 0.56 LSB.

Interpolative Oversampling Techniques

Ordinary DACs generate a discrete output level for every digital word applied to their input, and it is difficult to generate a large number of distinct output levels for long words. The oversampling interpolative DAC achieves fine resolution by covering the signal range with a few widely spaced levels and interpolating values between them. By rapidly oscillating between coarse output levels, the average output corresponding to the applied digital code can be generated with reduced noise in the signal band [8]. The general architecture of the interpolative oversampling DAC is shown in Fig. 62.18. A digital filter interpolates sample values of the input signal in order to raise the word rate to a frequency well above the Nyquist rate. The core of the technique is a digital truncator to truncate the input words to shorter output words. These shorter words are then converted into analog form at the high sample rate so that the truncation noise in the signal band may be satisfactorily low. The sampling rate upconversion for this is usually done in stages using two upsampling digital filters. The first filter, usually a two to four times oversampling FIR, is to shape the signal band for sampling rate upconversion and to equalize the passband droop resulting from the second SINC filter for higher-rate oversampling.

A noise-shaping sigma-delta-sigma modulator can be built in digital form to make a digital truncator as shown in Fig. 62.19. Using a linearized model, the z-domain transfer function of the modulator is

$$Y(z) = \frac{\alpha H(z)}{1+\alpha H(z)} X(z) + \frac{1}{1+\alpha H(z)} Q(z) \tag{62.13}$$

where $Q(z)$ is the quantization noise and α is the quantizer gain. The loop filter $H(z)$ can be chosen so that the quantization noise may be high-pass filtered while the input signal is low-pass filtered. For the first-order modulator, the loop filtered is just an integrator with a transfer function of

© 2003 by CRC Press LLC

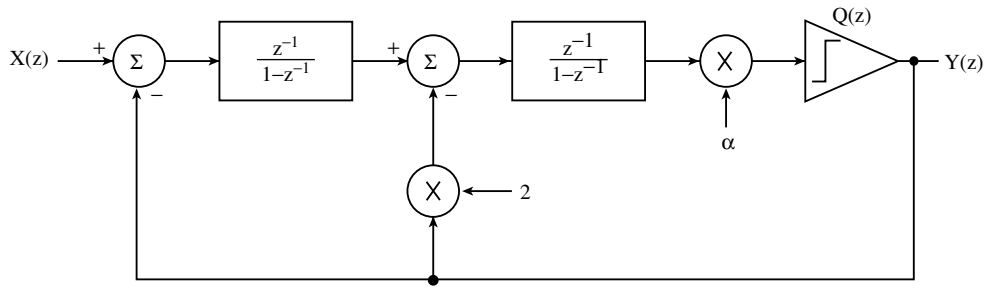

FIGURE 62.20 Second-order one-bit modulator.

$$H(z)=\frac{z^{-1}}{1-z^{-1}} \tag{62.14}$$

while for the second-order modulator, the transfer function is

$$H(z)=\frac{z^{-1}\left(2-z^{-1}\right)}{\left(1-z^{-1}\right)^2} \tag{62.15}$$

However, the standard second-order modulator is implemented, as shown in Fig.62.20, using a double integration loop. In general, first-order designs tend to produce correlated idling patterns. Second-order designs are vastly superior to first-order designs both in terms of the required oversampling ratio to achieve a particular signal-to-noise ratio as well as in the improved randomness of the idling patterns. However, even the second-order loop is not entirely free of correlated fixed patterns in the presence of small DC inputs. The second-order loop needs dithering to reduce fixed pattern noises, but loops of a higher order than third do not exhibit fixed pattern noises.

Stability. The quantizer gain α plays an important role in keeping the modulator stable. Considering α, the transfer function of the second-order loop shown in Fig. 62.20 becomes

$$Y(z)=\frac{\alpha z^{-2}X(z)+\left(1-z^{-1}\right)^2 Q(z)}{1-2(1-\alpha)z^{-1}+(1-\alpha)z^{-2}} \tag{62.16}$$

The root locus of the transfer function in the z-domain is shown in Fig. 62.21. As shown, the second-order loop becomes unstable for $\alpha > 4/3$ because one pole moves out of the unit circle. This in turn implies that the signal at the input of the quantizer becomes too large. Most delta-sigma modulators become unstable if the signal to the quantizer exceeds a certain limit. Higher-order modulators tend to be overloaded easily at higher quantizer gain than first-or second-order modulators. Therefore, for the stability reason, the integrator outputs of the loop filter are clamped so that the signal at the input of the quantizer is limited for linear operation. Digital truncators of a higher order than second are feasible in digital circuits because signal levels can be easily detected and controlled. The straightforward third order or higher loop using multiple loops is unstable, but higher order modulators can be built using either the cascaded MASH [11] or the single-bit higher order [12] architecture.

Dynamic Range. In general, for the Nth order loop, the noise falls by $6N + 3$ dB for every doubling of the sampling rate, providing $N + 0.5$ extra bits of resolution. Because the advantage of oversampling begins to appear when the oversampling ratio is > 2, a practically achievable dynamic range by oversampling is approximately

© 2003 by CRC Press LLC

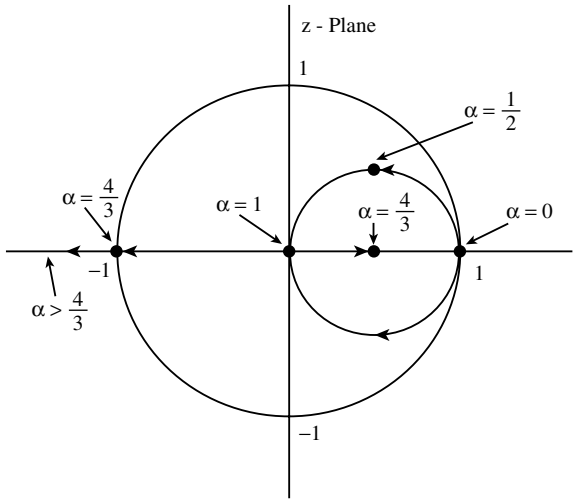

FIGURE 62.21 Root locus of the second-order loop transfer function.

$$\mathrm{DR} > \left(6N+3\right)\left(\log_2 M - 1\right)\ \mathrm{dB} \tag{62.17}$$

where M is the oversampling ratio. For example, a second-order loop with 256 times oversampling can give a dynamic range of > 105 dB, but the same dynamic range can be obtained using a third-order loop with only 64 times oversampling. The dynamic range is not a limit in the digital modulator. In practice, the dynamic range is limited in the rear-end analog DAC and postfilter.

One-Bit or Multi-Bit DAC. The rear end of the interpolative oversampling DAC is an analog DAC. Because the processing in the interpolation filter and truncator is digital instead of analog, achieving precision is easy. Therefore, the oversampling DAC owes its performance to the rear-end analog part because the conversion of the truncated digital words into analog form takes place in the rear-end DAC. The one-bit quantizer can be easily overloaded and needs clamping to be stable, while multi-bit quantizers are more stable due to their small quantization errors. However, the multi-bit system is limited by the accuracy of the multi-bit DAC. Although the analog techniques such as dynamic matching or self-calibration can improve the performance of the multi-bit DAC, the one-bit DAC is simpler to implement and its performance is not limited by component matching. It is true that a continuous time filter can convert the one-bit digital bitsteam into an analog waveform, but it is difficult to construct an ideal undistorted digital waveform without clock jitter. However, if the bitstream is converted into a charge packet, a high linearity is guaranteed due to the uniformity of the charge packets.

A typical differential one-bit switched-capacitor DAC with one-pole roll-off can be built as shown in Fig. 62.22 using two-phase nonoverlapping clocks 1 and 2. There are many advantages in a fully differential implementation. The dynamic range increases by 3 dB because the signal is doubled (6 dB) but the noise gains by 3 dB. It also rejects most noisy coupling through power supplies or through the substrate as a common-mode signal. Furthermore, the linearity is improved because the even-order nonlinearity components of the capacitors and the op amp are canceled. In the implementation of Fig. 62.22, a resistor as a loss element can be replaced by a capacitor switched in and out at f_c as illustrated. The bandwidths of these filters in both cases are set by $1/RC_I$ and f_cC_R/C_I, respectively, Also, the filter DC gains are defined by $Rf_c\ C_S$ and C_S/C_R, respectively. The digital bitstream is converted into a charge packet by sampling the reference voltage on the bottom plates of the sampling capacitors (C_S). If the digital bit is ZERO, $-V_{\mathrm{ref}}$ is sampled during the clock phase 1 and the charge on C_S is dumped on the lossy integrator during 2. On the other hand, if the digital bit is ONE, V_{ref} is sampled instead. To reduce the input-dependent switch-feedthrough component, the switches connected to the top plates should be

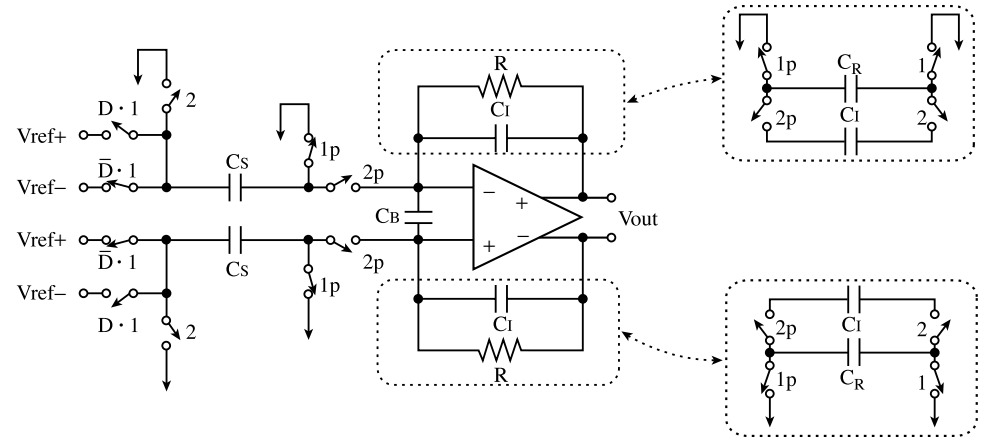

FIGURE 62.22 Switched-capacitor one-bit DAC/filter.

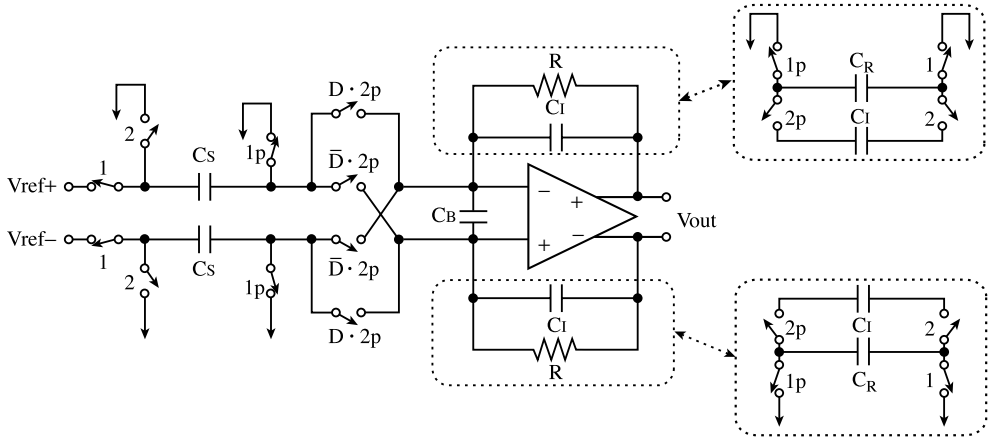

FIGURE 23 Alternative one-bit DAC sampling constant V_{ref}.

turned off slightly earlier than the bottom plate switches using 1*p* and 2*p*. Alternatively, a slightly different one-bit DAC is possible by sampling a constant reference voltage by inverting the polarity of the integration depending on the digital bit as shown in Fig. 62.23.

The op amp for this application should have a high DC gain and a fast slew rate. The op amp DC gain requirement is a little alleviated considering the linear open-loop transfer characteristic of most op amps within a limited swing range. As discussed earlier, the slew-limited settling generates an error proportional to the square of the magnitude. Therefore, a nonslewing op amp such as a class AB input op amp performs better for this application. The op amp starts to slew when a larger voltage than its linear input range is applied. When the charge packet of the sampled reference voltage is dumped onto the input summing node, it causes a voltage step on the summing node. The bypass capacitor C_B between two summing nodes helps to reduce this voltage step to prevent the op amp from slewing. The large the C_B, the smaller the voltage step. However, a too-large C_B will narrowband the feedback amplifier, and the settling will take longer as a result.

Postfiltering Requirement. Although the one-pole roll-off will substantially attenuate high-frequency components around f_c, the one-bit DAC should be followed by a continuous time postfilter so that the charge packets can be smoothed out. Unlike the delta-sigma modulator which filters out the out-of-band-shaped noise using digital filters, the demodulator output noise can be filtered only by analog filters.

© 2003 by CRC Press LLC

Because the shaped noise is out-of-band, it does not affect the inband performance directly, but the large out-of-band high-frequency noise tends to generate inband intermodulation components and limit the dynamic range of the system. Therefore, the shaped high-frequency noise needs to be filtered with a low-pass filter one order higher than the order of the modulator. It is challenging to meet this postfiltering requirement with analog filtering techniques. Analog filters for this application are often implemented in continuous time using a cascade of Sallen–Key filters made of emitter follower unity-gain buffers, but both switched-capacitor and continuous time filtering techniques have improved significantly to be applied to this application. The other possibility is the hybrid implementation of an FIR filter using digital delays and an analog current swimming network. Because the output is a bitstream, current sources weighted using coefficients of an FIR filter are switched to the current summer depending on the digital bit to make a low-pass FIR filter.

Sources of Conversion Errors

Glitch

The basic function of the DAC is the conversion of digital numbers into analog waveforms. A distortion-free DAC creates instantaneously an output voltage that is proportional to the input digital number. In reality, DACs cannot achieve this impossible goal. If the input digital number changes from one value to a different one, the DAC output voltage always reaches a new value sometime later. For DACs, the shape of the transient response is a function governed in large part by two mechanisms, glitch and slew rate limit. The ideal transient response of a DAC to a step is a single-time constant exponential function, which only generates an error growing linearly with the input signal, as explained in Fig. 62.3. Any other transient responses give rise to errors that have no bearing on the input signal. The glitch impulse is described in terms of a picovolts times seconds or equivalent unit.

Glitches are caused by small time differences between some current sources turning off and others turning on. Take, for example, the major code transition at half scale from 011 … 11 to 100 … 00. Here, the MSB current source turns on while all other current sources turn off. The small difference in switching times results in a narrow half-scale glitch, as shown in Fig. 62.24. Such a glitch, for example, can produce distorted characters in CRT display applications. To alleviate both glitch and slew-rate problems related to transients, a DAC is followed by a S/H amplifier, usually called a deglitcher. The deglitcher stays in the hold mode while the DAC changes its output value. After the switching transients have settled, the deglitcher is changed to the sampling mode. By making the hold time suitably long, the output of the deglitcher can be made independent of the DAC transient response. Thus, the distortion during transients can be circumvented by using a fast S/H amplifier. However, the slew rate of the deglitcher is on the same order as that of the DAC, and the transient distortion will still be present, now as an artifact of the deglitcher.

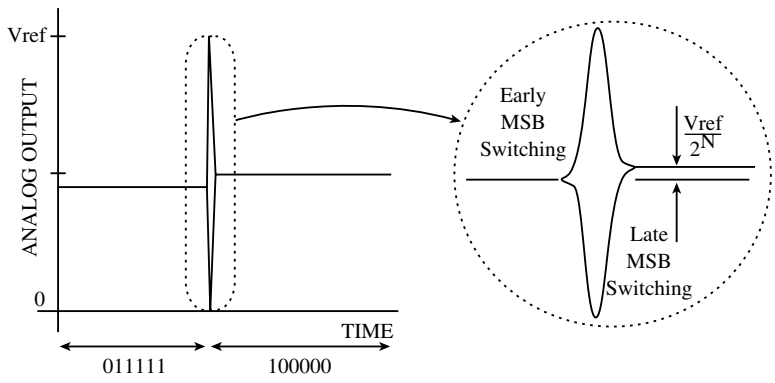

FIGURE 62.24 Glitch impulse at a major carry.

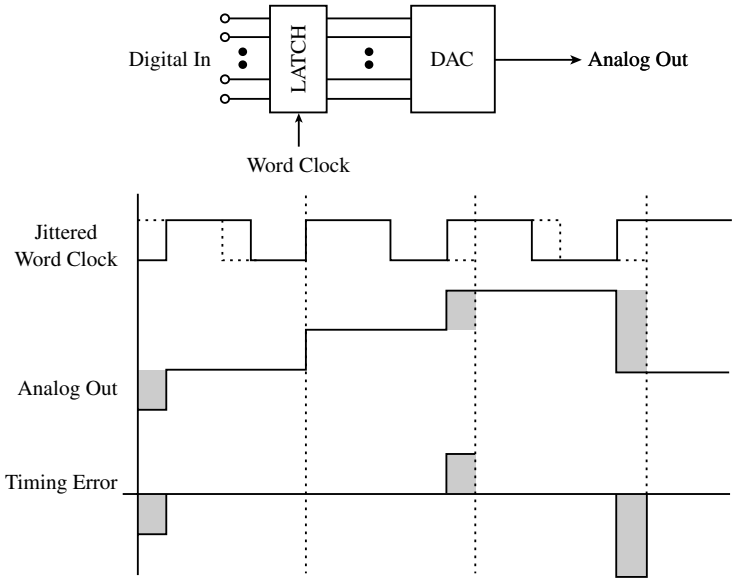

FIGURE 62.25 Word clock jitter effect.

Timing Error-Word Clock Jitter

Although a DAC is ideally linear, it needs precise timing to correctly reproduce an analog output signal. If the samples do not generate an analog waveform with the identical timing with which they were taken, distortion will result, as explained in Fig. 62.25. Jitter can be loosely defined as timing errors in analog-to-digital and digital-to-analog conversion. When the analog voltage is reconstructed using a DAC with timing variations in the word clock, the sample amplitudes, the ONEs and ZEROs are correct, but they come out at the wrong time. Because the right amplitude at the wrong time is the wrong amplitude, a timing jitter in the word clock produces an amplitude variation in the DAC output, causing the waveform to change shape. This in turn introduces either spurious components related to the jitter frequency or raises the noise floor of a DAC, unless the jitter is periodic. If the jitter has a Gaussian distribution with a root mean square jitter of Δt, the worst-case SNR resulting from this random word clock jitter is

$$\text{SNR} = -20 \times \log \frac{2\pi f \Delta t}{M^{1/2}} \tag{62.18}$$

where f is the signal frequency and M is the oversampling ratio. The oversampling ratio M is defined as

$$M = \frac{f_c}{2f_n} \tag{62.19}$$

where f_c is the word clock frequency and f_n is the noise bandwidth. The timing jitter error is more critical in reproducing high-frequency components. In other words, to make an N-bit DAC, an upper limit for the tolerable word clock jitter is

$$\Delta t < \frac{1}{2\pi B 2^N} \left(\frac{2M}{3} \right)^{1/2} \tag{62.20}$$

where B is the bandwidth of the baseband. This implies that the error power induced in the baseband by clock jitter should be no larger than the quantization noise resulting from an ideal N-bit DAC. For example, a Nyquist-sampling 16-bit DAC with a 22-kHz bandwidth should have a word clock jitter of <90 ps.

© 2003 by CRC Press LLC

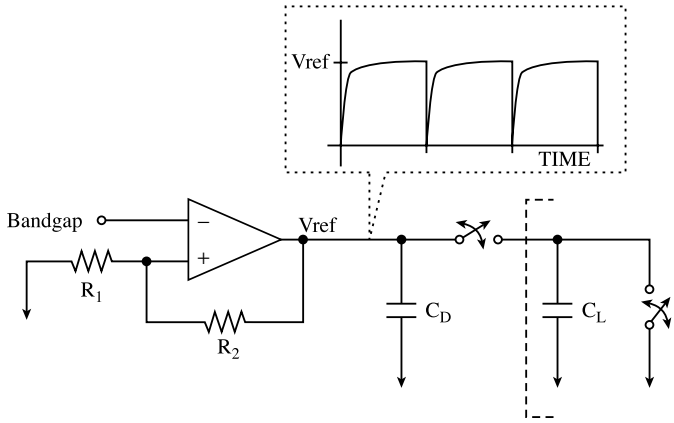

FIGURE 62.26 Voltage reference periodically charging a load capacitor.

These timing errors are caused by variation in the clock signal that controls the time when the DAC converts each digital word to an analog voltage. Usually, the term "clock jitter" results from everything inside a digital processor (noise from digital circuitry, inductance and capacitance of a clock bus or of a printed circuit board trace) as well as the instability of the clock source. For example, noise in digital circuitry causes the zero-crossing points to shift slightly. If the digital signal has an average slope of 10 V/μs, just 1 mV_{rms} of noise will cause 100 ps of root mean square jitter.

Voltage Reference

Ideally, the voltage reference V_{ref} is a constant temperature- and supply-independent voltage with a zero output resistance. The most common voltage reference source is a silicon bandgap voltage reference of about 1.2 V. Depending on the process used, the bandgap reference voltage has a temperature coefficient of typically 20 to 100 ppm/°C at room temperature when it is set to a voltage ranging from 1.2 to 1.3 V. To generate a different reference voltage other than 1.2 V, op amps are often used to make inverting and noninverting amplifiers with trimmable feedback gains. Because the bandgap voltage for zero temperature coefficient is not clearly defined and process dependent, it is common to trim this voltage at a wafer level, and it is extremely difficult to achieve an absolute accuracy over a wide range of temperature. However, most DAC applications, except for precision instruments, do not require an absolute accuracy of the reference voltage, and the load-driving capability of the op amp used in the voltage reference is of paramount interest.

When a DAC is used as a subblock of an ADC, the DAC has only to settle to a final value within a given clock period. In such applications it is not important how the DAC settles. However, the DAC as a stand-along device should have a single-pole response without a glitch and a slew limit. Except for the current-ratioed DAC, the voltage reference is periodically loaded and disturbed by a switched-in load at the clock rate, and the reference output should be restored immediately so that the DAC can settle fast. When disturbed, the voltage reference needs to settle with a time-constant shorter than that of the DAC with an unlimited slew rate. Figure 62.26 illustrates this situation when the voltage reference periodically refreshes the loading capacitor. If the op amp unity-gain bandwidth is $1/\tau_0$ rad/s, the op amp restores the output with a time constant $(1+R_2/R_1)\,\tau_0$ of the feedback amplifier. The large capacitor C_D helps to prevent the op amp from slewing because the voltage dip of $V_{ref}\,C_L/(C_D + C_L)$ decreases as C_D increases.

Noise

Noise is a fundamental limit in high-resolution DACs. The resolution of a DAC is limited by a quantization noise given by (62.2), unless the circuit contributes higher noise. There are many noise sources in real DACs. The DAC output is corrupted by noises directly coupled from bouncing power supplies, bias lines, and ground, as well as the noise sources such as thermal noise, flicker noise, and shot noise. To reduce

© 2003 by CRC Press LLC

the former noise sources, it is necessary to carefully separate analog and digital supplies and to eliminate sets of ground loops using a star-ground configuration. The use of a fully-differential architecture helps to reduce such coupling noises. However, the latter set of noise sources is predictable and can be reduced by a low-noise design.

The dominant noise source of a resistor-string DAC shown in Fig. 62.4 is a white thermal noise of resistors. If the output resistance of the DAC is R_{out}, the root mean square output noise of the DAC is $(4kTR_{out})^{1/2}$ V/Hz$^{1/2}$, where k is the Boltzman constant and T is the absolute temperature. The thermal noise is about 4 nV/Hz$^{1/2}$ if R_{out} is 1 kΩ. The output resistance of this DAC depends on the digital input code. The worst-case R_{out} is one quarter of the total resistance of the string when the output is connected to the center tap. For lower noise, the total resistance should be minimized at the cost of high power consumption. The noise of the voltage reference appears at the output after being divided by the resistor string. The voltage noise of the output buffer, if used, is directly added to this noise.

On the other hand, the noise source of the current-ratioed DAC of Figs. 62.6 and 62.7 is the current noise contributed either by the shot noise of the current source or by the parallel resistor connected to the output node. If the total output current is I_{out} and the total output shunt resistance is R_p, the root mean square output shot noise is 2 qI_{out} A/Hz$^{1/2}$ and the root mean square current noise contributed by the shunt resistor is 4 kT/R_p A/H$_Z^{1/2}$, where q is 1.6×10^{-19} C. The shot noise of a 50-μA current and the current noise of a 1-kΩ shunt resistor give the same root mean square noise of 4 pA/Hz$^{1/2}$. The shunt feedback resistance of the transresistance amplifier also contributes to the total noise. If the current DAC is terminated by a low-impedance source of 50 to 75 Ω, the current noise is usually dominated by this termination resistor.

The main source of the capacitor-array DAC shown in Figs. 62.8 and 62.9 is a well-known kT/C noise. The sampled root mean square noise voltage of the capacitor of C is $(kT/C)^{1/2}$ V without regard to the switch-on resistance. The 1-pF sampling capacitor gives a 64-μV sampled noise. This noise is evenly distributed over the Nyquist band (half the sampling frequency), and puts a lower limit on the smallest signal the DAC can handle. Furthermore, the reference and ground noises are divided by the C divider and appear at the output of the DAC. When applied to the oversampling converters either in delta-sigma modulators or in a one-bit DAC, shown in Figs. 62.22 and 62.23, the kT/C noise in the signal band is lower than the Nyquist-rate converters by the oversampling ratio of M given by (62.19).

Low-Spurious DAC Design Examples

Modern broadband digital communication systems such as cable modem, cellular baseband, and wireless local area network consist of multiple channels. For high bit rate transmission of 54 Mbit/s over 20-MHz bandwidth, the RF standards such as IEEE 802.11a and Hyperlan2 use the orthogonal frequency division multiplexing scheme that divides the signal band into 52 of 300-kHz narrowband channels. It is challenging to preserve signal integrity of such a complex waveform. Multiple channels are mixed in many different ways when analog signal processing is nonlinear. For example, the multi-channel spectrum is perfect when digitally generated, but it is degraded while being converted into analog waveform due to the DAC nonlinearity. To generate an accurate multi-channel spectrum without mixing, DAC should be linear both in static and dynamic performance. High spurious-free dynamic range is the most important for frequency-domain applications. Recently, a few techniques such as spatial averaging [13]–[15], self-trimming [16], and dynamic linearity enhancement [16]–[17] are reported.

Spatial Averaging for Static Linearity

DAC static linearity measured in terms of DNL and INL depends on how DAC components are arranged. In most stand-alone DACs, an array of current sources is predominantly used. It is well known that the binary-weighted array is simple to decode but exhibits poor DNL, while the thermometer-coded array is complex to decode but exhibits good DNL. In fact, the complexity of the thermometer-coded current DAC grows exponentially. Therefore, in typical applications above 8 to 10 bits, the MSB part is coded in thermometer while the LSB part is coded in binary. The thermometer-coded DAC array occupies a large

© 2003 by CRC Press LLC

area, and current source matching is limited by overall gradient effect. In a large thermometer-coded array, systematic and graded errors are far greater in effect than random device mismatch errors. They result from many factors such as edge effect, current source output resistance, supply voltage drop, thermal gradient, and process gradients of doping and thickness across the die, etc. In integrated circuit design, the common-centroid layout scheme has been used to effectively match devices when limited by the gradient effect.

Since the thermometer-coded array is physically large, a two-dimensional common-centroid scheme should be used. To improve INL, the two-dimensional array can be split into four quadrants biased separately using common-centroid bias circuits [13]. To improve INL further, each current source can be split into four small slices connected in parallel, and each slice is placed in one of the four different quadrants [14]. This results in the first-order spatial averaging of the systematic and gradient errors. In general, the gradient effect is first-order, but the second-order effect limits DAC INL performance at 14-bit level or higher. Further partitioning the unit current source into 16 small slices connected in parallel can remove the residual gradient effect [15]. Unlike the first-order centroid scheme, the second-order spatial averaging scheme uses four common-centroid slices placed in four different quadrants. In theory, the matching improves as the array is split into many smaller pieces and the common-centroid scheme is used in each small piece. However, the complexity grows significantly, and the operating speed is inevitably reduced.

Self-Trimming for Static Linearity

The two-dimensional geometric averaging is very costly in terms of chip area and the operating speed as the array gets larger. Calibration techniques as discussed are effective in overcoming device mismatch and gradient effects in IC process. One recent trend is self-trimming. The concept is to adjust the current source values electronically like laser trimming. Although laser trimming is a one-time adjustment, the self-trimming is adaptive and continuously engaged. A trimmable floating current source is shown in Fig. 62.27, which can be used as one MSB current source in the thermometer-coded array [16]. The floating current source made of transistors N_4 and P_2 is switched from the top side by transistors N_6 and N_7. When the current source needs trimming, the bottom transistor N_2 is turned on, and the current is

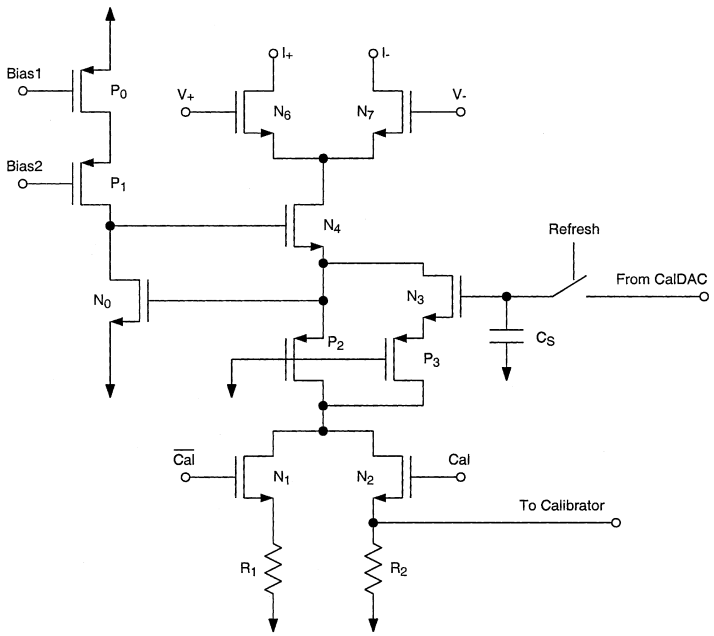

FIGURE 62.27 Trimmable floating current source.

© 2003 by CRC Press LLC

switched to the measuring resistor R_2. This arrangement of trimming is transparent to the normal operation and is performed in background. An oversampling calibrator based on delta-sigma modulation repeatedly monitors the voltage across R_2, accurately compares it with the preset reference voltage, and constantly feedbacks the error signal that periodically updates the capacitor C_s to adjust the current source.

Dynamic Linearity Enhancement

The static linearity up to over 14 bits can be achieved either with spatial averaging or with self-trimming, but the dynamic linearity heavily depends on how the DAC output settles. For example, the wireless baseband spectrum covers over 20-MHz bandwidth, but generating such a wideband signal with high static and dynamic linearity is not a trivial task. Furthermore, in scaled CMOS, devices are more nonlinear and low supply voltage often limits the DAC linearity. In standard current DACs, each current source is switched to the output at different times due to clock skew, and adds parasitic capacitance to the output node, which results in code-dependent output settling. The clock skew and the code-dependent settling are most prominent among many factors limiting dynamic DAC linearity. Isolating the output node from current sources and synchronizing the code transitions are simple solutions for these, but the clock skew is difficult to deal with high precision. It is often suggested that the DAC's dynamic linearity can be improved if its output is sampled and held using a deglitcher. In fact, the deglitcher is functionally a track and hold circuit, but it is also difficult to implement at high frequencies with high precision.

The return-to-zero (RZ) scheme solves the deglitcher problem as explained in Fig. 62.28(a) [17]. While the error in the track and hold stays for the half period, the error in the RZ exponentially decays. The logic behind this is that rather than sampling analog voltage accurately, it is easier to let the output keep on changing exponentially. Exponential settling is a linear process. The same effect as RZ can be achieved in a simpler maner, called track and attenuate [16]. Rather than resetting the DAC output, just attenuating it achieves the same goal. Fig. 62.28(b) illustrates the DAC output stage performing the track and attenuate function. The differential DAC output current comes into the folded-cascode node V_x, which is isolated from the output node. The output nodes track the signal during the half clock period, but are bypassed by three transistors N_+, N_-, and N_{DIFF} for attenuation during the remaining half clock period. The difference of the RZ DAC from the conventional DAC is that the output spectrum nulls at multiples of twice the sampling frequency, which in turn provides less attenuation in the passband.

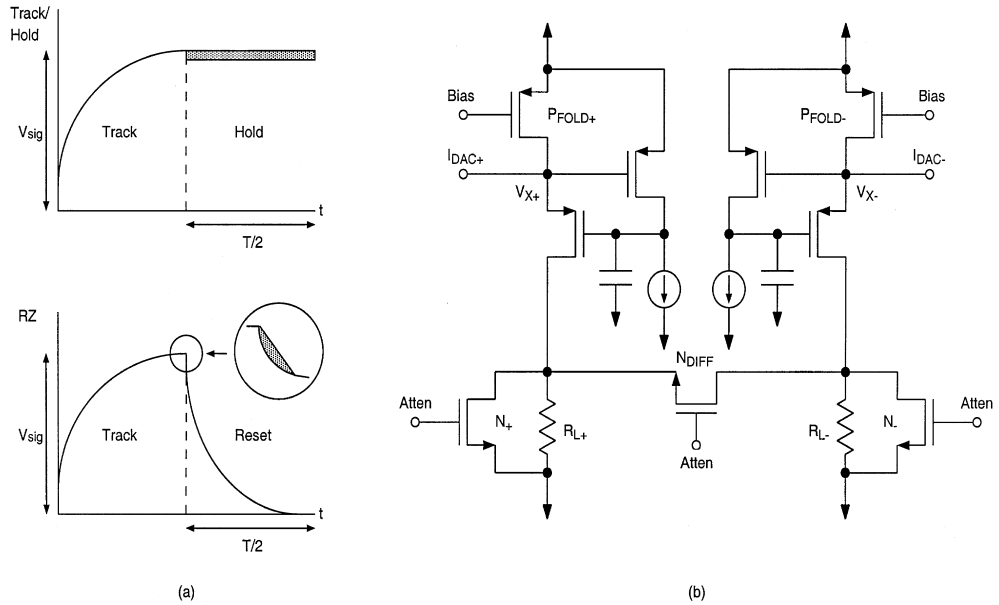

FIGURE 62.28 (a) Track and hold vs. RZ. (b) Track/attenuate output stage.

62.2 Analog-to-Digital Converters

Ramesh Harjani

Introduction

With the increased complexity possible in modern-day integrated circuits analog-to-digital (ADC) and digital-to-analog (DAC) converters have become ubiquitous components of mixed-signal integrated circuits. Analog-to-digital converters transform an analog signal, V_A, into an N-bit digital representation, V_d. Such a converter is said to have a resolution of N bits. The digital signal V_d is an approximation of the original analog signal, V_A, and the maximum error during this conversion process for an N-bit converter is equal to $1/2^N$ of the full-scale value. This error is called the quantization error.

A number of topologies exist for ADC. They can be classified as Nyquist rate converters or oversampled converters. Nyquist rate converters sample the input at the minimum sampling rate, i.e., two times the

© 2003 by CRC Press LLC

maximum signal frequency. As the name implies, oversampled converters take more samples than is mandated by the Nyquist criterion to generate extremely high resolution. Nyquist rate converters are usually classified as (1) high-speed, (2) medium-speed, and (3) high-resolution converters. However, the different architectures are better categorized by evaluating the number of clock cycles they use to perform the analog-to-digital conversion. For example, for N-bits of resolution a high-speed converter performs the conversion in one or two clock cycles, a medium-speed converter performs the conversion in N clock cycles, and a high-resolution converter performs the conversion in 2^N clock cycles. Thus, we classify them here as 1-clock, N-clock and 2^N-clock converters.

Before describing the details of the various ADC architectures we discuss some of the performance characteristics of ADCs in general and describe some test techniques that are used to measure these characteristics.

Analog-to-Digital Converter Test Techniques

Analog-to-digital converters are primarily tested using parametric techniques. That is, a key set of parameters that characterize an ADC are verified. An ADC is characterized by its static and dynamic performance. In static performance, we are primarily concerned about the linearity of the I-O transfer characteristics, and in dynamic performance we are concerned about the operation of the converter at full operating speed.

Figure 62.29 shows the transfer characteristics for an ideal 3-bit converter. The dashed line shows the transfer characteristics of an infinite precision converter and the bold line shows the transfer characteristics of a 3-bit version. We note that the least significant bit (LSB) value is equal to $1/2^N$ of the full-scale value. Figures 62.30 to 62.33 show examples of the static performance characteristics of an ADC. A gain error is said to be present when the maximum digital value does not correspond to the full-scale analog value. An offset error corresponds to a horizontal shift in the transfer characteristics. The integral nonlinearity error specifies the maximum deviation of the transfer characteristics from the ideal code center. Differential nonlinearity specifies the deviation of each stepsize from $1/2^N$ of the full-scale value.

Dynamic ADC performance characteristics include signal-to-noise ratio (SNR), effective bits, aperture errors, and input signal bandwidth. During full-speed operation some additional errors become evident because of the finite settling time and bandwidth limitations of the circuits within the ADC. The SNR and effective bits are dynamic ways of measuring the minimum resolution and errors in the transfer characteristics. Different terms are used to specify similar performance parameters largely because different measurement techniques are used to generate them. The input signal bandwidth specifies the maximum frequency of the input signal.

Because of the large number of performance specifications for ADCs quite a few techniques are used to test them as well. These testing techniques also reflect the different types of performance characteristics, i.e., static and dynamic. The more traditional methods of testing ADC are primarily concerned with checking the static characteristics of these converters. Examples of such test techniques include analog

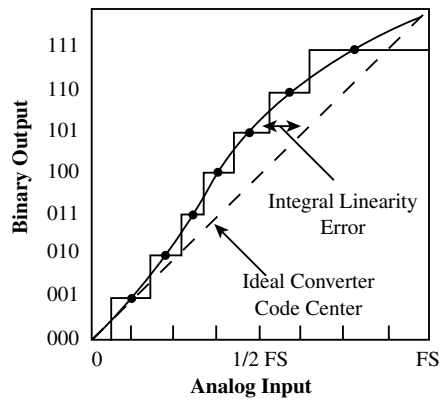

FIGURE 62.32 Integral nonlinearity error.

difference signal methods, crossplot methods, and servo loop code transition measurement methods [3]. Dynamic techniques to test linearity are based on using a well-known and near-full-scale input signal and evaluating the output code probability over a large input sample size. This technique is called the **code density test** or the **histogram test**. The output code probability for a linear ramp input is uniform for all codes. However, it is difficult to generate extremely accurate ramp signals at high speed, therefore, sine-wave signals are used. Unfortunately, with a sine wave the output code probability is no longer uniform but is instead "cusp-shaped". An estimate of the differential nonlinearity can be generated by evaluating the difference between the expected code probability and measured values. The code density

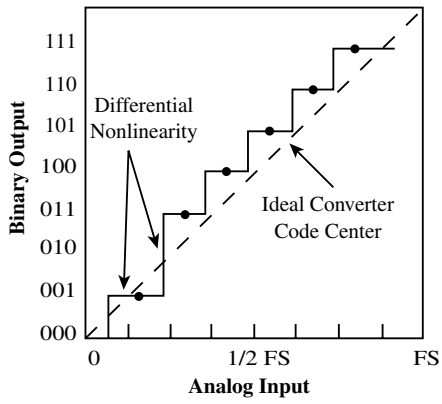

FIGURE 62.33 Differential nonlinearity error.

test requires a large number of data samples in the range of several hundreds of thousands. Additionally, a small number of large magnitude errors are easily masked in this technique. More recently, frequency domain-based techniques have been used to measure the harmonic content of the converted signal to provide an estimate of the SNR and effective number of bits. In this technique, a discrete time Fourier transform (DTFT) is performed on the output data sequence and is used to measure the data converter performance characteristics. Although the number of data samples required are fewer than the code density approach, this approach still requires a few thousand data samples. Additionally, proper windowing functions and synchronized sampling may be required to reduce spectral leakage.

Data converters are relatively time-consuming to test. However, rather than explain all the techniques that can be used to test data converters, we concentrate on a single method, the crossplot method, to provide the reader with some insight into the complexity of testing ADCs. For additional details about the other methods, readers are referred to [3]. A block diagram for the crossplot method is shown in Fig. 62.34. In the crossplot technique, the output of the lowest two or three bits of an ADC are fed to the *Y* input of an oscilloscope and a separate triangular *dither* signal is fed to the *X* input of the oscilloscope. The input to the ADC is generated using a discrete summing amplifier that adds the output of a DAC, which is itself swept through its input space at a much slower rate, and the dither signal, mentioned

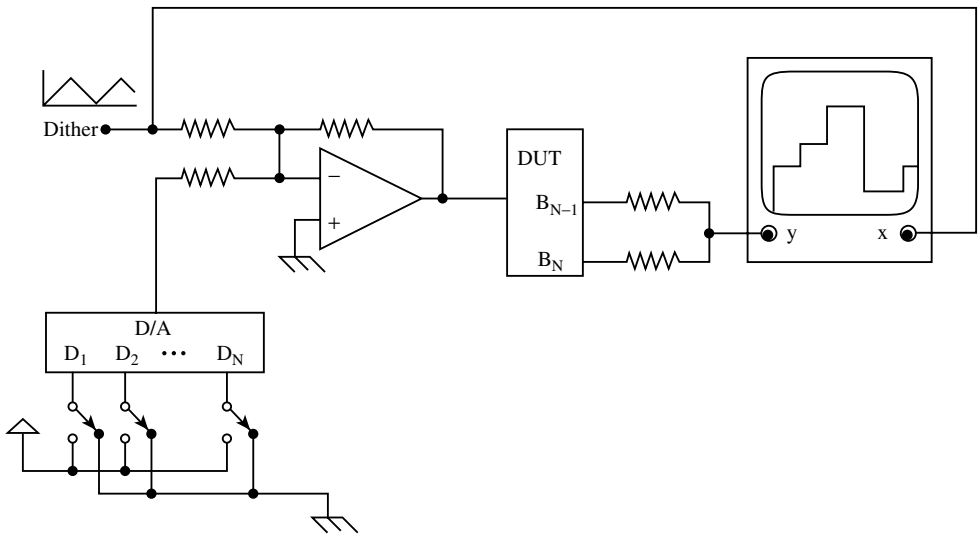

FIGURE 62.34 Crossplot technique used to test ADC static characteristics. (*Source:* M. J. Demler, *High-Speed Analog-to-Digital Conversion*. New York: Academic Press, 1991, p. 162.)

earlier. This technique generates a staircase waveform on the oscilloscope. Therefore, the linearity of the last two or three bits around a fixed bias voltage, which is generated by the DAC, can be seen easily on an oscilloscope. The primary advantage of this technique is that it uses fairly inexpensive equipment. However, it is extremely time consuming to evaluate all 2^N combinations and the technique provides no information about the integral linearity, offset, and gain errors. In general, techniques that are used to test ADCs are fairly complex and either require a large sample size, i.e., high cost, or use extremely complex equipment to perform the tests.

Having described the basic characteristics of ADC, we now describe of the different ADC architectures in detail. We first consider Nyquist rate converter topologies and then describe oversampled converters.

Nyquist Rate Converters

As mentioned earlier, Nyquist rate converters are classified as 1-clock converters, N-clock converters, and 2^N-clock converters. Examples of 1-clock converters include the flash architecture, the pipelined architecture [11, 12], and the voltage folding architecture. Examples of N-clock converters include the successive-approximation architecture [9] and the algorithmic architecture [6]. Examples of 2^N-clock converters include the single-slope and dual-slope architectures [4].

1-Clock Converters

Flash Converters. Flash or parallel converters are the highest rate converters and are sometimes also called **video rate converters** because they operate at rates necessary for video signals. Parallel converters are O(1)-clock converters in that they require one or two clock cycles to perform an N-bit conversion. The basic principle of operation is fairly simple and is easily explained with the help of Fig. 62.35. This figure is a block diagram for a 3-bit flash converter. The input is compared to $(2^3 - 1)$ comparators. The comparison voltage for the ith comparators is set to be equal to $(iV_{FS})/(2^3)$, where V_{FS} is the full-scale voltage. The resulting outputs are then converted from thermometer code to binary code. In general, the time required to perform the analog-to-digital conversion is equal to the comparator resolution time plus the time taken to perform the digital code conversion, i.e., one clock cycle. The reference voltages for the comparators are usually generated using an equally spaced resistor string that is offset by $R/2$, as shown in Fig. 62.36. The primary advantage of providing the $R/2$ offset is that it allows the code center to pass through the origin. The resolution of integrated MOS flash converters is limited to approximately 8 bits. This is primarily due to the matching constraints placed on the resistors and also because of the exponential increase in the number of components ($\approx 2^N$) required for higher resolution. The speed for MOS flash converters is usually limited to about 50 MHz. However, if higher speed operation is required, then the process of time interleaving may be employed. Here, M (N-bit) ADCs are operated in parallel, but each is delayed somewhat, as shown in Fig. 62.37 [1]. By starting the conversion operation for A/D_2 before the operation of A/D_1 is complete allows the complete interleaved converter to operate at M times the speed of each individual converter. Although the technique allows for higher operating speed, the number of parallel paths has increased. Therefore, due to size limitations the resolution is usually lower than for simple flash converters.

Subranging Converters. The exponential area penalty ($\alpha\ 2^N$) for flash converters can be mitigated by using subranging techniques without incurring severe speed penalties. Here, instead of deciding all N-bits at one time, only a subset of these is decided during the first clock phase, and the rest are decided in the following clock phases. If two clock phases are used to decide all N -bits, this is called a two-step subranging converter topology.

A block diagram for a two-step subranging converter is shown in Fig. 62.38. In this converter topology the α most significant bits (MSBs) are decided by the coarse ADC, the results of which are then passed on to an α-bit DAC. The output voltage of the DAC is subtracted from the input signal. The resulting voltage is amplified 2^α times and then a $(N - \alpha)$-bit fine converter is used to resolve the remaining bits. The entire process — coarse conversion, digital-to-analog subtraction, amplification, and fine conversion — is performed in one clock period. The coarse and fine converters are usually implemented as simple flash

© 2003 by CRC Press LLC

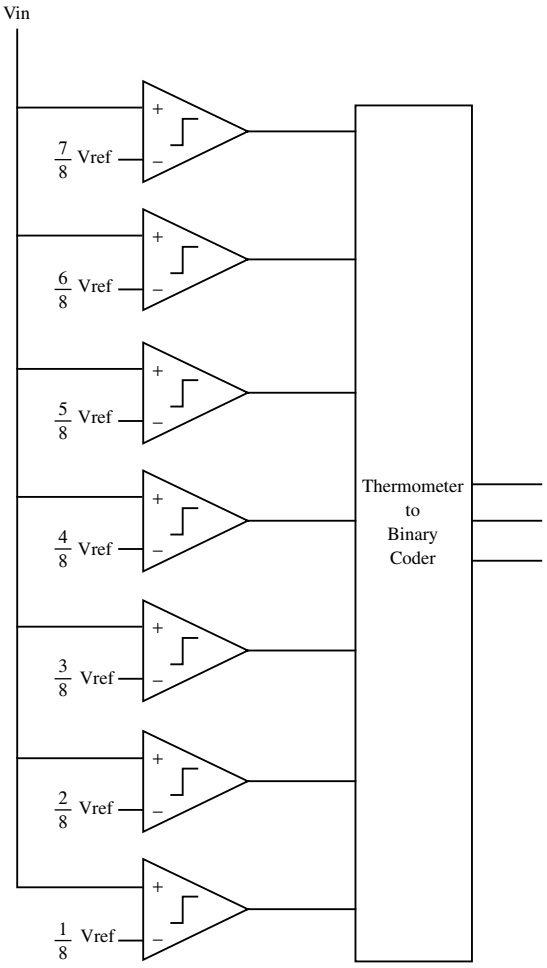

FIGURE 62.35 3-bit flash converter block diagram.

converters. Therefore, the operating speed of a pure subranging converter is at least twice as slow as that of a flash converter. However, the total number of comparators (and associated circuits) is reduced from 2^N to $2^\alpha + 2^{N-\alpha}$. The savings in area can be substantial. Usually, the value of α is selected to be roughly equal to $N/2$. For example, for $N = 10$ and selecting $\alpha = 5$, the number of comparators reduce from $2^{10} = 1024$ to $2^6 = 64$, which is a savings of 93.75%. This subranging process can be extended further to a larger number of sequential stages; however, the total propagation delay usually limits the operation speed fairly significantly.

Pipelined Converters. Instead of operating both the coarse and fine converter in the same clock period a sample-and-hold (S/H) could be added to the circuit in Fig. 62.38, such that when the fine converter is resolving the lower $(N - \alpha)$ bits for the first input sample the coarse converter can begin resolving the upper α bits for the next input sample. This kind of converter can be made to operate at speeds comparable to flash converters and is called a pipelined converter. A block diagram for a two-stage pipelined converter is shown in Fig. 62.39. Because the α MSBs are decided during the previous clock period, the results from the fine and coarse converters need to be synchronized by delaying the output of the coarse converter by a single clock period. As with the subranging converter the number of comparators have decreased from 2^N to $2^{N-\alpha} + 2^\alpha$.

© 2003 by CRC Press LLC

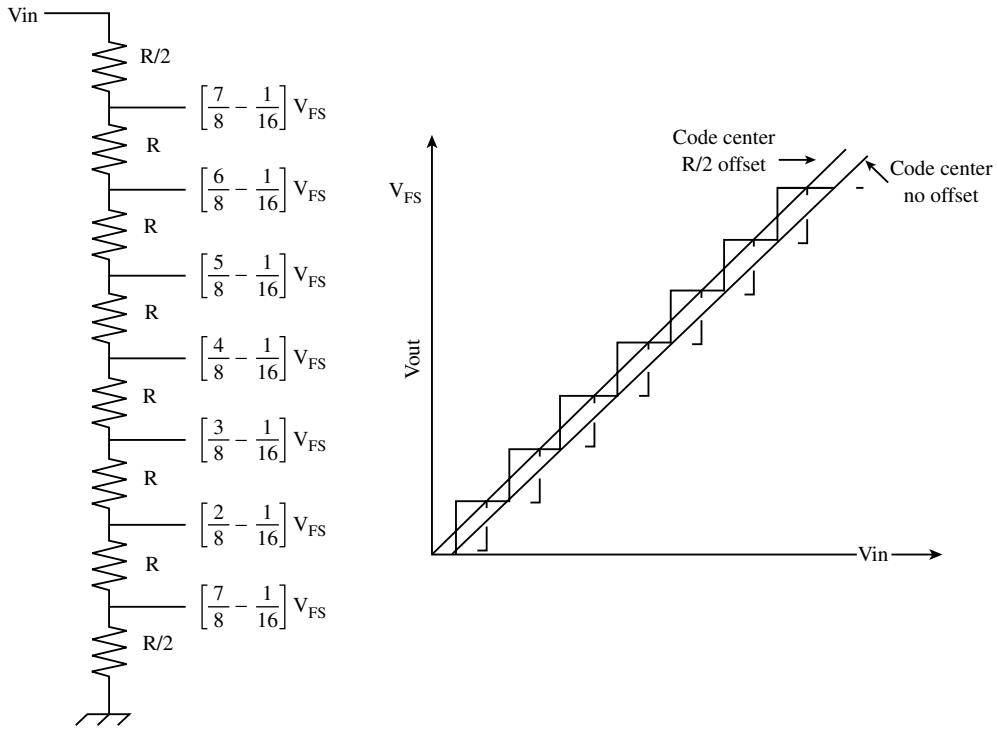

FIGURE 62.36 Flash converter 1/2 LSB offset.

Unlike the subranging topology, the pipeline methodology can easily be extended to N sequential stages, each resolving only 1 bit, because of the sample-and-held circuits between each of the stages. The block diagram for such an N-step converter is shown in Fig. 62.40. In this figure, note that only one comparator is used per stage and the interstage gain block (also performing the S/H function) has a gain of two. Once again for synchronization purposes, shift registers are used. This pipelined converter [11, 12] operates as follows. The input is first compared to see if it is greater than V_{ref}. If the input is greater than V_{ref}, then we set the MSB bit. If the MSB is set, then V_{ref} is subtracted from the input voltage. However, if the MSB is not set, nothing is done. The resulting voltage is then doubled. During the next clock cycle, the resulting voltage is once again compared to V_{ref} to give the MSB-1 bit. While the second stage generates the second MSB for the first input, the first stage processes a new input. When the pipeline is filled, N inputs are being processed simultaneously. Several shift registers are used to ensure that all the data bits corresponding to a single input are output simultaneously. This process continues until we finally generate the LSB. The analog output of the ith stage can be written as

$$V_i = 2\left[V_{i-1} - b_i V_{\text{ref}}\right]z^{-1} \tag{62.21}$$

where b_i is equal to 1 if the ith bit is set and equal to 0 otherwise.

Figure 62.41 is a simple circuit realization for a pipelined ADC [13]. Other more advanced topologies [12] reduce some of the problems associated with this topology, but operate on the same principle. Only one stage of an N-bit converter is shown in this figure. In this first stage, the amplifier A_1 performs the comparison function and the amplifier A_2 performs the 2× multiplication and the conditional subtraction function. Both amplifiers, along with the associated capacitors and switches, also implement a S/H function. Let us first concentrate on the comparison function. For a sufficiently large gain, during ϕ_1 the capacitor C_h is charged to $V_a - V_{off}$, where V_{off} is equal to the amplifier offset voltage. During ϕ_2 the reference voltage, V_{ref}, is connected to the positively charged terminal of capacitor C_h and the

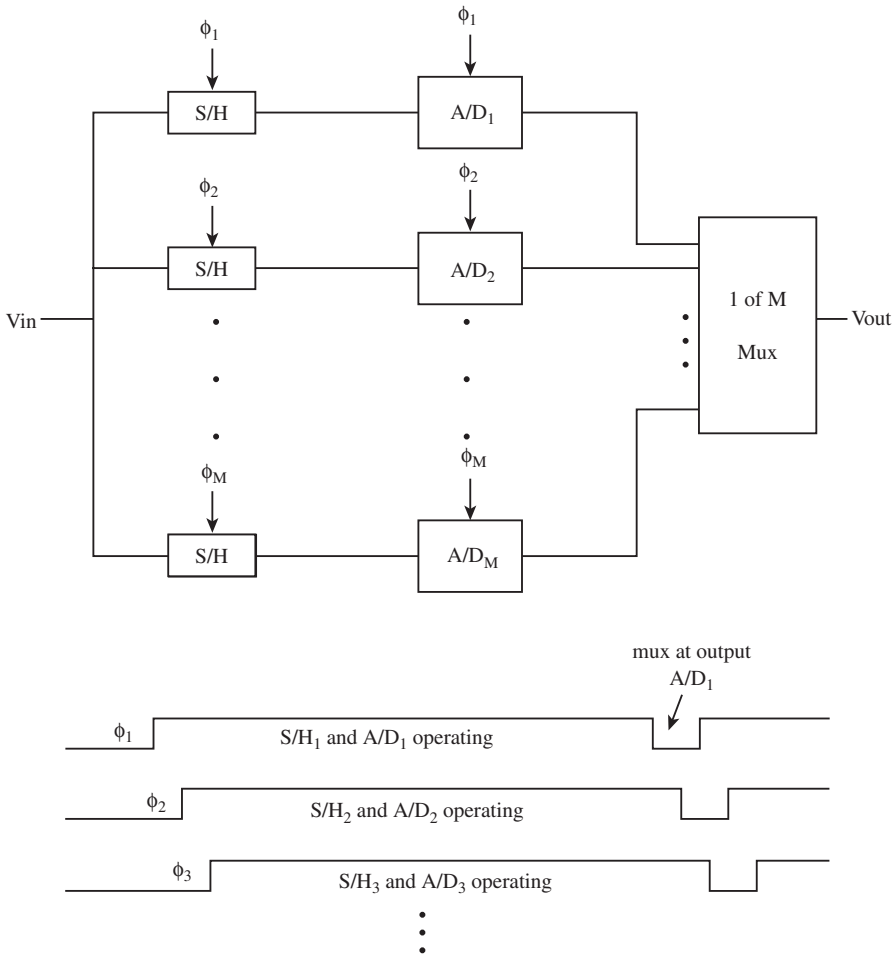

FIGURE 62.37 Time interleaved converter block diagram.

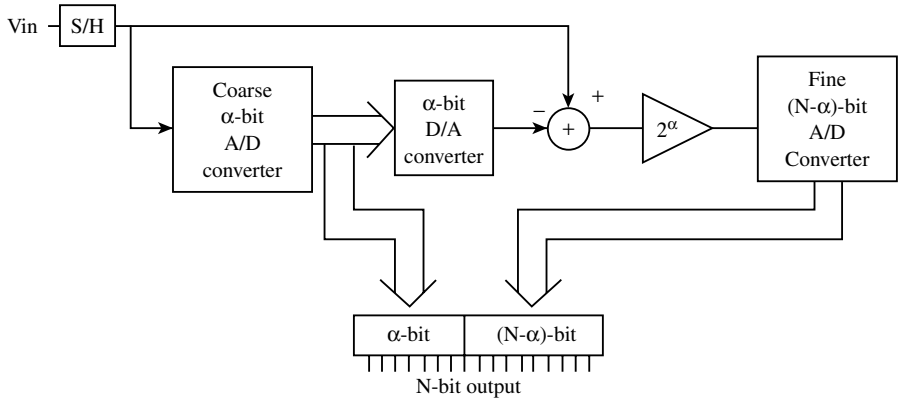

FIGURE 62.38 Subranging converter block diagram.

feedback around the amplifier is removed. During this period the amplifier A_1 acts as a comparator and compares the voltage $[V_{ref} - (V_a - V_{off})]$ against V_{off}; i.e., the effect of the amplifier offset voltage is completely canceled. The preceding discussion is valid only for sufficiently large gain. However, if the gain

of amplifier A_1 is not sufficiently large then the charge transfer is not complete and an error is introduced in the comparison; i.e., the effective comparison is not with V_{ref} but with $V_{ref} + \Delta V$. The error in the comparison is dependent on the input signal voltage. Note that the first stage samples the input at ϕ_1 while the next stage samples the input at ϕ_2. Likewise, the third stage samples the input at ϕ_1 and the fourth stage samples the input at ϕ_2, and so forth.

Digital-Error Correction in Multistep Converters. Pipelined and subranging converters that have an interstage gain >1 can utilize digital-error correction [14] to improve linearity. We shall illustrate the principle of digital-error correction with the help of a 4-bit two-stage pipelined converter. Each of the stages resolves two bits. Digital-error correction can be used to correct for linearity errors in all except the last stage. Additionally, it is unable to correct for digital-to-analog linearity and op amp settling time errors. Therefore, for our two-stage example we will only be able to correct for errors in the first stage and we shall assume an ideal DAC.

Figure 62.42 is the block diagram for the 4-bit two-stage pipelined converter without digital-error correction. This circuit is a 4-bit version of Fig. 62.39. The input signal is sample-and-held by S/H_1. The course MSB bits for the overall converter are generated by the first-stage subconverter (A/D_1). The analog value corresponding to these bits is then generated by the first-stage digital-to-analog subconverter (D/A_1). The difference between the input signal and the digital-to-analog output is called the residue. This residue is amplified by the interstage gain stage ($G = 4$) and passed on to the second-stage analog-to-digital subconverter. The second-stage analog-to-digital subconverter (A/D_1) then generates the lower two bits. Because the second stage is working on the signal after one-clock delay, an intermediate delay stage is added to synchronize the outputs of the two stages.

The residue for an ideal converter varies from $-\frac{1}{2}$ LSB to $+\frac{1}{2}$ LSB of the first-stage subconverter resolution, as shown in Fig. 62.43. In the case of nonlinearity in the first subconverter the residue will

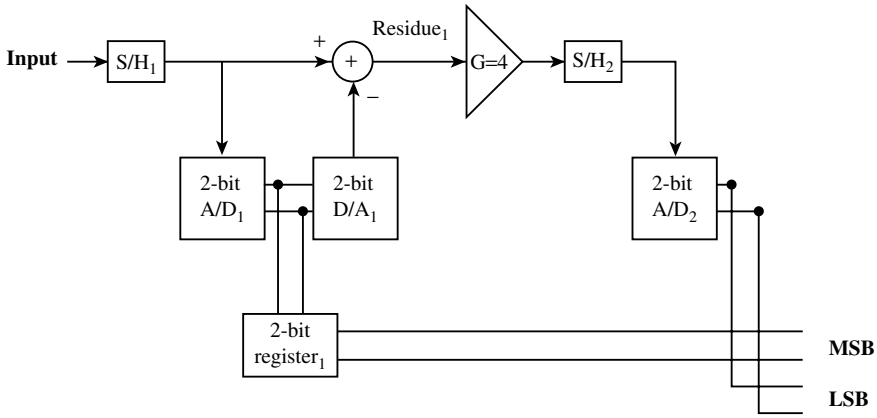

FIGURE 62.42 4-bit, two-stage, pipelined converter block diagram without error correction.

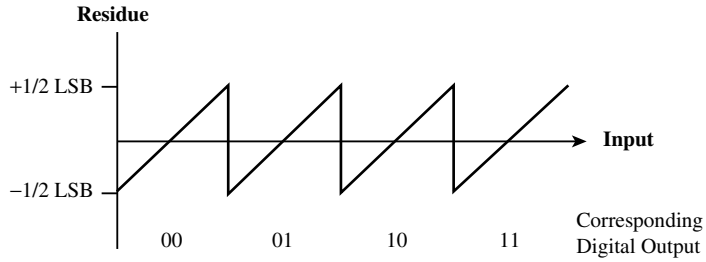

FIGURE 62.43 Ideal subconverter residue.

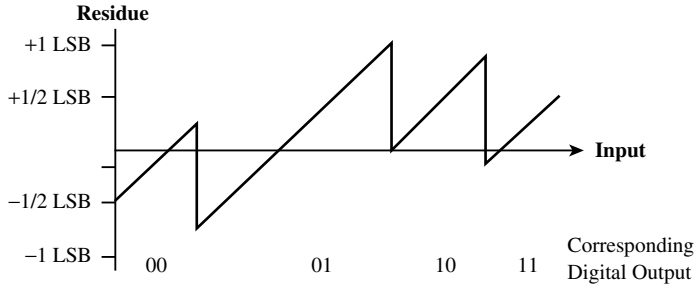

FIGURE 62.44 Nonideal subconverter residue.

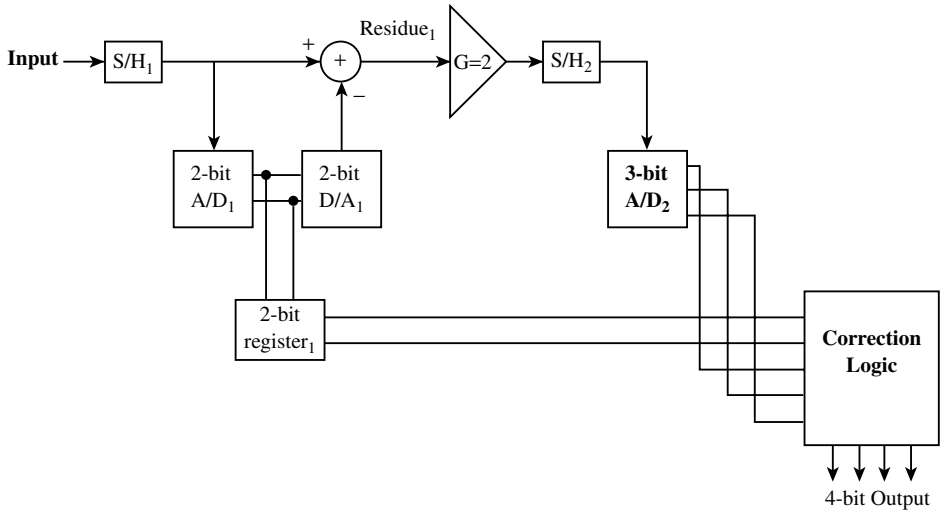

FIGURE 62.45 4-bit, two-stage, pipelined converter block diagram with error correction.

have excursions above and below the $\pm\frac{1}{2}$ LSB value, as shown in Fig. 62.44. For an ideal digital-to-analog conversion, the residue corresponding to each digital code is still accurate and no data have been lost as yet. In the traditional pipelined converter shown in Fig. 62.42 any residue value from the first converter that is greater than $\pm\frac{1}{2}$ LSB of the first stage saturates the second stage and produces errors.

If, however, we change the overall converter topology such that the resolution of the second subconverter is increased by 1 bit, i.e., we double the number of levels, and reduce the interstage gain by half, then we can detect when the residue exceeds the $\pm\frac{1}{2}$ LSB levels and correct for its effect digitally. Figure 62.45 is a block diagram for the pipelined converter in Fig. 62.42 with digital-error correction. Whenever the residue from the first stage exceeds $+\frac{1}{2}$ LSB it implies that the digital output of the first stage subconverter is too small. Likewise, whenever the residue is less than $-\frac{1}{2}$ LSB it implies that the digital output of the first stage is too large. By adding a $\frac{1}{2}$ LSB offset at the input of the first analog-to-digital subconverter and at the output of the first DAC the input to the second subconverter for an ideal first subconverter is restricted between $\frac{1}{4}$ full-scale and $\frac{3}{4}$ full-scale. Any excursion outside this region implies an error in the first analog-to-digital subconverter. The approximate value for this error is measured by the second-stage subconverter and is then subtracted digitally from the final value. Nonlinearities from the second stage are not corrected via this scheme; however, as the interstage gain is >1 the effect of the nonlinearities in the second stage will have a much lower effect than those resulting from the first stage. Nonlinearities in the DAC can be reduced substantially by utilizing reference feedforward compensation [15]. Here, the reference for the second stage changes dynamically and is obtained by amplifying the first-stage digital-to-analog subconverter segment voltage that corresponds to the most

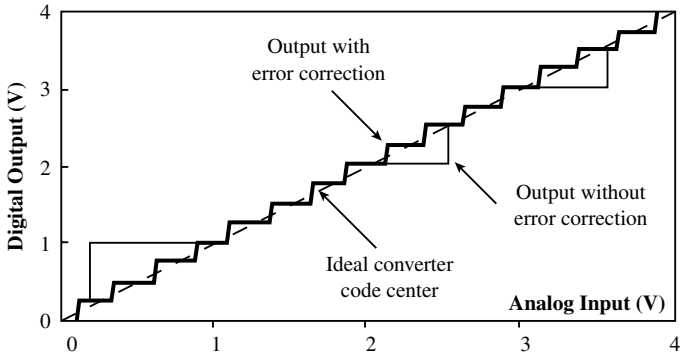

FIGURE 62.46 Digital-error correction simulation results.

current digital output code of the first-stage analog-to-digital subconverter. Figure 62.46 presents the simulation results for the 4-bit two-stage pipelined converter with and without digital error correction. For purposes of clarity the second-stage subconverter is made ideal. In a real converter some nonlinearity would still exist, but would be limited to that introduced by the last stage. Traditionally, even though the resolution of the first subconverter is only 2 bits, it needs to be linear to the overall converter resolution. Digital-error correction can reduce the linearity requirements such that it is commensurate with its resolution.

N-Clock Converters

Both the successive approximation and algorithmic analog-to-digital topologies require N clock cycles to perform an N-bit conversion. They both perform 1 bit of conversion per clock cycle. The successive approximation converter is a subclass of the subranging converter, in which during each clock cycle only 1 bit of resolution is generated. The algorithmic converter is a variation of the pipelined converter, in which the pipeline is folded back into a loop. Both topologies essentially perform a binary search to generate the digital value. However, in the case of the successive approximation converter the binary search is performed on the reference voltage, while in the case of the algorithmic converter the search is performed on the input signal.

Successive Approximation Converters. A block diagram for the successive approximation converter is shown in Fig. 62.47. Because the conversion requires N-clock cycles a S/H version of the input signal is provided to the negative input of the comparator. The comparator controls the digital logic circuit that performs the binary search. This logic circuit is called the successive approximation register (SAR). The output of the SAR is used to drive the DAC that is connected to the positive input of the comparator.

During the first clock period, the input is compared with the MSB, i.e., the MSB is temporarily raised high. If the output of the comparator remains high, then the input lies somewhere between 0 and $V_{ref}/2$,

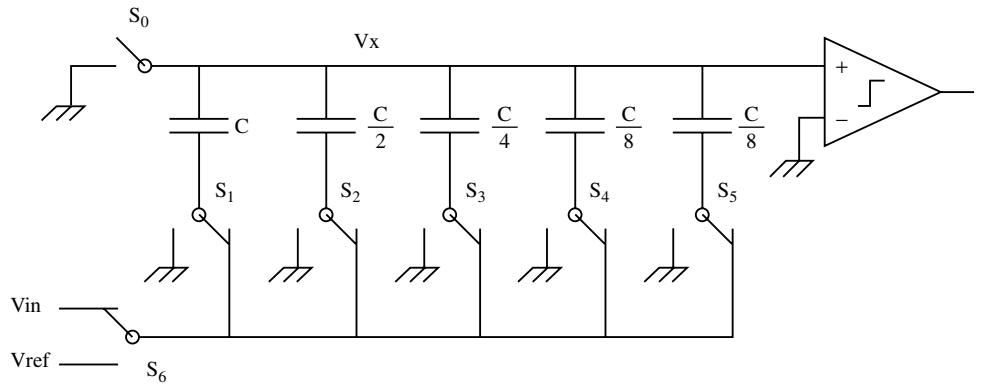

FIGURE 62.49 Charge-distribution implementation of the successive approximation architecture.

and the MSB is reset to 0. However, if the comparator output is low, then the input signal is somewhere between $V_{ref}/2$ and V_{ref}, and the MSB is set high. During the next clock period the MSB-1 bit is evaluated in the same manner. This procedure is repeated such that at the end of N clock periods all N bits have been resolved. Figure 62.48 is the binary search procedure for a 4-bit converter and shows the comparator output sequence that corresponds to an input equal to 72% of V_{ref}.

The successive approximation converter is one of the most popular topologies in both MOS and bipolar technologies. In MOS technologies the charge-redistribution implementation [9] of the successive approximation methodology is the most commonly used. The circuit diagram of a 4-bit charge redistribution converter is shown in Fig. 62.49. In this circuit, the binary weighted capacitors $\{C, C/2, \ldots, C/8\}$ and the switches $\{S_1, S_2, \ldots, S_5\}$ form the 4-bit scaling DAC. For each conversion the circuit operates as a sequence of three phases. During the first phase (sample) switch S_0 is closed and all the other switches $\{S_1, S_2, \ldots, S_6\}$ are connected such that the input voltage V_{in} is sampled onto all the capacitors. During the next phase (hold) S_0 is open and the bottom plates of all the capacitors are connected to ground; i.e., switches $\{S_1, S_2, \ldots, S_5\}$ are switched to ground. The voltage, V_x, at the top plate of the capacitors at this

© 2003 by CRC Press LLC

time is equal to $-V_{in}$ and the total charge in all the capacitors is equal to $-2CV_{in}$. The final phase (redistribution) begins by testing the input voltage against the MSB. This is accomplished by keeping the switches $\{S_1, S_2, \ldots, S_5\}$ connected to ground and switching S_1 and S_6 such that the bottom plate of the largest capacitor is connected to V_{ref}. The voltage at the top plate of the capacitor is equal to

$$V_x = \frac{V_{ref}}{2} - V_{in} \tag{62.22}$$

If $V_x > 0$ then the comparator output goes high, signifying that $V_{in} < (V_{ref}/2)$ and switch S_1 is switched back to ground. If the comparator output is low, then $V_{in} > (V_{ref}/2)$ and the switch S_1 is left connected to V_{ref} and the MSB is set high. In a similar fashion the next bit, MSB-1, is evaluated. This procedure is continued until all N bits have resolved. After the conversion process the voltage at the top plate is such that

$$V_x = -V_{in} + \left\{ b_3 \frac{V_{ref}}{2^1} + b_2 \frac{V_{ref}}{2^2} + b_1 \frac{V_{ref}}{2^3} + b_0 \frac{V_{ref}}{2^0} \right\} \tag{62.23a}$$

$$-1\text{LSB} < V_x < 0 \tag{62.23b}$$

where b_i is $\{0, 1\}$ depending upon if bit_i was set to 0 or 1.

One of the advantages of the charge-redistribution topology is that the parasitic capacitance from the switches has little effect on the accuracy. Additionally, the clock feedthrough from switch S_0 only causes an offset and the clock feedthrough from switches $\{S_1, S_2, \ldots, S_5\}$ is input signal independent because they are always connected to either ground or V_{ref}. However, any mismatch in the binary ratios of the capacitors in the array causes nonlinearity, which limits the accuracy to 10 or 12 bits.

Self-Calibration Successive Approximation Converters. Fortunately, self-calibrating [7] techniques have been introduced that correct for errors in the binary ratios of the capacitors. Figure 62.50 is the block diagram for a successive approximation-based self-calibrating ADC. The circuit consists of an N-bit binary weighted capacitor array main DAC, an M-bit resistor string sub-DAC, and a calibration DAC. Digital logic is used to control the circuit during calibration and also to store the error voltages.

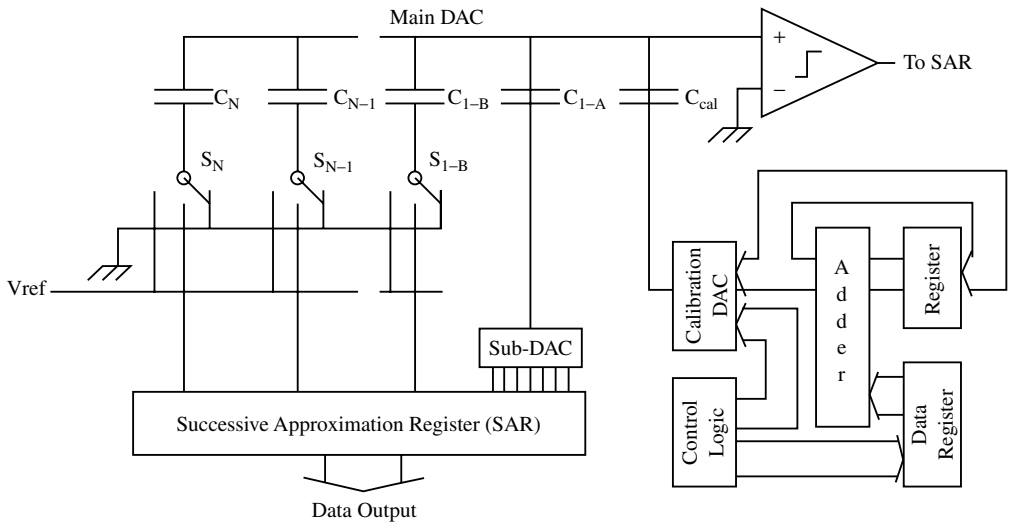

FIGURE 62.50 Self-calibration charge redistribution converter.

© 2003 by CRC Press LLC

Let each weighted capacitor C_i have a normalized error in its ratio $(1 + \varepsilon_i)$ from its ideal value:

$$C_i = 2^{i-1}C\left(1+\varepsilon_i\right) \tag{62.24}$$

Each capacitor contributes an error voltage at the top plate which is equal to

$$V_{e_i} = \frac{V_{\text{ref}}}{2^N} 2^{i-1}\varepsilon_i \quad i = 1B, 2, ..., N \tag{62.25}$$

Therefore, the total linearity error is equal to

$$V_{\text{error}} = \sum_{i=1B}^{N} V_{\varepsilon_i} b_i \tag{62.26}$$

where b_i is the logic value of the ith bit.

The calibration cycle begins by measuring the error contribution from the largest capacitor and progressing to the smallest. The error from the MSB capacitor is evaluated by closing S_0 and setting switches $\{S_1, S_2, \ldots, S_5\}$ such that all the capacitors except C_{MSB} are charged to V_{ref}. Next, the switch S_0 is opened and switches $\{S_1, S_2, \ldots, S_5\}$ are switched to connect the bottom plates to ground. Under ideal conditions, i.e., $C_{\text{MSB}} = 2^{N-1}C$, the voltage at the top plate is equal to zero. It should be noted that the total capacitance is equal to $2C$. However, because $C_{\text{MSB}} = 2^{N-1}C(1 + \varepsilon_{\text{MSB}})$, the top plate voltage $V_x = (V_{\text{ref}}/2)\varepsilon_{\text{MSB}}$, such that $V_{x_{\text{MSB}}} = 2V_{\varepsilon_{\text{MSB}}}$. Therefore, the error voltage at the top plate is a direct measure of the corresponding error in the capacitor ratio. A successive approximation search using the sub-DAC is used to measure these voltages. The relationship between the measured residual voltage and the error voltage is equal to

$$V_{\varepsilon_i} = \frac{1}{2}\left\{V_{x_i} - \sum_{j=i+1}^{N} V_{\varepsilon_i}\right\} \tag{62.27}$$

which corresponds to the equivalent error terms on the digital side. These digital correction terms are stored and subsequently added or subtracted during the normal operation cycle. Self-calibration improves the resolution of successive approximation converters to approximately 15 or 16 bits.

Algorithmic Converters. As stated earlier, the algorithmic ADC is formed by modifying a pipelined converter. Here, the pipeline has been closed to form a loop. All N-bits are evaluated by a single stage, therefore implying that a N-bit conversion requires N clock cycles. A block diagram for the algorithmic converter is shown in Fig. 62.51 [6] and consists of a S/H, a 2× amplifier, a comparator, and a reference subtraction circuit. The circuit operates as follows. The input is first sampled and held by setting S_1 to V_{in}. This signal is then multiplied by 2 (by the 2× amplifier). The result of this multiplication, V_0, is compared to V_{ref}. If $V_{o_N} > V_{\text{ref}}$ then the most significant bit, b_N, is set to 1 or it is set to 0. If b_N is equal to 1, then S_2 is connected to V_{ref} such that V_{b_N} is equal to

$$V_{b_N} = 2V_{0_N} - b_N V_{\text{ref}} \quad b_N = \{0, 1\} \tag{62.28}$$

This voltage is then sample-and-held and used to evaluate the MSB-1 bit. This procedure continues until all N-bits are resolved. The general expression for V_0 is equal to

$$V_{0_i} = \left[2V_{0_{i-1}} - b_i V_{\text{ref}}\right] z^{-1} \tag{62.29}$$

where b_i is the comparator output for the ith evaluation and z^{-1} implies a delay of one clock period.

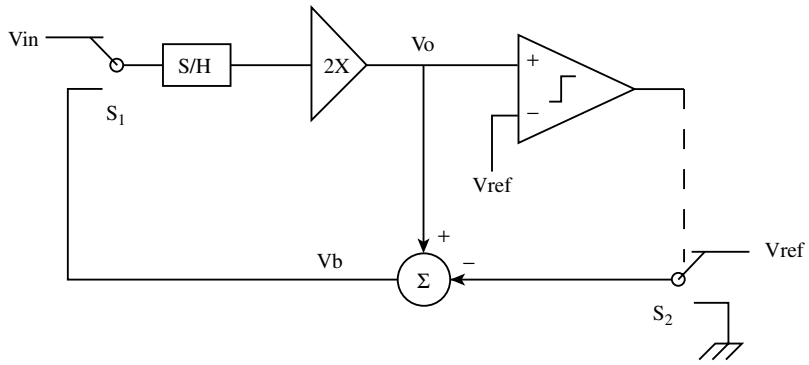

FIGURE 62.51 Algorithmic ADC block diagram.

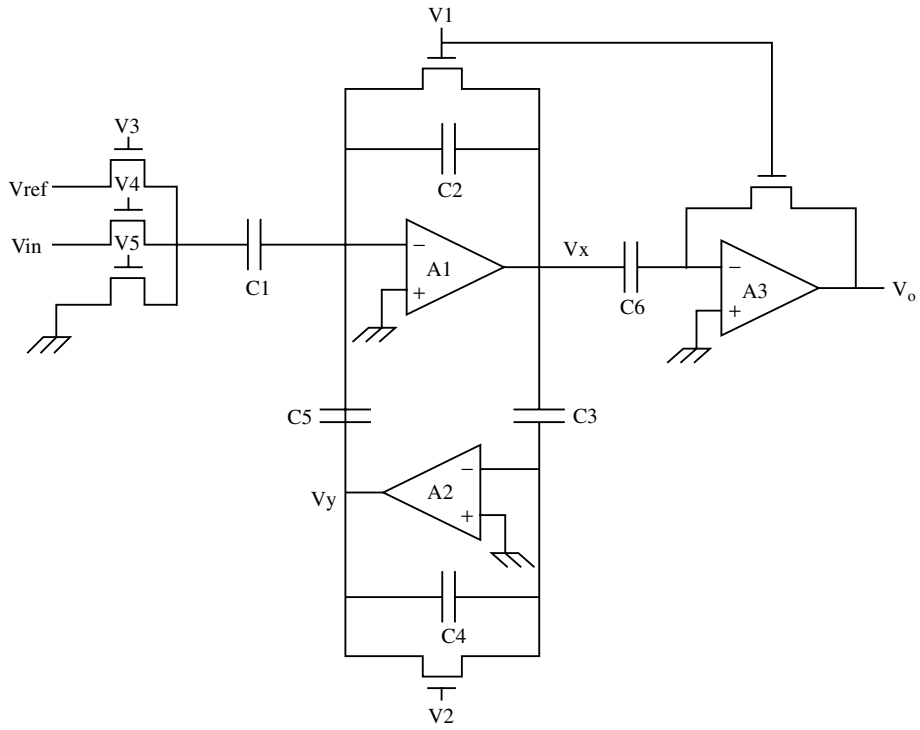

FIGURE 62.52 Example circuit implementation of the algorithmic converter.

A circuit implementation for this ADC topology is shown in Fig. 62.52 [10]. This circuit uses three amplifiers, five ratio-matched capacitors (C_1 to C_5), an arbitrary valued capacitor, C_6, and a comparator. Two implifiers and the capacitors (C_1 to C_5) form the recirculating register and the gain of two amplifiers. The amplifier A_3 and capacitor C_6 form an offset compensated comparator. The switches controlled by V_3, V_4, and V_5 load the input or selectively subtract the reference voltage. The conversion is started by setting V_1, V_2, and V_3 high. This forces V_x and V_Y to 0 and loads V_{in} into C_1. Then, V_1 is set low and V_5 is set high. Therefore, the charge $V_{in} * C_1$ is transferred from C_1 to C_2. C_1 is made to be equal to C_2, therefore, $V_x = V_{in}$ (C_3 is also charged to V_x). Because V_1 has been set low the comparator output goes high if $V_{in} > 0$, or else it remains low. This determines the MSB. The MSB-1 is determined by setting V_2 low and setting V_1 high. This forces the charge from C_3 to transfer to C_4 ($V_4 = V_x$; C_5 is also charged to

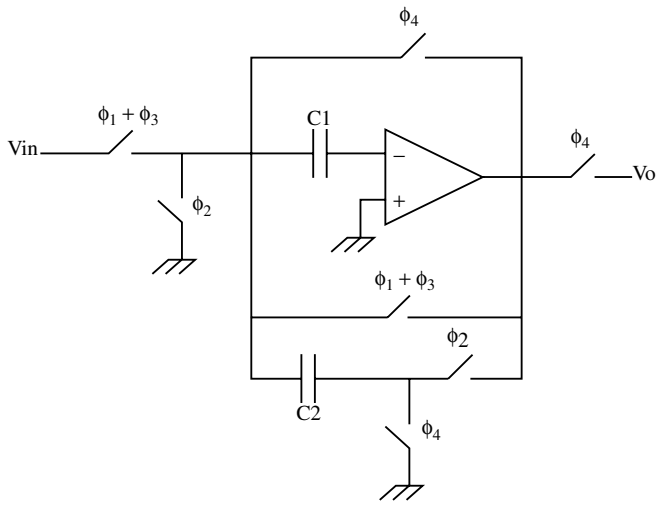

FIGURE 62.53 Ratio-independent multiply-by-two circuit.

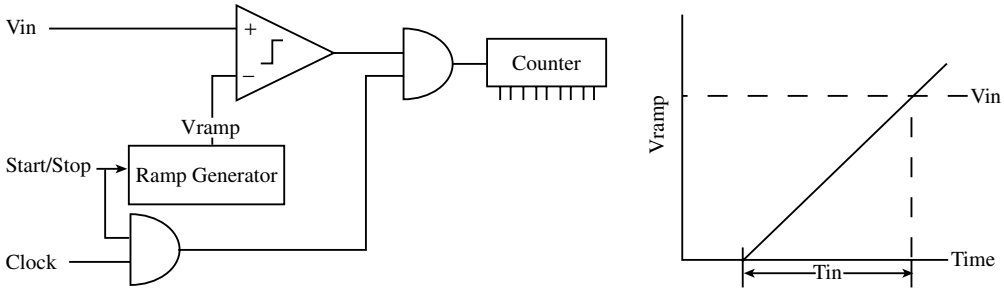

FIGURE 62.54 Single-slope integrating converter.

V_4). During the same period C_1 is connected to ground if MSB = 1, or it is connected to V_{ref}. Next, V_2 is set low and V_1 is set high, while C_1 is switched from ground to V_{ref} for V_{ref} to ground. This transfers a charge equivalent to $C_1 \pm V_{ref}$ from C_1 to C_2 and transfers the charge in C_5, $C_5 * V_y$, to C_2. The capacitor C_5 is made to be twice as large as C_2, therefore, the voltage at V_x is equal to $2 * V_{in} \pm V_{ref}$. This process is repeated and the comparator determines bit MSB-1. This circuit has been shown to provide up to 10 bits of resolution at a maximum conversion rate of 200 kHz.

The maximum resolution of the algorithmic converter is limited by the ratio matching of the capacitors, clock feedthrough, capacitor voltage coefficient, parasitic capacitance, and offset voltages. The previous topology solves the problem of parasitic capacitances and amplifier offset voltage, however, its maximum resolution is limited by the ratio matching of the capacitors that are used to realize the gain of two amplifiers. This problem is partially resolved by using a ratio-independent multiply-by-two algorithm [6] to increase the maximum resolution to the 12-bit level. The ratio-independent multiply-by-two algorithm is easily explained by the circuit shown in Fig. 62.53. During ϕ_1, capacitor C_1 is charged to V_{in}. This charge is then transferred onto C_2 during ϕ_2. The charge on C_2 is equal to $V_{in} * C_1$. During ϕ_3 C_2 is disconnected from the feedback path and V_{in} is once again sampled onto C_1. During ϕ_4 the charge in C_2 is added to C_1. The total charge in C_1 is now equal to $C_1 V_{in} + C_1 V_{in} = 2C_1 V_{in}$ and is completely independent of the value of C_2. Therefore, the voltage at the output at ϕ_4 is equal to $2V_{in}$. The only constraint is that the input voltage be held steady, i.e., S/H during ϕ_1 and ϕ_3.

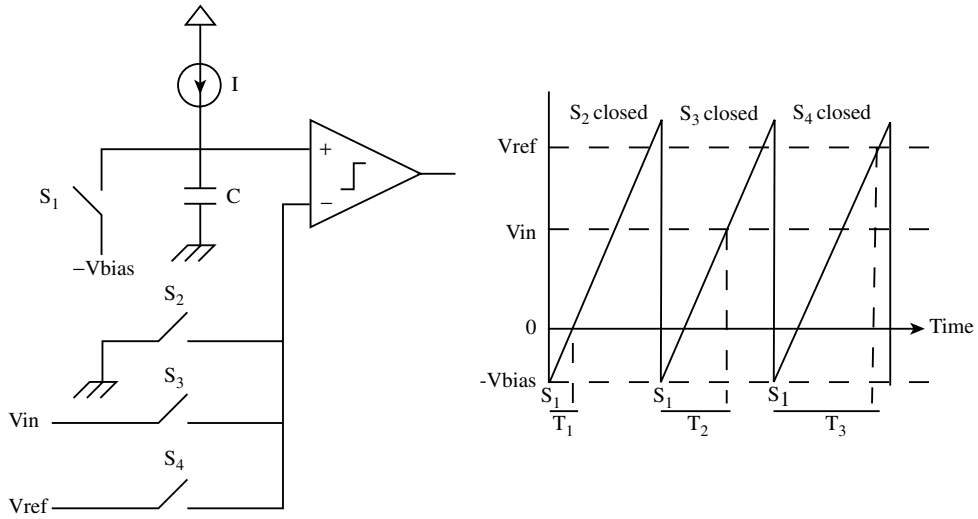

FIGURE 62.55 Single-slope integrating converter with calibration cycle.

2^N-Clock Converters

The basic principle of the integrating converter can be explained with the help of Fig. 62.54. A comparator compares the input signal with the output of a ramp voltage generator. The ramp voltage generator is zeroed after each measurement. The output of this comparator is used to gate the clock to an interval counter. The counter output corresponding to the ramp time T_{in} provides an accurate measure of the input voltage. The input voltage V_{in} is equal to $T_{in} * U$, where U is the ramp rate. Because the absolute values of components are not well controlled and also because of the large offset voltages associated with MOS amplifiers and comparators, a calibration or a reference cycle is usually added to calculate the ramp rate and the offset voltage. A simple circuit for a single-slope integrating converter that includes the calibration cycle is shown in Fig. 62.55 [4].

The ramp voltage is generated using a constant current source to charge a capacitor. The ramp voltage, V_{ramp}, is equal to $\int_0^t (I/c)dt$, which is equal to $(I\Delta t)/c$ for a constant current I. The ramp voltage is compared against the analog ground voltages, V_{in} and V_{ref}, respectively. The addition of the third calibration cycle eliminates any offset errors. The final resolution is dependent only on the linearity of the ramp generator, i.e., the linearity of the current source. In the single-slope approach just described, the calibration is done in digital. However, the complete calibration can be performed in analog as well, as in the dual-slope approach. Further improvements include a charge balancing technique [4] that uses an oscillating integration process to keep the voltage across the capacitor closer to zero, thereby reducing the linearity constraints on the ramp generator. The primary advantage of the integrating converter is the small number of precision analog components that are required to generate extremely high resolution. However, the primary disadvantage is the conversion time required. It takes 2^N clock cycles to generate a N-bit conversion.

Oversampled Converters

Oversampling converters have the advantage over Nyquist rate converters in that they do not require very tight tolerances from the analog components and also because they simplify the design of the anti-alias filter. Examples of oversampling converters include the noise-shaping architecture and the interpolative architecture. Our discussion centers around noise-shaping converters.

If the analog input signal V_{in} has a frequency spectrum from 0 to f_0 then $2f_0$ is defined as the Nyquist rate. Oversampling converters sample the input at a rate larger than the Nyquist frequency. If f_s is the

© 2003 by CRC Press LLC

sampling rate, then $(f_s)/(2f_0)$ = OSR is called the oversampling ratio. Oversampling converters use "signal averaging" along with a low-resolution converter to provide extremely high resolution. This technique can best be understood by considering the following example in Fig. 62.56.

Let the input be exactly in the middle of V_n and V_{n+1} and let it be sampled a number of times. If, in addition to the input signal, we add some random noise, then for a large number of samples the output would fall on V_n 50% of the time and on V_{n+1} the other 50% of the time. If the signal was a littler closer to V_{n+1}, then the percentage of times the output falls on V_{n+1} would increase. Using this averaging technique we can get a better estimate of the input signal. However, in simple oversampling the resolution only increases by $\sqrt{n}$, where n is the number of samples of V_{in} that are averaged. Therefore, to increase the resolution of the converter by one additional bit we are required to increase the number of samples by 4 x.

Noise-shaping converters use feedback to generate the necessary noise and additionally perform frequency shaping of the noise spectrum to reduce the amount of oversampling necessary. This can be illustrated with the help of Fig. 62.57. The output from H_1 is quantized by an N-bit ADC. This digitial value is then converted to an analog value by the N-bit DAC. This value is subtracted from the input and the result is sent to H_1. Here, we assume an N-bit converter for simplicity, however, for the special case in which $N = 1$ the noise-shaping converter is called a sigma-delta converter. The quantization process approximates an analog value by a finite-resolution digital value. This step introduces a quantization error, Q_n. Further, if we assume that the quantization error is not correlated to the input, the system can now be modeled as a linear system, as shown in Fig. 62.58. Here, we note that the error

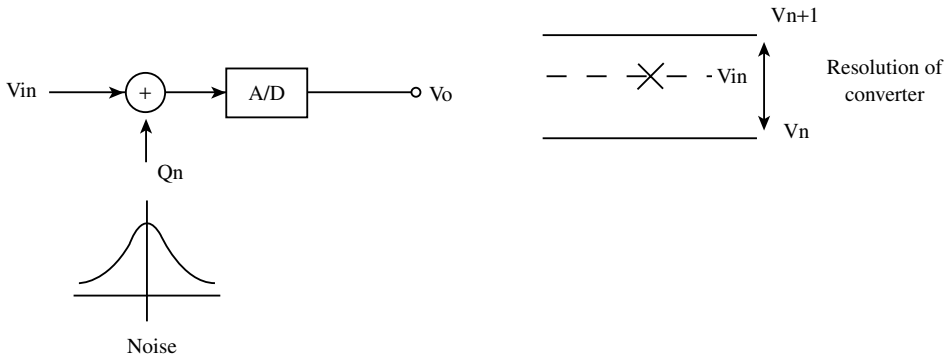

FIGURE 62.56 Higher resolution provided by oversampling.

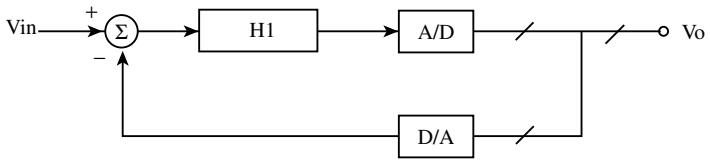

FIGURE 62.57 Noise-shaping oversampling converters.

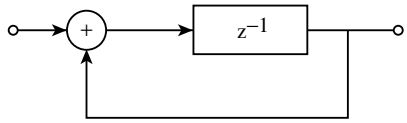

FIGURE 62.59 Forward path delay integrator.

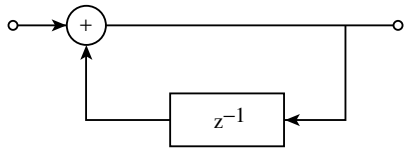

FIGURE 62.60 Feedback path delay integrator.

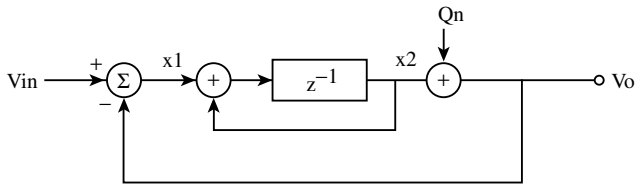

FIGURE 62.61 First-order noise-shaping converter.

introduced by the analog-to-digital process is modeled by Q_n. The output voltage for this system can now be written as

$$V_0 = \frac{Q_n}{\left[1+H_1\right]} + \frac{V_{in}H_1}{\left[1+H_1\right]} \tag{62.30}$$

Data converters are sampled data systems, and as such are easier to analyse in the Z-domain. For most sigma-delta converters H_1 has the characteristics of a low-pass filter and is usually implemented as a switched-capacitor integrator. MOS switched-capacitor integrators can be implemented with either a delay in the forward signal path or a delay in the feedback path, and can be modeled in the Z-domain by Figs. 62.59 and 62.60, respectively.

We use the first integrator architecture because it simplifies some of the algebra. For a first-order sigma-delta converter H_1 is realized as a simple switched-capacitor integrator, i.e., $H_1 = (z^{-1})/(1 - z^{-1})$. Therefore, Fig. 62.58 can now be drawn as Fig. 62.61. Replacing H_1 by $(z^{-1})/(1 - z^{-1})$ in (62.30) we can write the transfer function for the first-order sigma-delta converter as

$$V_0 = V_{\text{in}}z^{-1} + Q_n\left(1-z^{-1}\right) \tag{62.31}$$

As can be seen from (62.31) the output is a delayed version of the input plus the quantization noise multiplied by the factor $(1 - z^{-1})$. This function has a high-pass characteristic, as shown in Fig. 62.62. We note here that the quantization noise is substantially reduced at lower frequencies and increases slightly at higher frequencies. In this figure, f_0 is the input signal bandwidth and $f_s/2 = \pi$ corresponds to the Nyquist rate of the oversampling converter. For simplicity the quantization noise is usually assumed to be white[1] with a spectral density equal to $e_{\text{rms}}\sqrt{2/f_s}$. Therefore, the magnitude of the output noise spectrum can be written as

[1]Quantization noise is clearly not uncorrelated or white for the first-order sigma-delta modulator, but becomes increasingly so for the higher-order systems.

© 2003 by CRC Press LLC

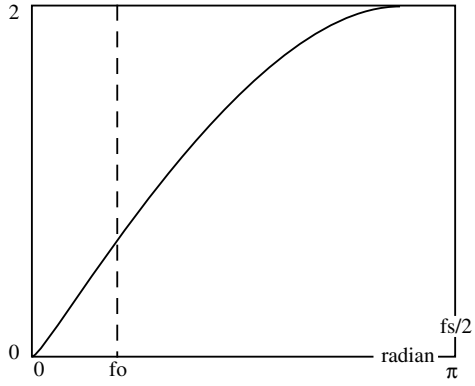

FIGURE 62.62 Magnitude response of the function $(1 - z^{-1})$.

$$N(f) = e_{rms}\sqrt{\frac{2}{f_s}}\left|1 - z^{-1}\right| = 2e_{rms}\sqrt{\frac{2}{f_s}}\sin\left(\frac{\pi f}{f_s}\right) \tag{62.32}$$

Further, if $f_0 \ll f_s$ we can approximate the root mean square noise in the signal band, $(0 < f < f_0)$, by

$$N_{f_0} \approx e_{\text{rms}}\frac{\pi}{3}\left(\frac{2f_0}{f_s}\right)^{3/2} \tag{62.33}$$

As the oversampling ratio increases the quantization noise in the signal band decreases; i.e., for a doubling of the oversampling ratio the quantization noise drops by $20\log(2)^{3/2} \approx 9$ dB. Therefore, for each doubling of the oversampling ratio we effectively increase the resolution of the oversampling converter by an additional 1.5 bits.

The previous analysis was based on the assumption that the quantization noise was not correlated to the input and uniformly distributed across the Nyquist band. We now reexamine these assumptions. The assumption that the quantization noise is not correlated with the input only holds for extremely busy input signals. This is particularly not true for the first-order modulator assumed in the analysis above, such that for extremely low frequency or DC inputs the first-order modulator generates pattern noise (also called tones), as shown in Fig. 62.63. The peaks of the pattern noise occur at input voltages that are integer divisors of the quantization step. It is possible to provide a conceptual explanation for this occurrence. For example, for an input that is an integer divisor of the quantization level the digital output of the quantizer repeats itself at an extremely low frequency. This low-frequency repetition causes noise power to be introduced into the signal band. The quantization noise for second- and higher-order models is significantly more uncorrelated and is usually assumed to be white.

The quantization error has a value that is limited to $\pm(1/2)$ LSB of the quantizer (the ADC in Fig. 62.47). If we assume that the quantization noise is white and uniformly distributed over the quantization level, then the average noise quantization is equal to

$$\int_{-\frac{1}{2}\text{LSB}}^{+\frac{1}{2}\text{LSB}} x^2 dx = \frac{\text{LSB}^2}{12} = P_n \tag{62.34}$$

Because the quantization noise is sampled at the clock frequency f_s, the entire noise power is aliased back into the overall converter Nyquist ban $[0 - (f_s/2)]$. Therefore, the spectral density of the quantization noise is equal to

© 2003 by CRC Press LLC

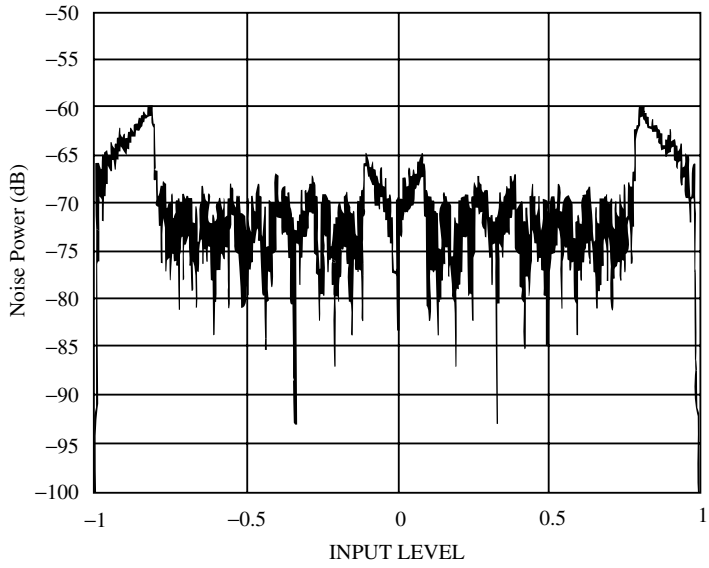

FIGURE 62.63 Pattern noise for a first-order sigma-delta modulator for DC inputs.

$$P_n = \frac{\text{LSB}^2}{12} = \int_0^{f_s/2} n_e(f)^2 \delta f = n_e(f)^2 \frac{f_s}{2} \tag{62.35a}$$

$$n_e(f) = P_n \sqrt{\frac{2}{f_s}} \tag{62.35b}$$

The SNR for an ADC is defined as 10 log(P_s/P_n), where P_s is the signal power. The signal power is highly waveform dependent. For example, the P_s for a full-scale sine wave input, (A/2) sin (ωT), which is applied to an N-bit quantizer, can be written in terms of the quantization level as

$$\frac{A^2}{8} = \frac{\left[\left(2^N - 1\right)\text{LSB}\right]^2}{8} \tag{62.36}$$

Therefore,

$$\text{SNR} = 10\log\left(\frac{P_s}{P_n}\right) = 10\log\left[\frac{12\left(2^N - 1\right)^2}{8}\right] \tag{62.37}$$

Higher-Order Modulators

In Fig. 62.61, we replaced H_1 for Fig. 62.58 with a first-order integrator. Clearly, H_1 can be replaced by other higher-order functions that have a low-pass characteristic.[2] For example, in Fig. 62.64 we show a second-order modulator. This modulator uses one forward delay integrator and one feedback delay integrator to avoid stability problems. The output voltage for this figure can be written as

[2]Actually, it is not necessary that they have low-pass characteristics. Bandpass characteristics may be preferred if the input signal is to be bandlimited.

© 2003 by CRC Press LLC

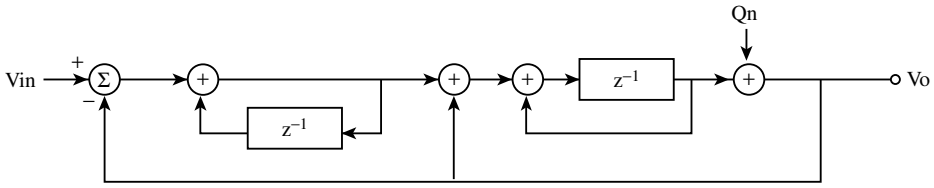

FIGURE 62.64 Second-order modulator block diagram.

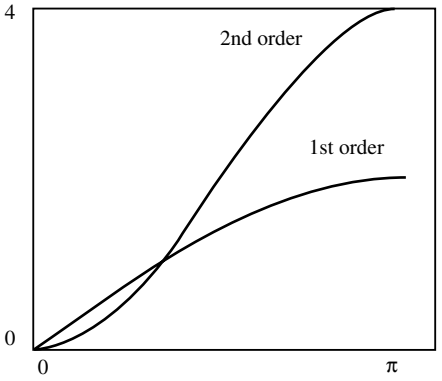

FIGURE 62.65 Noise shaping due to the second-order modulator in Fig. 62.62.

$$V_0 = V_{in}z^{-1} + Q_n\left(1 - z^{-1}\right)^2 \tag{62.38}$$

Note that the quantization noise is shaped by the second-order difference equation. This serves to further reduce the quantization noise at low frequencies. However, a further increase in the noise occurs at higher frequencies. A comparison of the noise shaping offered by the first and second-order modulators is shown in Fig. 62.65. Once again, assuming that $f_o \ll f_s$ we can write an expression for the root mean square noise in the signal band for the second-order modulator as

$$N_{f_0} \approx e_{rms}\frac{\pi^2}{\sqrt{5}}\left(\frac{2f_0}{f_s}\right)^{5/2} \tag{62.39}$$

The noise power in the signal bandwidth falls by 15 dB for every doubling of the oversampling ratio. One of the added advantages of the second-order modulator over the first-order modulator is that quantization noise has been shown to be less correlated to the input, therefore, less pattern noise.

From our analysis so far, it would seem that increasing the order of the filter would reduce the necessary oversampling ratio for a given resolution. This is true, however, the simple Candy-style modulator (shown in Figs. 62.61 and 62.64) with orders >2 results in stability problems. This is because for higher-order modulators the later integrator stages are easily overloaded and saturated. This in turn increases the noise in the signal band. However, higher-order modulators can be realized by using a cascade of lower order modulators in the MASH architecture [8]. In the cascaded MASH technique, both the digital output and the output of the integrator of each lower-order modulator is passed on to the next module. A second-order MASH architecture using two cascaded first-order sections is shown in Fig. 62.66. It can be shown that the output is equal to

$$Y = z^{-2}X - Q_{n_2}\left(1 - z^{-1}\right)^2 \tag{62.40}$$

© 2003 by CRC Press LLC

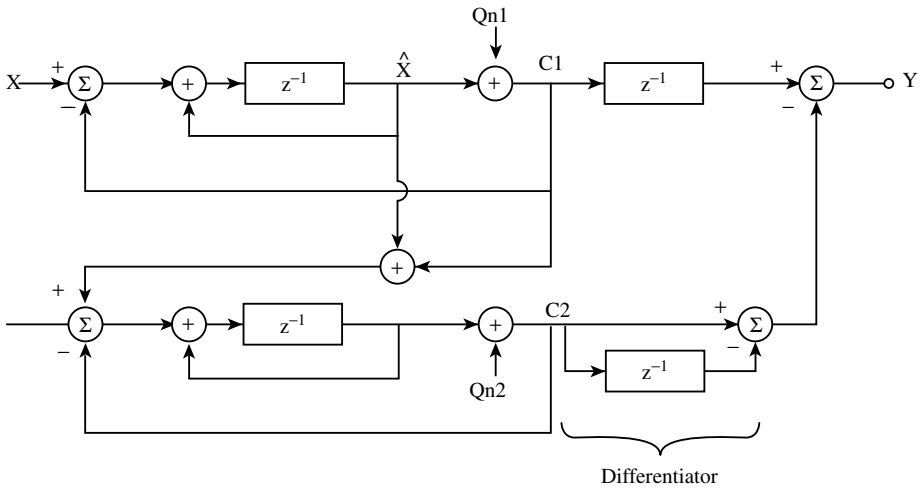

FIGURE 62.66 MASH architecture for a second-order modulator.

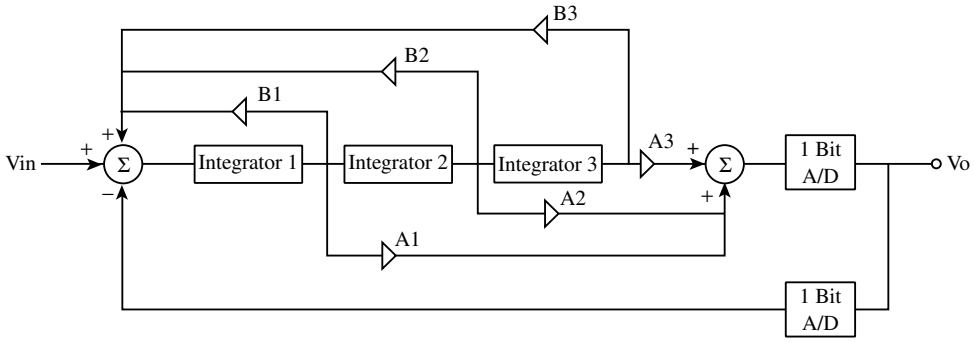

FIGURE 62.67 Finite pole-zero loop filter higher-order modulator.

Once again, we note that the quantization noise is multiplied by the second-order difference equation. The sign in front of the noise term is not important. However, for complete cancellation of the quantization noise from the first integrator the gain of the first loop needs to be identical to the gain of the second loop. Therefore, the amplifier gain and capacitor matching become extremely important. It has been shown that a 1% matching and an op amp gain of 80 dB are sufficient for 16 bits of accuracy [8].

An alternate methodology to stabilize higher-order oversampled coders is the use of finite poles and zeroes for the loop filter [16], H_1 in Fig. 62.57. Up until now, all the loop filters have been integrators with poles at DC and zeroes at extremely high frequencies. The loop filter can be realized using additional feedback and feedforward paths as shown in Fig. 62.67. A third-order modulator is shown in this figure. Having finite poles and zeroes serves two purposes: (1) the nonzero poles function to reduce the in-band noise by flattering the quantization noise transfer function at low frequencies, (2) the finite zeroes function to reduce the magnitude of the quantization noise at high frequencies. By reducing the magnitude of the quantization noise at high frequencies, even higher-order modulators can be made stable. Additionally, these modulators have been shown to be devoid of pattern noise artifacts.

Multi-Bit Quantizers

The primary reason for using single-bit or two-level quantizers is their inherent perfect linearity. Because only two levels can exist, a straight line can always be drawn between these two levels. On the other hand

© 2003 by CRC Press LLC

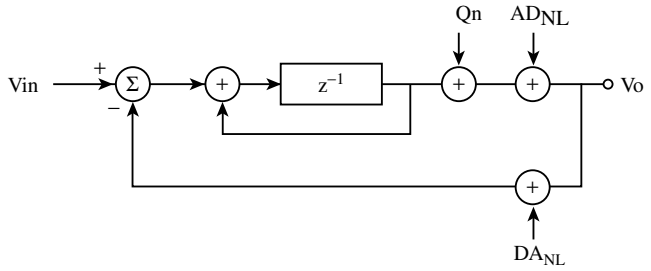

FIGURE 62.68 Model for nonlinearity associated with multi-bit quantizers.

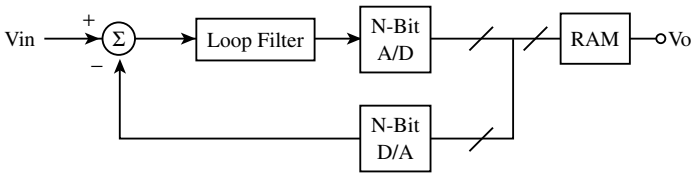

FIGURE 62.69 Digital error correction for multi-bit quantizers.

number of advantages are found in using multi-bit quantizers in oversampling converters. The quantization noise generated in the multi-bit-based based noise-shaping converter is significantly more "white" and uncorrelated with the input signal, thereby reducing the probability of pattern noise. Additionally, the quantization noise power goes down exponentially as the number of bits in the quantizer increases. However, the primary problem associated with multilevel quantizers is the nonlinearity errors present with the DAC in the modulator loop. This problem can be illustrated with the help of Fig. 62.68.

In Fig. 62.68, the error resulting from the nonlinearity in the multi-bit ADC is included as AD_{NL} and the error resulting from the nonlinearity in the multi-bit DAC is included as DA_{NL}. The output voltage is given by (62.43). Here, note that the analog-to-digital nonlinearity is suppressed by the loop filter, while the digital-to-analog nonlinearity is only subjected to a unit delay. Therefore, any digital-to-analog nonlinearity directly appears in the output. A number of methods have been applied to reduce the effects of nonlinearity associated with multi-bit quantizers. The two most promising methods that have emerged are digital error correction [18] and dynamic element matching [17,19].

$$V_0 = V_{\text{in}} z^{-1} - DA_{NL} z^{-1} + Q_n\left(1 - z^{-1}\right) + AD_{NL}\left(1 - z^{-1}\right) \tag{62.41}$$

A block diagram for digital error correction for multi-bit quantizer-based noise-shaping converters is shown in Fig. 62.69. The random access memory (RAM) and the multi-bit DAC have the same input signal. Because of the high gain in the loop at low frequencies the output of the DAC is almost identical to the input voltage, V_{in}. Now, if the digital RAM is programmed to generate the exact digital equivalent of the digital-to-analog output for any digital input, then the RAM output and the digital-to-analog output will be identical to each other. Because the output of the DAC is almost identical to the input voltage, the output voltage will also be the exact digital equivalent of the analog input. The RAM can be programmed by reconfiguring the modulator stages and feeding the system with a multi-bit digital ramp [18].

In the dynamic element matching approach, the various analog elements that are used to generate the different analog voltage levels are dynamically swapped around. The various elements can be swapped randomly [17] or in a periodic fashion [19]. The use of random permutations translates the nonlinearity of the DAC into random noise that is distributed throughtout the oversampling converter Nyquist range. This method virtually eliminates errors due to nonlinearity, but unfortunately it also increases the noise level in the signal band. In a variation of this basic technique, the various analog elements are swapped

© 2003 by CRC Press LLC

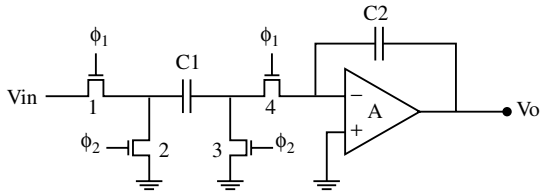

FIGURE 62.70 Example circuit implementation for a switched-capacitor integrator.

in a periodic fashion such that the nonlinearity in the DAC is translated into noise at higher frequencies. Individual level averaging further eliminates the possibility of pattern noise within the signal band [19].

Technology Constraints

One of the primary reasons for using sigma-delta converters is that they do not require good matching among the analog components. Therefore, for the two-level sigma-delta converter the nonidealities are introduced primarily by the integrator loop. To aid in the analysis of the various technology constraints we shall consider a particular implementation of an integrator (Fig. 62.70). The ideal transfer function for this circuit is given by $-1/(1 - z^{-1})$. To realize this ideal transfer function the circuit relies on the virtual ground generated at the negative input of the integrator to accomplish complete charge transfer during each clock period. However, limited amplifier gain does not generate a perfect virtual ground, thereby not accomplishing the complete transfer of charge during each clock period. The effect of the limited gain is similar to a leaky integrator and the transfer function for the leaky integrator can be written as

$$H(z) = \frac{-1}{1-\alpha z^{-1}} \tag{62.42a}$$

where

$$\alpha = \frac{1}{1-\frac{1}{A}\left(1+\frac{C_1}{C_2}\right)} \approx \frac{1}{1-\frac{2}{A}} \tag{62.42b}$$

The net effect of finite gain is to increase the modulation noise in the signal band as illustrated by Fig. 62.71 for the first-order modulator. In this figure, the *X*-axis is plotted from 0 to 1 rather than the

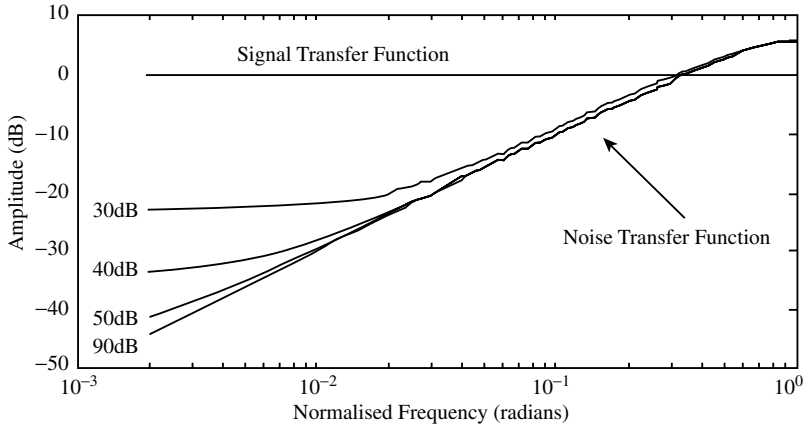

FIGURE 62.71 Effect of finite amplifier gain on noise transfer function using a linear model.

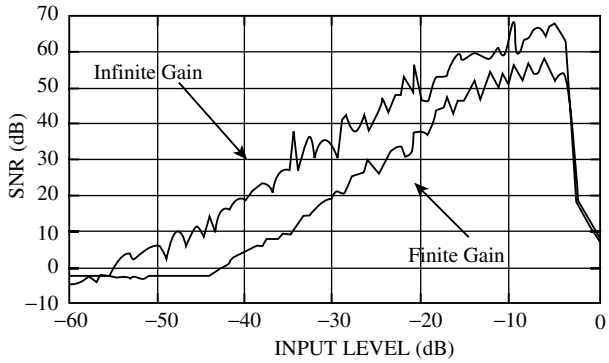

FIGURE 62.72 Effect of finite amplifier gain using difference equation simulations.

complete Nyquist band to emphasize the signal band. The noise transfer function has been plotted for a number of amplifier gains. When compared to Fig. 62.62, note the increase in the noise level in the signal band. The effect of finite gain is felt throughout the input signal magnitude range as shown in Fig. 62.72. The graph for Fig. 62.71 was generated using the linearized model for the modulator presented in (62.21) and the graph in Fig. 62.72 was generated using the difference equation method. The difference equation method does not make any assumptions about linearity nor does it assume that the input is uncorrelated with the quatizantion noise, however, it requires considerably more simulation time. Because of oversampling the bandwidth requirements for the op amps in the integrators are usually large. Unfortunately, it is extremely difficult to realize extremely high gain and extremely high bandwidth amplifiers in MOS. One solution that attempts to mitigate the finite gain effect is to estimate the amount of incomplete charge transfer and compensate for it [5].

Circuit noise provides additional limitations to the maximum resolution realizable by an oversampled converter. The primary noise sources are the thermal noise generated by the switches in the integrator, amplifier noise, charge injection, and clock feedthrough from the switches. Because of sampling, the thermal noise associated with the finite on resistance of the switches is aliased back into the Nyquist band of the oversampling converter. The total noise aliased into the baseband for large bandwidth amplifiers is equal to kT/C for each switch pair, where k is the Boltzmann constant, T is the temperature in degrees Kelvin, and C is the value of the sampling capacitor in the integrator. For the parasitic insensitive integrator in Fig. 62.70, the total noise from this source is equal to $2kT/C$. This noise is evenly spread across the Nyquist band, but only the fraction $2f_0/f_s$ of this noise appears in the signal band. The rest is filtered out by the digital LPF. Using this constraint, for a full-scale sine wave input the minimum sampling capacitance is given by

$$C_{\min} = 16 \cdot kT \cdot \mathrm{SNR}_{\mathrm{desired}} \tag{62.43}$$

The inband portion of the amplifier noise is also added to the output signal. In general, only the noise of the first amplifier is important for higher-order converters. For MOS amplifiers the flicker noise component is significantly more important as it tends to dominate in the signal band. When necessary, correlated double sampling techniques [5] can be used to reduce the effect of this noise source. Correlated double sampling, or autozeroing as it is sometimes called, has the added benefit that it eliminates any amplifier offset voltages. It is usually important to remove this offset voltage only for data acquisition applications.

Because tight component matching is not required of the analog components, sigma-delta converters are particularly well suited for mixed-signal applications. However, having digital circuits on the sample chip increases the switching noise that is injected into the substrate and into the power supply lines. Any portion of this noise that lies in the signal band is added to the input signal. Therefore, fully differential integrator topologies should be used for high-resolution converters. Substrate and supply noise are

© 2003 by CRC Press LLC

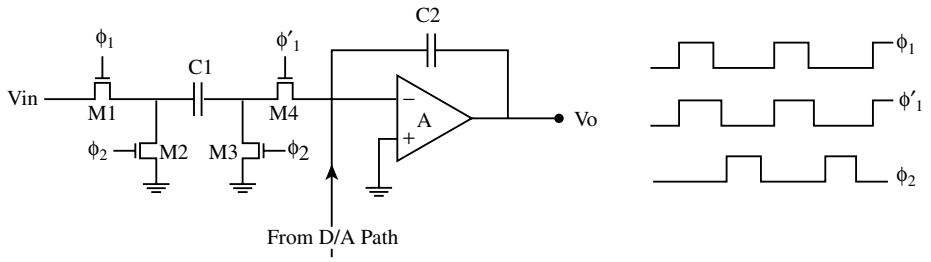

FIGURE 62.73 Proper clock phase to eliminate signal-dependent clock feedthrough.

common-mode signals and are reduced by the common-mode rejection ratio of the amplifier when using fully differential circuits.

In addition to the amplifier and the switching noise the charge injection from switches also sets a limit on the maximum resolution attainable component. Charge injection from switches has a signal-dependent component and a signal-independent component. The effect of the signal-independent component is to introduce an additional offset error that can easily be calibrated out, if necessary. However, the signal-dependent component, particularly from the input sampling transistor (transistor M_1 in Fig. 62.73), cannot be distinguished from input signal. This signal-dependent component is highly nonlinear and can be reduced substantially by using proper clock phasing. Signal-dependent charge injection from transistors M_1 and M_2 in Fig. 62.73 can be canceled to first order by delaying the turn off of ϕ'_1 slightly [6].

A number of topologies for the digital low-pass filters have been tried. However, it has been shown that simple finite impulse response (sinc) filters are probably the optimal choice. It has been shown that the number of stages of sinc filtering necessary is equal to the modulator order plus 1 [2]. Noise-shaping converters have the ability to provide extremely high resolution. However, care must be used when using simple linear assumptions. Clearly, for the first-order modulator the white noise assumption breaks down. Additionally, it has been shown that the simple linear model overestimates the realizable SNR. For example, the linearized model overestimates the attainable SNR by as much as 14 dB for the second-order modulator.

63.1 Introduction

As the complexity of VLSI systems continues to increase, the micro-electronic industry must possess an ability to reconfigure design and manufacturing resources and integrate design activities so that it can quickly adapt to the market changes and new technology. Gaining this ability imposes a twofold challenge: (1) to coordinate design activities that are geographically separated and (2) to represent an immense amount of knowledge from various disciplines in a unified format. The Internet can provide the catalyst by abridging many design activities with the resources around the world not only to exchange information but also to communicate ideas and methodologies.

In this chapter, we present a collaborative engineering framework that coordinates distributed design activities through the Internet. Engineers can represent, exchange, and access the design knowledge and carry out design activities. The crux of the framework is the formal representation of process flow using the process grammar, which provides the theoretical foundation for representation, abstraction, manipulation, and execution of design processes. The abstraction of process representation provides mechanisms to represent hierarchical decomposition and alternative methods, which enable designers to manipulate the process flow diagram and select the best method. In the framework, the process information is layered into separate specification and execution levels so that designers can capture processes and

© 2003 by CRC Press LLC

execute them dynamically. As the framework is being executed, a designer would be informed of the current status such as updating and tracing design changes and be able to handle exceptions. The framework can improve design productivity by accessing, reusing, and revising the previous process for a similar design. The cockpit of our framework interfaces with engineers to perform design tasks and to negotiate design tradeoff. The framework has the capability to launch whiteboards that enable the engineers in a distributed environment to view the common process flows and data and to concurrently execute dynamic activities such as process refinement, selection of alternative process, and design reviews. The proposed framework has a provision for various browsers where the tasks and data used in one activity can be organized and retrieved later for other activities.

One of the predominant challenges for microelectronic design is to handle the increased complexity of VLSI systems. At the turn of the century, it is expected that there will be 100 million transistors in a single chip with 0.1 micron features, which will require an even shorter design time (Spiller, 1997). This increase of chip complexity has given impetus to trends such as system on a chip, embedded system, and hardware/software co-design. To cope with this challenge, industry uses custom-off-the-shelf (COTS) components, relies on design reuse, and practices outsourcing design. In addition, design is highly modularized and carried out by many specialized teams in a geographically distributed environment. Multi-facets of design and manufacturing, such as manufacturability and low power, should be considered at the early stage of design. It is a major challenge to coordinate these design activities (Fairbairn, 1994). The difficulties are caused by due to the interdependencies among the activities, the delay in obtaining distant information, the inability to respond quickly to errors and changes, and general lack of communications. At the same time, the industry must contend with decreased expenditures on manufacturing facilities while maintaining rapid responses to market and technology changes.

To meet this challenge, the U.S. government has launched several programs. The Rapid Prototyping of Application Specific Signal Processor (RASSP) Program was initiated by the Department of Defense to bring about the timely design and manufacturing of signal processors. One of the main goals of the RASSP program was to provide an effective design environment to achieve a four-time improvement in the development cycle of digital systems (Chung, 1996). DARPA also initiated a program to develop and demonstrate key software elements for Integrated Product and Process Development (IPPD) and agile manufacturing applications. One of the foci of the earlier program was the development of infrastructure for distributed design and manufacturing. Recently, the program is continued to Rapid Design Exploration & Optimization (RaDEO) to support research, development, and demonstration of enabling technologies, tools, and infrastructure for the next generation of design environments for complex electro-mechanical systems. The design environment of RaDEO is planned to provide cognitive support to engineers by vastly improving their ability to explore, generate, track, store, and analyze design alternatives (Lyons, 1997).

The new information technologies, such as the Internet and mobile computing, are changing the way we communicate and conduct business. More and more design centers use PCs, and link them on the Internet/intranet. The web-based communication allows people to collaborate across space and time, between humans, humans and computers, and computers in a shared virtual world (Berners-Lee, 1994). This emerging technology holds the key to enhance design and manufacturing activities. The Internet can be used as the medium of a virtual environment where concepts and methodologies can be discussed, accessed, and improved by the participating engineers. Through the medium, resources and activities can be reorganized, reconfigured, and integrated by the participating organizations. This new paradigm certainly impacts the traditional means for designing and manufacturing a complex product. Using Java, programs can be implemented in a platform-independent way so that they can be executed in any machine with a Web browser. Common Object Request Broker Architecture (CORBA) (Yang and Duddy, 1996) provides distributed services for tools to communicate through the Internet (Vogel). Designers may be able to execute remote tools through the Internet and see the visualization of design data (Erkes, 1996; Chan, 1998; Chung and Kwong, 1998).

Even though the potential impact of this technology will be great on computer aided design, Electronic Design Automation (EDA) industry has been slow in adapting this new technology (Spiller and Newton,

© 2003 by CRC Press LLC

1997). Until recently, EDA frameworks used to be a collection of point tools. These complete suites of tools are integrated tightly by the framework using their proprietary technology. These frameworks have been suitable enough to carry out a routine task where the process of design is fixed. However, new tools appear constantly. To mix and match various tools outside of a particular framework is very difficult. Moreover, tools, expertise, and materials for design and manufacturing of a single system are dispersed geographically. Now, we have reached the stage where a single tool or framework is not sufficient enough to handle the increasing complexity of a chip and emerging new technology. A new framework is necessary which is open and scalable. It must support collaborative design activities so that designers can add new tools to the framework, and interface them with other CAD systems. There are two key functions of the framework: (1) managing the process and (2) maintaining the relationship among many design representations. For design data management, refer to (Katz, 1987). In this chapter, we focus on the process management aspect.

To cope with the complex process of VLSI system design, we need a higher level of viewing of a complete process, i.e., the abstraction of process by hiding all details that need not to be considered for the purpose at hand. As pointed out in National Institute of Standards and Technology reports (Schlenoff et al., 1996; Knutilla et al., 1998), a "unified process specification language" should have the following major requirements: abstraction, alternative task, complex groups of tasks, and complex sequences.

In this chapter we first review the functional requirements of the process management in VLSI system design. We then present the Internet-based Micro-Electronic Design Automation (IMEDA) System. IMEDA is a Web-based collaborative engineering framework where engineers can represent, exchange, and access design knowledge and perform the design activities through the Internet. The crux of the framework is a formal representation of process flow using process grammar. Similar to the language grammar, production rules of the process grammar map tasks into admissible process flows (Baldwin, 1995a). The production rules allow a complex activity to be represented more concisely with a small number of high-level tasks. The process grammar provides the theoretical foundation for representation, abstraction, manipulation, and execution of design and manufacturing processes. It facilitates the communication at an appropriate level of complexity. The abstraction mechanism provides a natural way of browsing the process repository and facilitates process reuse and improvement. The strong theoretical foundation of our approach allows users to analyze and predict the behavior of a particular process. The cockpit of our framework interfaces with engineers to perform design tasks and to negotiate design trade-off. The framework guides the designer in selecting tools and design methodologies, and it generates process configurations that provide optimal solutions with a given set of constraints. The just-in-time binding and the location transparency of tools maximize the utilization of company resources. The framework is equipped with whiteboards so that engineers in a distributed environment can view the common process flows and data and concurrently execute dynamic activities such as process refinement, selection of alternative processes, and design reviews. With the grammar, the framework gracefully handles exceptions and alternative productions. A layered approach is used to separate the specification of design process and execution parameters. One of the main advantages of this separation is freeing designers from the over-specification and graceful exception handling. The framework, implemented using Java, is open and extensible. New process, tools, and user-defined process knowledge and constraints can be added easily.

63.2 Functional Requirements of Framework

Design methodology is defined as a collection of principles and procedures employed in the design of engineering systems. Baldwin and Chung (Baldwin, 1995a) define design methodology management as selecting and executing methodologies so that the input specifications are transformed into desired output specifications. Kleinfeldt (1994), states that "design methodology management provides for the definition, presentation, execution, and control of design methodology in a flexible, configured way." Given a methodology, we can select a process or processes for that particular methodology.

Each design activity, whether big or small, can be treated as a task. A complex design task is hierarchically decomposed into simpler subtasks, and each subtask in turn may be further decomposed. Each

© 2003 by CRC Press LLC

task can be considered as a transformation from input specification to output specification. The term *workflow* is used to represent the details of a process including its *structure in terms of all the required tasks and their interdependencies*. Some process may be ill-structured, and capturing it as a workflow may not be easy. Exceptions, conditional executions, and human involvement during the process make it difficult to model the process as a workflow.

There can be many different tools or alternative processes to accomplish a task. Thus, a design process requires design decisions such as selecting tools and processes as well as selecting appropriate design parameters. At a very high level of design, the input specifications and constraints are very general and may even be ill-structured. As we continue to decompose and perform the tasks based on design decisions, the output specifications are refined and the constraints on each task become more restrictive. When the output of a task does not meet certain requirements or constraints, a new process, tools, or parameters must be selected. Therefore, the design process is typically iterative and based on previous design experience. Design process is also a collaborative process, involving many different engineering activities and requiring the coordination among engineers, their activities, and the design results.

Until recently, it was the designer's responsibility to determine which tools to use and in what order to use them. However, managing the design process itself has become difficult, since each tool has its own capabilities and limitations. Moreover, new tools are developed and new processes are introduced continually. The situation is further aggravated because of incompatible assumptions and data formats between tools. To manage the process, we need a framework to monitor the process, carry out design tasks, support cooperative teamwork, and maintain the relationship among many design representations (Chiueh and Katz, 1990; Katz et al., 1987). The framework must support concurrent engineering activities by integrating various CAD tools and process and component libraries into a seamless environment. Figure 63.1 shows the RASSP enterprise system architecture (Welsh et al., 1995). It integrates tools, tool frameworks, and data management functions into an enterprise environment. The key functionality of the RASSP system is managing the RASSP design methodology by "process automation", that is, controlling CAD program execution through workflow.

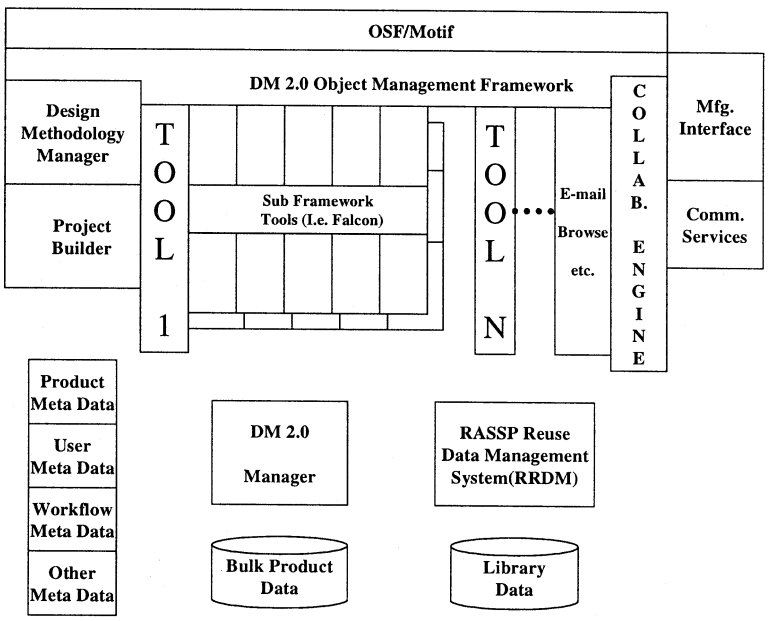

FIGURE 63.1 RASSP enterprise system architecture.

© 2003 by CRC Press LLC

The Building Blocks of Process

The lowest level of a building block of a design process is a tool. A *tool* is an unbreakable unit of a CAD program. It usually performs a specific task by transforming given input specifications into output specifications. A *task* is defined as design activities that include information about what tools to use and how to use them. It can be decomposed into smaller subtasks. The simplest form of the task, called an *atomic task*, is the one that cannot be decomposed into subtasks. In essence, an atomic task is defined as an encapsulated tool. A task is called *logical* if it is not atomic. A workflow of a logical task describes the details of how the task is decomposed into subtasks, and the data and control dependencies such as the relationship between design data used in the subtasks. For a given task, there can be several workflows, each of which denotes a possible way of accomplishing the task. A *methodology* is a collection of workflow supported together with information on which workflow should be selected in a particular instance.

Functional Requirements of Workflow Management

To be effective, a framework must integrate many design automation tools and allow the designer to specify acceptable methodologies and tools together with information such as when and how they may be used. Such a framework must not only guide the designer in selecting tools and design methodologies, but also aid the designer in constructing a workflow that is suitable to complete the design under given constraints. The constructed workflow should guarantee that required steps are not skipped; built-in design checks are incorporated into the workflow. The framework must also keep the relationships between various design representations, maintain the consistency between designs and support cooperative teamwork, and allow the designer to interact with the system to adjust design parameters or to modify the previous design process. The framework must be extendible to accommodate rapidly changing technologies and emerging new tools. Such a framework can facilitate developing new hardware systems as well as redesigning a system from a previous design.

During a design process, a particular methodology or workflow selected by a designer must be based on available tools, resources (computing and human), and design data. For example, a company may impose a rule that if input is a VHDL behavioral description, then designers should use Model Technology's VHDL simulator, but if the input is Verlig, they must use ViewLogic simulator. Or, if a component uses Xilinx, then all other components must also use Xilinx. Methodology must be driven by local expertise and individual preference, which in turn, are based on the designer's experience.

The process management should not constrain the designer. Instead, it must free designers from routine tasks, and guide the execution of workflow. User interaction and a designer's freedom are especially important when exceptions are encountered during the execution of flows, or when designers are going to modify the workflow locally. The system must support such activities through "controlled interactions" with designers.

Process management can be divided into two parts:

- A formal specification of supported methodologies and tools that must show the tasks and data involved in a workflow and their relationships.
- An execution environment that helps designers to construct workflow and execute them.

Process Specification

Methodology management must provide facilities to specify design processes. Specification of processes involves tasks and their structures (i.e., workflow). The task involved and the flow of process, that is the way the process can be accomplished in terms of its subtasks, must be defined. Processes must be encapsulated and presented to designers in a usable way. Designers want an environment to guide them in building a workflow and to help them execute it during the design process. Designers must be able to browse related processes, and compare, analyze, and modify them.

© 2003 by CRC Press LLC

Tasks

Designers should be able to define the tasks that can be logical or atomic, organize the defined tasks, and retrieve them. Task abstraction refers to using and viewing a task for specific purposes and ignoring the irrelevant aspects of the task. In general, object-oriented approaches are used for this purpose. Abstraction of the task may be accomplished by defining tasks in terms of "the operations the task is performing" without detailing the operations themselves. Abstraction of tasks allows users to clearly see the behavior of them and use them without knowing the details of their internal implementations. Using the generalization–specialization hierarchy (Chung, 1990), similar tasks can be grouped together. In the hierarchy, a node in the lower level inherits its attributes from its predecessors. By inheriting the behavior of a task, the program can be shared, and by inheriting the representation of a task (in terms of its flow), the structure (workflow) can be shared. The Process Handbook (Malone, in press) embodies concepts of specialization and decomposition to represent processes.

There are various approaches associated with binding a specific tool to an atomic task. A tool can be bound to a task statically at the compile time, or dynamically at the run time based on available resources and constraints. When a new tool is installed, designers should be able to modify the existing bindings. The simplest approach is to modify the source code or write a script file and recompile the system. The ideal case is plug and play, meaning that CAD vendors address the need of tool interoperability, e.g., the Tool Encapsulation Specification (TES) proposed by CFI (CFI, 1995).

Workflow

To define a workflow, we must specify the tasks involved in the workflow, data, and their relationship. A set of workflows defined by methodology developers enforces the user to follow the flows imposed by the company or group. Flows may also serve to guide users in developing their own flows. Designers would retrieve the cataloged flows, modify them, and use them for their own purposes based on the guidelines imposed by the developer. It is necessary to generate legal flows. A blackboard approach was used in (Lander et al., 1995) to generate a particular flow suitable for a given task. In Nelsis (Bosch, 1991), branches of a flow are explicitly represented using "or" nodes and "merge" nodes. A task can be accomplished in various ways. It is necessary to represent alternative methodologies for the task succinctly so that designers can access alternative methodologies and select the best one based on what-if analysis. IDEF3.X (IDEF) is used to graphically model workflow in RASSP environment. Figure 63.2 shows an example of workflow using IDEF3.X. A node denotes a task. It has inputs, outputs, mechanism, and conditions. IDEF definition that has been around for 20 years mainly to capture flat modeling such as a shop floor process. IDEF specification, however, requires complete information such as control mechanisms and scheduling at the specification time, making the captured process difficult to understand. In IDEF, "or" nodes are used to represent the alternative paths. It does not have an explicit mechanism to represent alternative workflow. IDEF is ideal only for documenting the current practice and not suitable for executing iterative process which is determined during the execution of the process. Perhaps, the most important aspect missing from most process management systems is the abstraction mechanism (Schlenoff et al., 1996).

Execution Environment

The execution environment provides dynamic execution of tasks and tools and binds data to tools, either manually or automatically. Few frameworks separate the execution environment from the specification of design process. A task can be executed in several modes (Kleinfeldth et al., 1994): manual mode, manual execution of flow, automatic flow execution, and automatic flow generation. In manual flow execution, the environment executes a task in the context of a flow. In an automatic flow execution environment, tasks are executed based on the order specified on the flow graph. In automatic flow generation, the framework generates workflow dynamically and executes them without the guidance of designers. Many frameworks use blackboard- or knowledge-based approaches to generate workflow. However, it is important for designers to be able to analyze the workflow created and share it with others.

© 2003 by CRC Press LLC

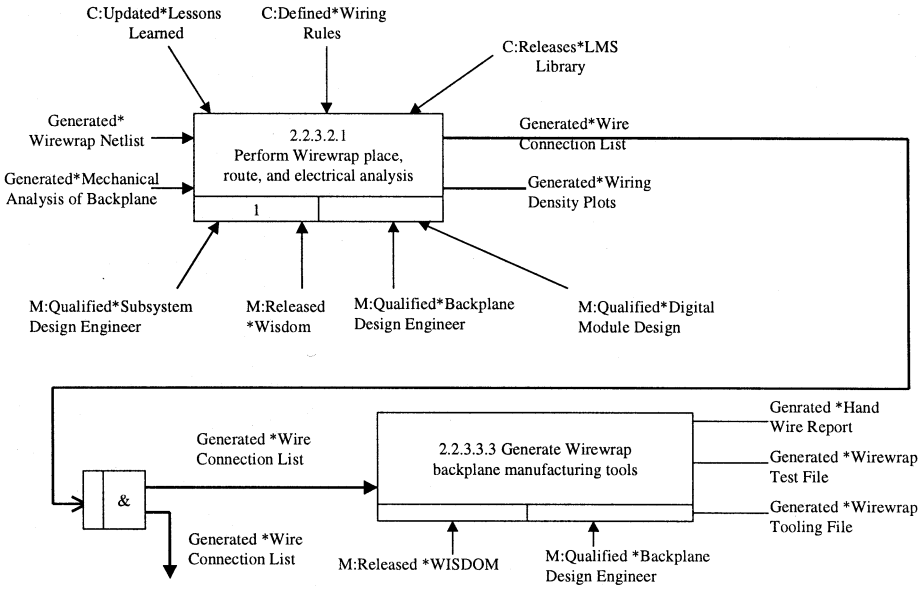

FIGURE 63.2 Workflow example using IDEF definition.

That is, repeatability and predictability are important factors if frameworks support dynamic creation of workflow.

Each task may be associated with pre- and post-conditions. Before a task is executed, the pre-condition of the task is evaluated. If the condition is not satisfied, the framework either waits until the condition is met, or aborts the task and selects another alternative. After the task is executed, its post-condition is evaluated to determine if the result meets the exit criteria. If the evaluation is unsatisfactory, another alternative should be tried.

When a task is complex involving many subtasks and each subtask in turn has many alternatives, generating a workflow for the task that would successfully accomplish the task is not easy. If the first try of an alternative is not successful, another alternative should be tried. In some cases, backtrack occurs which nullifies all the executions of previous workflow.

Literature Surveys

Many systems have been proposed to generate design process (Knapp and Parker, 1991) and manage workflow (Dellen et al., 1997; Lavana et al., 1997; Schurmann and Altmeyer, 1997; Sutton and Director, 1998). Many of them use the web technology to coordinate various activities in business (Andreoli et al., 1998), manufacturing (Berners-Lee et al., 1994; Cutkosy et al., 1996; Erkes et al., 1996), and micro-electronic design (Rastogi et al., 1993; Chan et al., 1998). WELD (Chan et al., 1998) is a network infrastructure for a distributed design system that offers users the ability to create a customizable and adaptable virtual design system that can couple tools, libraries, design, and validation services. It provides support not only for designing but also for manufacturing, consulting, component acquisition, and product distribution, encompassing the developments of companies, universities, and individuals throughout the world. Lavana et al. (1997) proposed an Internet-based collaborative design. They use Petri nets as a modeling tool for describing and executing workflow. User teams, at different sites, control the workflow execution by selection of its path. Minerva II (Sutton and Director, 1998) is a software tool that provides design process management capabilities serving multiple designers working with multiple CAD frameworks. The proposed system generates design plan and realizes unified design process management across multiple CAD frameworks and potentially across multiple design disciplines. ExPro

© 2003 by CRC Press LLC

(Rastogi et al., 1993) is an expert-system-based process management system for the semiconductor design process.

Several systems can automatically determine what tools to execute. OASIS (OASIS, 1992) uses Unix makefile style to describe a set of rules for controlling individual design steps. The Design Planning Engine of the ADAM system (Knapp and Parker, 1986; Knapp and Parker, 1991) produces a plan graph using a forward chaining approach. Acceptable methodologies are specified by listing pre-conditions and post-conditions for each tool in a lisp-like language. Estimation programs are used to guide the chaining. Ulysses (Bushnell and Director, 1986) and Cadweld (Daniell and Director, 1991) are blackboard systems used to control design processes. A knowledge source, which encapsulates each tool, views the information on the blackboard and determines when the tool would be appropriate. The task management is integrated into the CAD framework and Task Model is interpreted by a blackboard architecture instead of a fixed inference mechanism. Minerva (Jacome and Director, 1992) and the OCT task manager (Chiueh and Katz, 1990) use hierarchical strategies for planning the design process. Hierarchical planning strategies take advantage of knowledge about how to perform abstract tasks which involve several subtasks.

To represent design process and workflow, many languages and schema have been proposed. NELSIS (Bosch et al., 1991) framework is based on a central, object-oriented database and on a flow management. It uses a dataflow graph as Flow Model and provides the hierarchical definition and execution of design flow. PLAYOUT (Schurmann and Altmeyer, 1997) framework is based on separate Task and Flow Models which are highly interrelated among themselves and the Product Model. In (Barthelmann, 1996), graph grammar is proposed in defining the task of software process management. Westfechtel (1996) proposed "process-net" to generate the process flow dynamically. However, in many of these systems, the relationship between task and data is not explicitly represented. Therefore, representing the case in which a task generates more than one datum and each of them goes to a different task is not easy. In (Schurmann, 1997), Task Model (describing the I/O behavior of design tools) is used as a link between the Product Model and the Flow Model. The proposed system integrates data and process management to provide traceability. Many systems use IDEF to represent a process (Chung et al., 1996; IDEF; Stavas). IDEF specification, however, requires complete information such as control mechanisms and scheduling at the specification time, making the captured process difficult to understand.

Although there are many other systems that address the problem of managing process, most proposed system use either a rule-based approach or a hard-coded process flow. They frequently require source code modification for any change in process. Moreover, they do not have mathematical formalism. Without the formalism, it is difficult to handle the iterative nature of the engineering process and to simulate the causal effects of any changes in parameters and resources. Consequently, coordinating the dynamic nature of processes is not well supported in most systems. It is difficult to analyze the rationale how an output is generated and where a failure has occurred. They also lack a systematic way of generating all permissible process flows at any level of abstraction while providing means to hide the details of the flow when they are not needed. Most systems have the tendency to over-specify the flow information, requiring complete details of a process flow before executing the process. In most real situations, the complete flow information may not be known after the process has been executed: they are limited in their ability to address the underlying problem of process flexibility. They are rather rigid and not centered on users, and do not handle exceptions gracefully. Thus, the major functions for the collaborative framework such as adding new tools and sharing and improving the process flow cannot be realized. Most of them are weak in at least one of the following criteria suggested by NIST (Schlenoff et al., 1996): process abstraction, alternative tasks, complex groups of tasks, and complex sequences.

63.3 IMEDA System

The internet-based micro-electronic design automation (IMEDA) System is a general management framework for performing various tasks in design and manufacturing of complex micro-electronic systems. It provides a means to integrate many specialized tools such as CAD and analysis packages, and allows the designer to specify acceptable methodologies and tools together with information such as when and how

© 2003 by CRC Press LLC

they may be used. IMEDA is a collaborative engineering framework that coordinates design activities distributed geographically. The framework facilitates the flow of multimedia data sets representing design process, production, and management information among the organizational units of a virtual enterprise. IMEDA uses process grammar (Baldwin and Chung, 1995) to represent the dynamic behavior of the design and manufacturing process. In a sense, IMEDA is similar to agent-based approach such as Redux (Petrie, 1996). Redux, however, does not provide process abstraction mechanism or facility to display the process flow explicitly.

The major functionality of the framework includes:

- Formal representation of the design process using the process grammar that captures a complex sequence of activities of micro-electronic design.
- Execution environment that selects a process, elaborates the process, invokes tools, pre- and post-evaluates the productions if the results meet the criterion, and notifies designers.
- User interface that allows designers to interact with the framework, guides the design process, and edits the process and productions.
- Tool integration and communication mechanism using Internet Socket and HTTP.
- Access control that provides a mechanism to secure the activity and notification and approval that provide the mechanisms to disperse design changes to, and responses from, subscribers

IMEDA is a distributed framework. design knowledge, including process information, manager programs, etc., are maintained in a distributed fashion by local servers. The following Fig. 63.3 illustrates how IMEDA links tools and sites for distributed design activities. The main components of IMEDA are

- **System Cockpit**: It controls all interactions between the user and the system and between the system components. The cockpit will be implemented as a Java applet and may be executable on any platform for which a Java enabled browser is available. It keeps track of the current design status and informs the user of possible actions. It allows users to collaboratively create and edit process flows, production libraries, and design data.
- **Manager Programs:** These encapsulate design knowledge. Using pre-evaluation functions, managers estimate the possibility of success for each alternative. They invoke tools and call post-evaluation functions to determine if a tool's output meets the specified requirements. The interface servers allow cockpits and other Java-coded programs to view and manipulate production, task

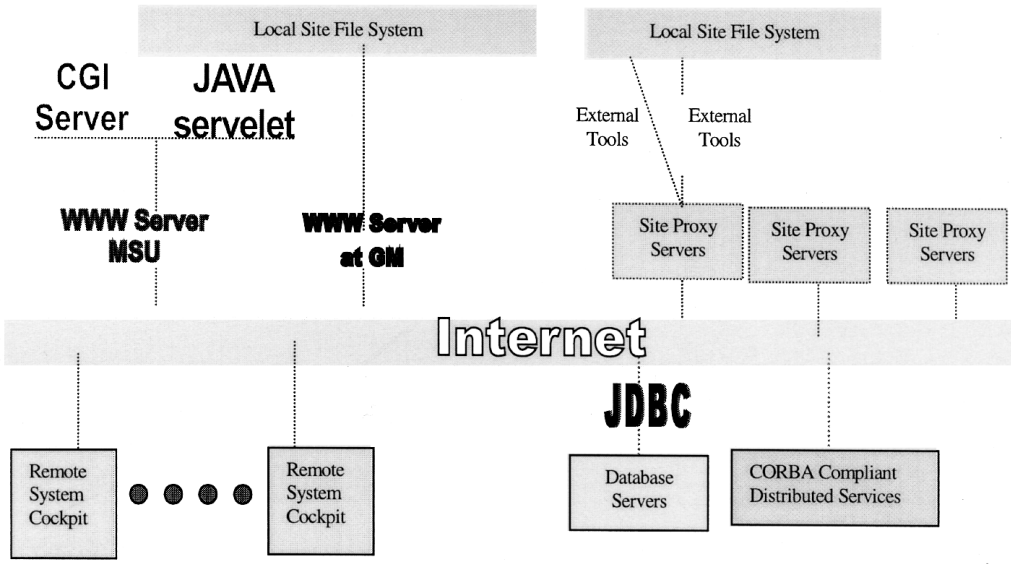

FIGURE 63.3 The architecture of IMEDA.

© 2003 by CRC Press LLC

and design data libraries. Manager programs must be maintained by tool integrators to reflect site-specific information such as company design practices and different ways of installing tools.

- **Browsers:** The task browser organizes the tasks in a generalization-specialization (GS) hierarchy and contains all the productions available for each task. The data-specification browser organizes the data-specifications in a GS hierarchy and contains all the children.
- **External Tools**. These programs are the objects invoked by the framework during design activities. Each atomic task in a process flow is bound to an external tool. External tools are written typically by the domain experts.
- **Site Proxy Server:** Any physical site that will host external tools must have a site proxy server running. These servers provide an interface between the cockpit and the external tools. The site server receives requests from system cockpits, and invokes the appropriate tool. Following the tool completion, the site server notifies the requesting cockpit, returning results, etc.
- **CGI Servers and Java Servlets:** The system cockpit may also access modules and services provided by CGI servers or the more recently introduced Java servlets. Currently, the system integrates modules of this type as direct components of the system (as opposed to external tools that may vary with the flow).
- **Database Servers:** Access to component data is a very important function. Using an API called JBDC, the framework can directly access virtually any commercially available database server remotely.
- **Whiteboard:** The shared cockpit, or "whiteboard" is a communication medium to share information among users in a distributed environment. It allows designers to interact with the system and guides the design process collaboratively. Designers will be able to examine design results and current process flows, post messages, and carry out design activities both concurrently and collaboratively. Three types of whiteboards are the process board, the chat board, and the freeform drawing board. Their functionality includes: (i) process board to the common process flow graph indicating the current task being executed and the intermediate results arrived at before the current task; (ii) drawing board to load visual design data, and to design and simulate process; and (iii) chat board to allow participants to communicate with each other via text-based dialog box.

IMEDA uses a methodology specification based on a process flow graphs and process grammars (Baldwin and Chung, 1995). Process grammars are the means for transforming high-level process flow graphs into progressively more detailed graphs by applying a set of substitution rules, called productions, to nodes that represent logical tasks. It provides not only the process aspect of design activities but also a mechanism to coordinate them. The formalism in process grammar facilitates abstraction mechanisms to represent hierarchical decomposition and alternative methods, which enable designers to manipulate the process flow diagram and select the best method. The formalism provides the theoretical foundations for the development of IMEDA.

IMEDA contains the database of admissible flows, called process specifications. With the initial task, constraints, and execution environment parameters, including personal profile, IMEDA guides designers in constructing process flow graphs in a top-down manner by applying productions. It also provides designers with the ability to discover process configurations that provide optimal solutions. It maintains consistency among designs and allows the designer to interact with the system and adjust design parameters, or modify the previous design process. As the framework is being executed, a designer can be informed of the current status of design such as updating and tracing design changes and be able to handling exception.

Real-world processes are typically very complex by their very nature; IMEDA provides designers the ability to analyze, organize, and optimize processes in a way never before possible. More importantly, the framework can improve design productivity by accessing, reusing, and revising the previous process for a similar design.

The unique features of our framework include:

Process Abstraction/Modeling — Process grammars provide abstraction mechanism for modeling admissible process flows. The abstraction mechanism allows a complex activity to be represented

© 2003 by CRC Press LLC

more concisely with a small number of higher-level tasks, providing a natural way of browsing the process repository. The strong theoretical foundation of our approach allows users to analyze and predict the behavior of a particular process. With the grammar, the process flow gracefully handles exceptions and alternative productions. When a task has alternative productions, backtracking occurs to select other productions.

Separation of Process Specification and Execution Environment — Execution environment information such as complex control parameters and constraints is hidden from the process specification. The information of these two layers is merely linked together to show the current task being executed on a process flow. The represented process flow can be executed in both automatic and manual modes. In the automatic mode, the framework executes all possible combinations to find a solution. In the manual mode, users can explore design space.

Communication and Collaboration — To promote real-time collaboration among participants, the framework is equipped with the whiteboard, a communication medium to share information. Users can browse related processes, compare them with other processes, analyze, and simulate them. Locally managed process flows and productions can be integrated by the framework in the central server. The framework manages the production rules governing the higher level tasks, while lower level tasks and their productions are managed by local servers. This permits the framework to be effective in orchestrating a large-scale activity.

Efficient Search of Design Process and Solution — IMEDA is able to select the best process and generate a process plan, or select a production dynamically and create a process flow. The process grammar easily captures design alternatives. The execution environment selects and executes the best one. If the selected process does not meet the requirement, then the framework backtracks and selects another alternative. This backtrack occurs recursively until a solution is found. If you allow a designer to select the best solution among many feasible ones, the framework may generate many multiple versions of the solution.

Process Simulation — The quality of a product depends on the tools (maturity, speed, and special strength of the tool), process (or workflow selected), and design data (selected from the reuse library). Our framework predicts the quality of results (product) and assesses the risk and reliability. This information can be used to select the best process/work flow suitable for a project.

Parallel Execution of Several Processes and Multiple Versions — To reduce the design time and risk, it is necessary to execute independent tasks in parallel whenever they are available. Sometimes, it is necessary to investigate several alternatives simultaneously to reduce the design time and risk. Or the designer may want to execute multiple versions with different design parameters. The key issue in this case is scheduling the tasks to optimize the resource requirements.

Life Cycle Support of Process Management — The process can be regarded as a product. A process (such as airplane designing or shipbuilding) may last many years. During this time, it may be necessary for the process itself to be modified because of new tools and technologies. Life cycle support includes updating the process dynamically, and testing/validating the design process, version history and configuration management of the design process. Tests and validations of the design processes, the simulation of processes, and impact analysis are necessary tools.

63.4 Formal Representation of Design Process[1]

IMEDA uses a methodology specification based on a process flow graphs and process grammars (Baldwin and Chung, 1995). The grammar is an extension of graph grammar originally proposed by Ehrig (1979) and has been applied to interconnection network (Derk and DeBrunner, 1998) and software engineering (Heiman et al., 1997).

[1]Materials in this section are excerpted from R. Baldwin and M.J. Chung, *IEEE Computers,* pp. 54–63, Feb. 1995. With permission.

Process Flow Graph

A process flow graph depicts tasks, data, and the relationships among them, describing the sequence of tasks for an activity. Three basic symbols are used to represent a process flow graph. Oval nodes represent logical tasks, two-concentric oval nodes represent Atomic Tasks, rectangular nodes represent data specifications and diamond nodes represent selectors. A task that can be decomposed into subtasks is called *logical*. Logical task nodes represent abstract tasks that could be done with several different tools or tool combinations. A task that cannot be decomposed is *atomic*. An atomic task node, commonly called a tool invocation, represents a run of an application program.

A *selector* is a task node that selects data or parameter. Data specifications are design data, where the output specification produced by a task can be consumed by another task as an input specification. Each data specification node, identified by a rectangle, is labeled with a data specification type. Using the graphical elements of the flow graph, engineers can create a process flow in a top-down fashion. These elements can be combined into a process flow graph using directed arcs. The result is a bipartite acyclic directed graph that identifies clearly the task and data flow relationships among the tasks in a design activity. The set of edges indicates those data specifications used and produced by each task. Each specification must have at most one incoming edge. Data specifications with no incoming edges are inputs of the design exercise. $T(G)$, $S(G)$, and $E(G)$ are the sets of task nodes, specification nodes, and edges of graph G, respectively. Figure 63.4 shows a process flow graph that describes a possible rapid

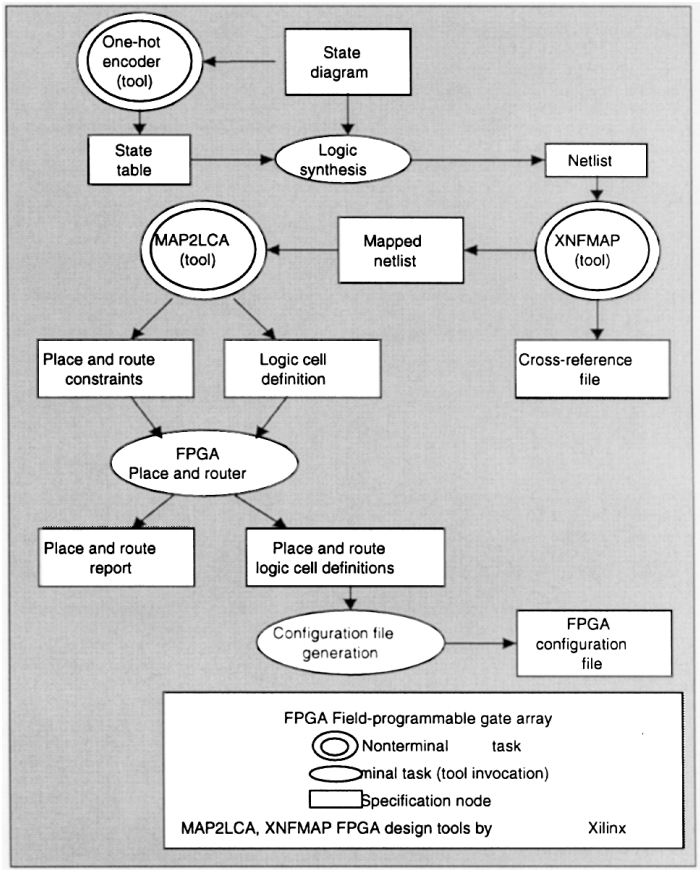

FIGURE 63.4 A sample process flow graph in which a state diagram is transformed into a field-programmable gate array configuration file.

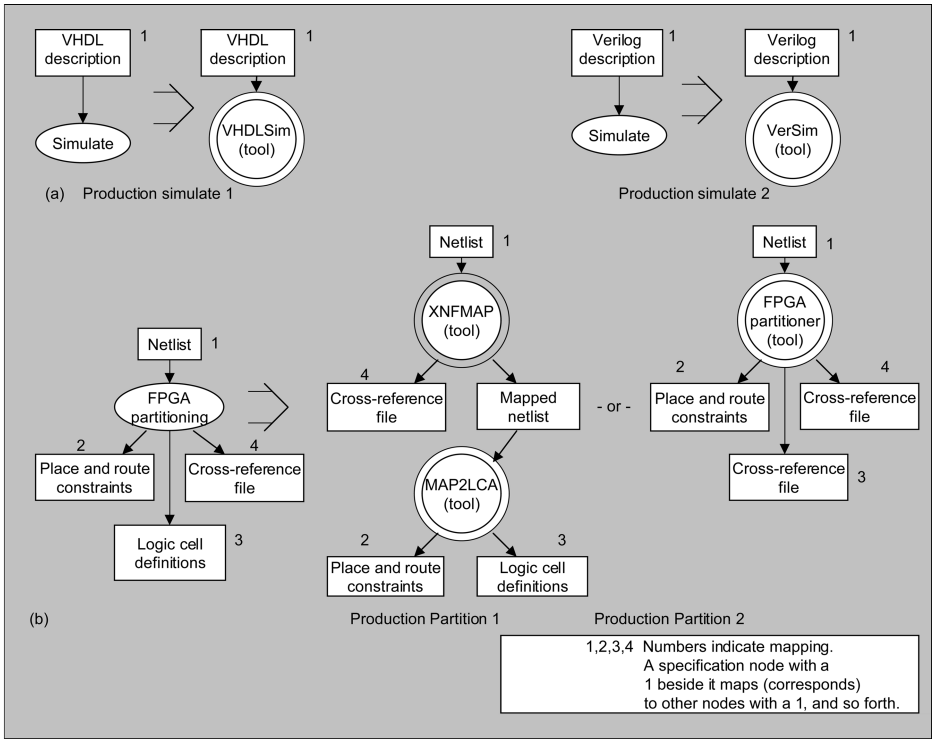

FIGURE 63.5 Graph production from a design process grammar. Two simulation alternatives based on input format are portrayed in (a); two partition alternatives representing different processes for an abstract task are protrayed in (b).

prototyping design process, in which a state diagram is transformed into a field-programmable gate array (FPGA) configuration file.

The various specification types form a class hierarchy where each child is a specialization of the parent. There may be several incompatible children. For example, VHDL and Verilog descriptions are both children of simulation models. We utilize these specification types to avoid data format incompatibilities between tools (see Fig. 63.5a). Process flow graphs can describe design processes to varying levels of detail. A graph containing many logical nodes abstractly describes what should be done without describing how it should be done (i.e., specifying which tools to use). Conversely, a graph in which all task nodes are atomic completely describes a methodology.

In our prototype, we use the following definitions: $In(N)$ is the set of input nodes of node N: $In(N) = \{ M \mid (M,N) \in E\}$. Out(N) is the set of output nodes of node N: $OUT(N) = \{ M \mid (N,M) \in E\}$. $I(G)$ is the set of input specifications of graph G: $\{ N \in S(G) \mid In(N) = \varnothing \}$.

Process Grammars

The designer specifies the overall objectives with the initial graph that lists available input specifications, desired output specifications, and the logical tasks to be performed. By means of process grammars, logical task nodes are replaced by the flows of detailed subtasks and intermediate specifications. The output specification nodes are also replaced by nodes that may have a child specification type.

The productions in a graph grammar permit the replacement of one subgraph by another. A production in a design process grammar can be expressed formally as a tuple $P = (G_{LHS}, G_{RHS}, \sigma_{in}, \sigma_{out})$, where G_{LHS} and G_{RHS} are process flow graphs for the left side and the right side of the production, respectively, such that (i) G_{LHS} has one logical task node representing the task to be replaced, (ii) σ_{in} is a mapping from the input specifications $I(G_{LHS})$ to $I(G_{RHS})$, indicating the relationship between two input specifications

© 2003 by CRC Press LLC

(each input specification of $I(G_{RHS})$ *is* a subtype of $I(G_{LHS})$), and (iii) σ_{out} is a mapping from the output specifications of G_{LHS} to output specifications of G_{RHS} indicating the correspondence between them. (each output specification must be mapped to a specification with the same type or a subtype). Figure 63.5 illustrates productions for two tasks, `simulate` and `FPGA partitioning`. The mappings are indicated by the numbers beside the specification nodes. Alternative productions may be necessary to handle different input specification types (as in Fig. 63.5a), or because they represent different processes- separated by the word "or" — for performing the abstract task (as in Fig. 63.5b).

Let A be the logical task node in $G_{LHS,}$ and A' be a logical task node in the original process flow graph G such that A has the same task label as A'. The production rule P can be applied to A', which means that A' can be replaced with G_{RHS} only if each input and output specifications of A' matches to input and output specifications of G_{LHS}, respectively. If there are several production rules with the same left side flow graph, it implies that there are alternative production rules for the logical task. Formally, the production matches A' if:

(i) A' has the same task label as A.
(ii) There is a mapping ρ_{in}, from $In(A)$ to $In(A')$, indicating how the inputs should be mapped. For all nodes $N \in In(A)$, $\rho_{in}(N)$ should have the same type as N or a subtype.
(iii) There is a mapping, ρ_{out}, from $Out(A')$ to $Out(A)$, indicating how the outputs should be mapped. For all nodes $N \in Out(A')$, $\rho_{out}(N)$ should have the same type as N or a subtype.

The mappings are used to determine how edges that connected the replaced subgraph to the remainder should be redirected to nodes in the new subgraph. Once a match is found in graph G, the production is applied as follows:

(i) Insert G_{RHS}–$I(G_{RHS})$ into G. The inputs of the replaced tasks are not replaced.
(ii) For every N in $I(G_{RHS})$ and edge (N,M) in G_{RHS}, add edge $(\rho_{in}(\sigma_{in}(N)),M)$ to G. That is to connect the inputs of A' to the new task nodes that will use them.
(iii) For every N in Out(A') and edge (N,M) in G, replace edge (N,M) with edge $(\sigma_{out}(\rho_{out}(N)),M)$. That is to connect the new output nodes to the tasks that will use them.
(iv) Remove A' and Out(A') from G, along with all edges incident on them.

Figure 63.6 illustrates a derivation in which the FPGA partitioning task is planned, using a production from Fig. 63.5b.

The process grammar provides mechanism of specifying alternative methods for a logical task. A high-level flow graph can then be decomposed into detailed flow graphs by applying *production rules* to a logical task. A *production rule* is a substitution that permits the replacement of a logical task node with a flow graph that represents a possible way of performing the task. The concept of applying productions to logical tasks is somewhat analogous to the idea of productions in traditional (i.e., non-graph) grammars. In this sense, logical tasks correspond to *logical symbols* in grammar, and atomic tasks correspond to *terminal symbols*.

63.5 Execution Environment of the Framework

Figure 63.7 illustrates the architecture of our proposed system, which applies the theory developed in the previous section. Decisions to select or invoke tools are split between the designers and a set of manager programs, where manager programs are making the routine decisions and the designers make decisions that requires higher-level thinking. A program called Cockpit coordinates the interaction among manager programs and the designers. Tool sets and methodology preferences will differ among sites and over time. Therefore, our assumption is that each unit designates a person (or group) to act as system integrator, who writes and maintains the tool-dependent code in the system. We provide the tool-independent code and template to simplify the task of writing tool-dependent code.

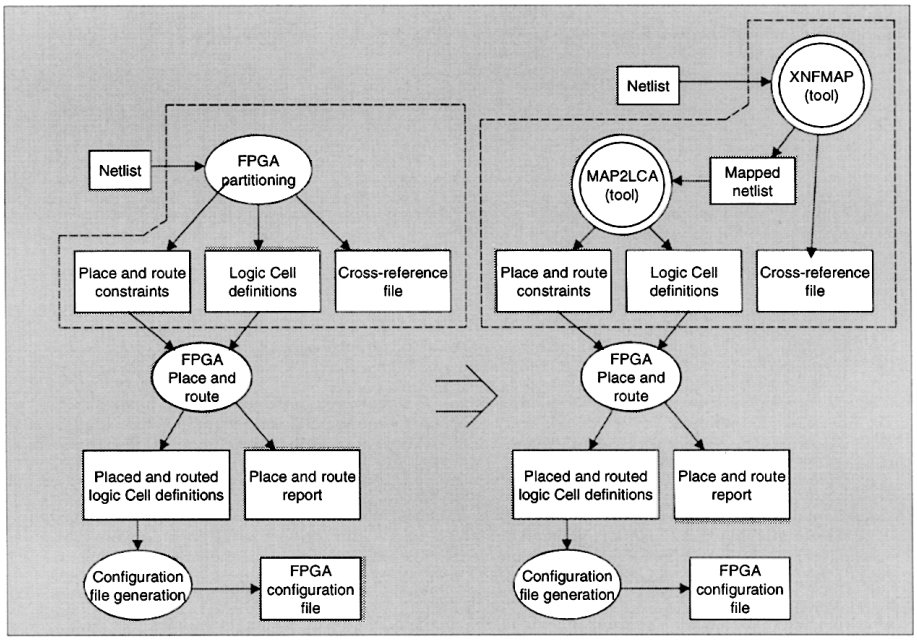

FIGURE 63.6 A sample graph dertivation. Nodes in the outlined region, left, are replaced with nodes in the outlined region, right, according to production partition 1 in Fig. 63.5.

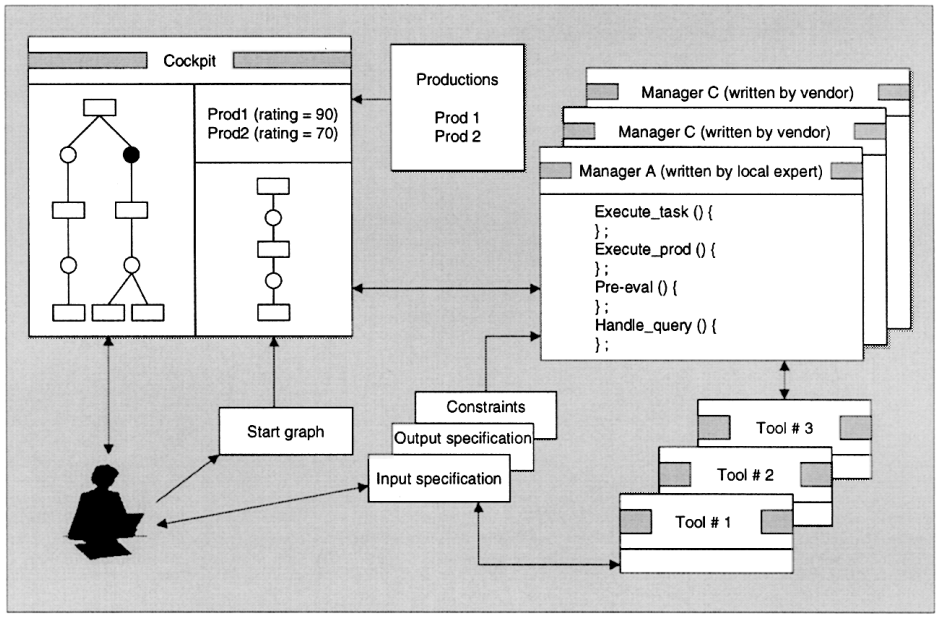

FIGURE 63.7 The proposed system based on Cockpit.

The Cockpit Program

The designer interacts with Cockpit, a program which keeps track of the current process flow graph and informs the designer of possible actions such as productions that could be applied or tasks that could be executed. Cockpit contains no task-specific knowledge; its information about the design process comes

© 2003 by CRC Press LLC

entirely from a file of graph productions. When new tools are acquired or new design processes are developed, the system integrator modifies this file by adding, deleting, and editing productions.

To assist the designer in choosing an appropriate action, Cockpit interacts with several manager programs that encapsulate design knowledge. Two types of manager programs are used: task managers and production managers. Task managers invoke tools and determine which productions to execute for logical task nodes. Production managers provide ratings for the productions and schedule the execution of tasks on the right-hand side of the production. Managers communicate with each other using messages issued by Cockpit.

Our prototype system operates as follows. Cockpit reads the initial process flow graph from an input file generated by using a text editor. Cockpit then iteratively identifies when productions can be applied to logical task nodes and requests that the production managers assign the ratings to indicate how appropriate the productions are for those tasks. The process flow graph and the ratings of possible production applications are displayed for the designer, who directs Cockpit through a graphical user interface to apply a production or execute a task at any time. When asked to execute a task, Cockpit sends a message to a task manager. For an atomic task node, the task manager simply invokes the corresponding tool. For a logical task, the task manager must choose one or more productions, as identified by a Cockpit. The Cockpit applies the production and requests the production manager to execute the new expanded process.

Manager Programs

Manager programs must be maintained by system integrators to reflect site-specific information, such as company design practices and tool installation methods. Typically, a manager program has its own thread. A Cockpit may have several manager programs, and therefore multi-threads. We define a communication protocol between Cockpit and manager programs and provide templates for manager programs. The manager programs provide five operations: pre-evaluation, tool invocation, logical task execution, production execution, and query handling. Each operation described next corresponds to a C++ or Java function in the templates, which system integrators can customize as needed.

Pre-evaluation: Production managers assign ratings to help designers and task managers select the most appropriate productions. The rating indicates the likelihood of success from applying this production. The strategies used by the system integrator provide most of the code to handle the rating. In some cases, it may be sufficient to assign ratings statically, based on the success of past productions. These static ratings can be adjusted downward when the production has already been tried unsuccessfully on this task node (which could be determined using the query mechanism). Alternatively, the ratings may be an arbitrarily complex function of parameters obtained through the query mechanism or by examining the input files. Sophisticated manager programs may continuously gather and analyze process metrics that indicate those conditions leading to success, adjust adjusting ratings accordingly.

Tool Invocation: Atomic task mangers must invoke the corresponding software tool when requested by Cockpit, then determine whether the tool completed successfully. In many cases, information may be predetermined and entered in a standard template, which uses the tool's result status to determine success. In other cases, the manager must determine tool parameters using task-specific knowledge or determine success by checking task-specific constraints. Either situation would require further customization of the manager program.

Logical Task Execution: Logical task managers for logical tasks must select productions to execute the logical task. Cockpit informs the task manager of available productions and their ratings. The task manager can either direct Cockpit to apply and execute one or more productions, or it can decide that none of the productions is worthwhile and report failure. The task manager can also request that the productions be reevaluated when new information has been generated that might influence the ratings, such as a production's failure. If a production succeeds, the task manager checks any constraints; if they are satisfied, it reports success.

© 2003 by CRC Press LLC

Production Execution: Production managers execute each task on the right-hand side of the production at the appropriate time and possibly check constraints. If one of the tasks fails or a constraint is violated, backtracking can occur. The production manager can use task-specific knowledge to determine which tasks to repeat. If the production manager cannot handle the failure itself, it reports the failure to Cockpit, and the managers of higher level tasks and productions attempt to handle it.

Query Handling: Both production and task managers participate in the query mechanism. A production manager can send queries to its parent (the task manager for the logical task being performed) or to one of its children (a task manager of a subtask). Similarly, a task manager can send a query to its parent production manager or to one of its children (a production manager of the production it executed). The manager templates define C functions, which take string arguments, for sending these queries. System integrators call these functions but do not need to modify them. The manager templates also contain functions which are modified by system integrators for responding to queries. Common queries can be handled by template code; for example, a production manager can frequently ask its parent whether the production has already been attempted for that task and whether it succeeded. The manager template handles any unrecognized query from a child manager by forwarding it to the parent manager. Code must be added to handle queries for task-specific information such as the estimated circuit area or latency.

Execution Example

Now we describe a synthesis scenario that illustrates our prototype architecture in use. In this scenario, the objective is to design a controller from a state diagram, which will ultimately be done following the process flow graph in Fig. 63.4. There are performance and cost constraints on the design, and the requirement to produce a prototype quickly. The productions used are intended to be representative but not unique. For simplicity, we assume that a single designer is performing the design with, therefore, only one Cockpit.

The start graph for this scenario contains only the primary task, chip synthesis, and specification nodes for its inputs and outputs (like the graph in the left in Fig. 63.8). Cockpit tells us that the production of Fig. 63.8 can be applied. We ask Cockpit to apply it. The chip synthesis node is then replaced by nodes for state encoding, logic synthesis, and physical synthesis, along with intermediate specification nodes. Next, we want to plan the physical synthesis task. Tasks can be planned in an order other than they are to be performed. Cockpit determines that any of the productions shown in Fig. 63.9 may be applied, then queries each production's task manager program asking it to rate the production's appropriateness in the current situation. Based on the need to implement the design quickly, the productions for standard cell synthesis and full custom synthesis are rated low while the production for FPGA synthesis is rated high. Ratings are displayed to help us decide.

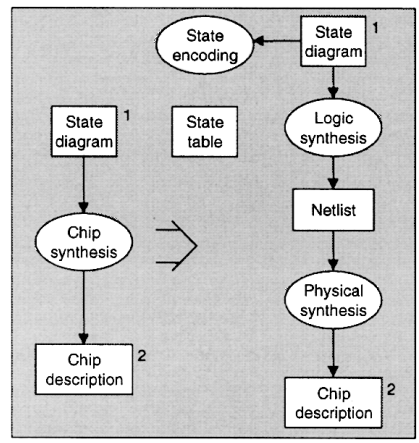

FIGURE 63.8 Productions for chip synthesis.

When we plan the state encoding task, Cockpit finds two productions: one to use the tool Minbits Encoder and the other to use the tool One-hot Encoder. One-hot Encoder works well for FPGAs, while Minbits Encoder works better for other technologies. To assign proper ratings to these productions, their production managers must find out which implementation technology will be used. First, they send a query to their parent manager, the state encoding task manager. This manager forwards the message to its parent, the chip synthesis production manager. In turn, this manager forwards the query to the physical

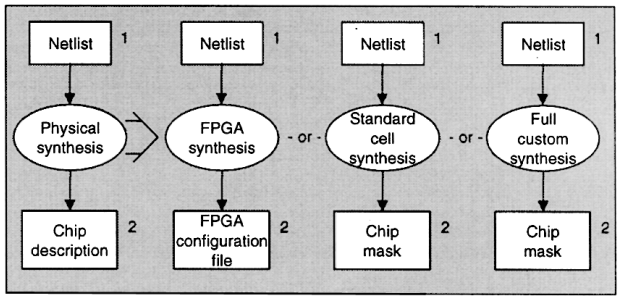

FIGURE 63.9 Productions for physical synthesis.

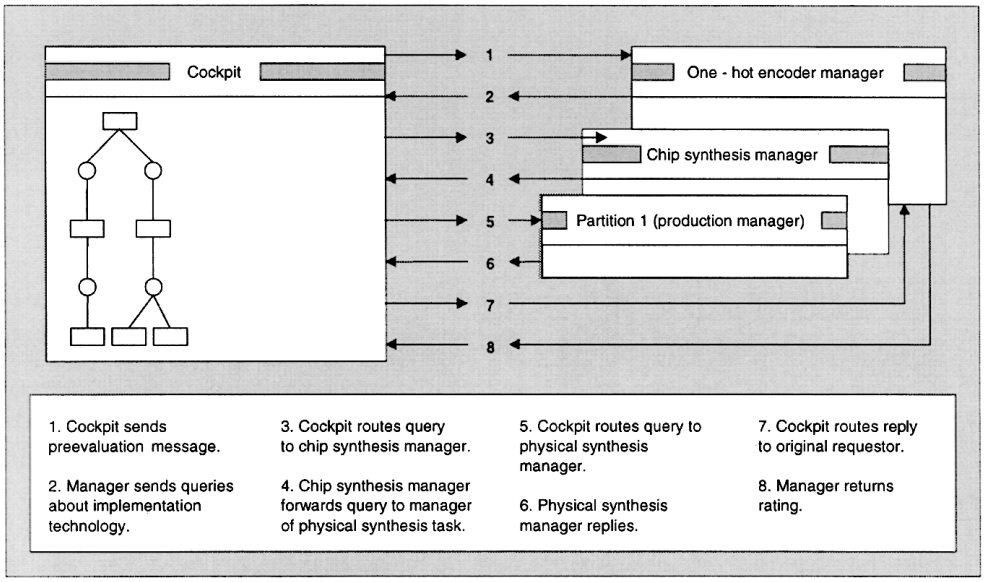

FIGURE 63.10 Sequence of actions for query handling.

synthesis task manager for an answer. All messages are routed by Cockpit, which is aware of the entire task hierarchy. This sequence of actions is illustrated in Fig. 63.10.

After further planning and tool invocations, a netlist is produced for our controller. The next step is the FPGA synthesis task. We apply the production in Fig. 63.11 and proceed to the FPGA partitioning task. The knowledge to automate this task has already been encoded into the requisite manager programs, so we direct Cockpit to execute the FPGA partitioning task. It finds the two productions illustrated in Fig. 63.5b and requests their ratings, Next, Cockpit sends an execute message, along with the ratings, to the FPGA partitioning task manager. This manager's strategy is to always execute the highest-rated production, which in this case is production Partition 1. (Other task managers might have asked that both productions be executed or, if neither were promising, immediately reported failure.) This sequence of actions is shown in Fig. 63.12.

Because the Partition 1 manager used an as-soon-as-possible task scheduling strategy, it asks Cockpit to execute XNFMAP immediately. The other subtask, MAP2LCA, is executed when XNFMAP complete successfully. After both tasks complete successfully, Cockpit reports success to the FPGA partitioning task manager. This action sequence is illustrated in Fig. 63.13.

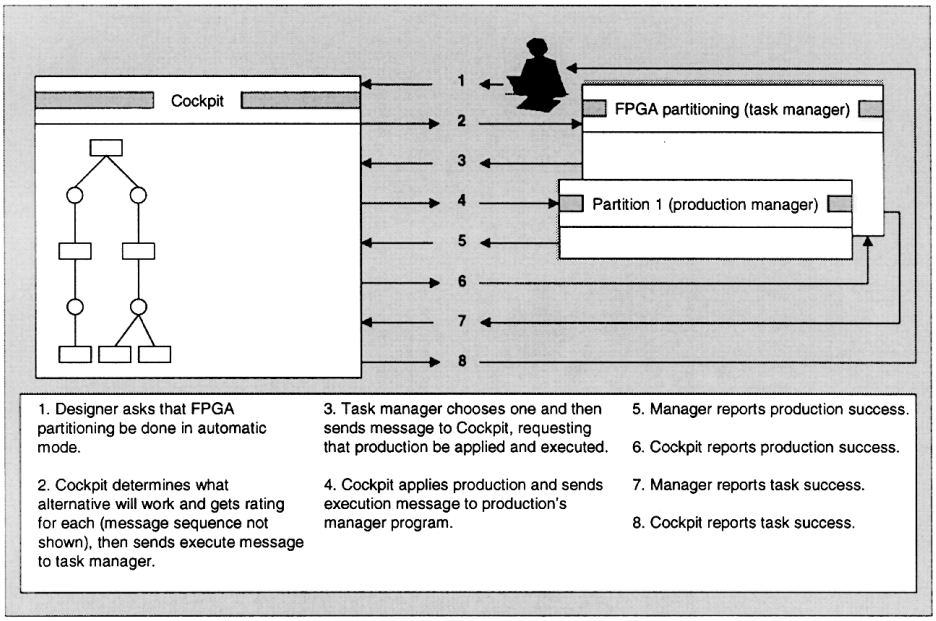

FIGURE 63.12 Sequence of action during automatic task execution.

Scheduling

In this subsection, we describe a detailed description and discussion of auto-mode scheduling, including the implementation of the *linear scheduler*. The ability to search through the configuration space of a design process for a design configuration that meets user-specified constraints is important. For example, assume that a user has defined a process for designing a digital filter with several different alternative ways of performing logical tasks such as "FPGA Partitioning" and "Select the Filter Architecture." One constraint that an engineer may wish to place on the design might be: "Find a process configuration that produces a filter that has maximum delay at most 10 nanoseconds." Given such a constraint, the framework must search through the configuration space of the filter design process, looking for a sequence of valid atomic

© 2003 by CRC Press LLC

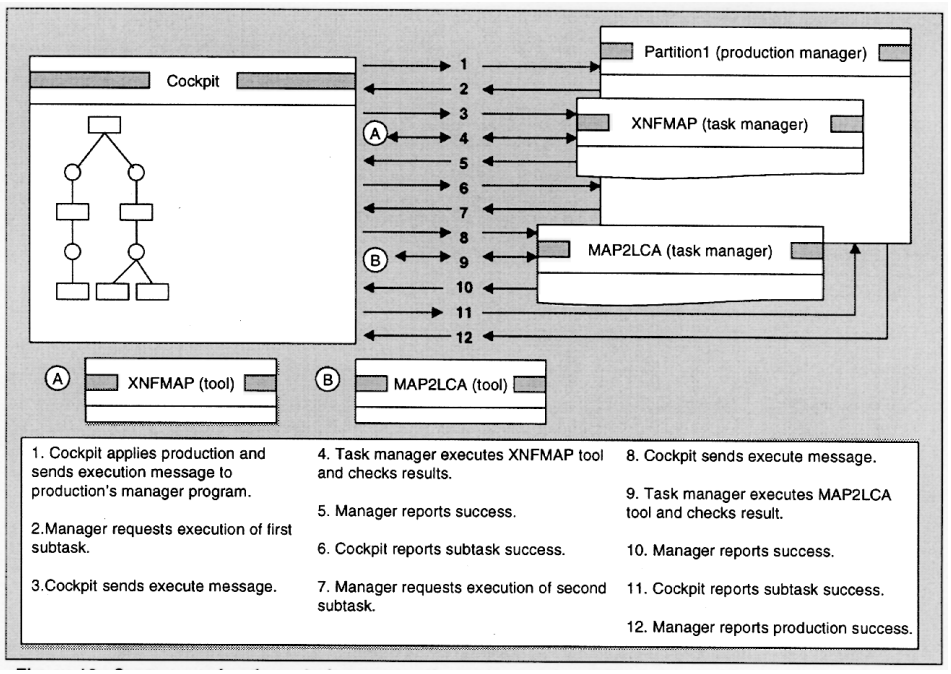

FIGURE 63.13 Sequence of actions during automatic production execution.

tasks that produces a filter with "maximum delay at most 10 nanoseconds." We call the framework component that performs this search a *scheduler*. There are, of course, many different ways of searching through the design process configuration space. In general, a successful scheduler will provide the following functionality:

- **Completeness (Identification of Successful Configurations):** Given a particular configuration of a process, the correct scheduler will be able to conclusively determine whether the configuration meets user-specified constraints. The scheduler must guarantee that before reporting failure, all possible process configurations have been considered, and if there is a successful configuration, the algorithm must find it.
- **Reasonable Performance:** The configuration space of a process grows exponentially (in the number of tasks). Ideally, a scheduler will be able to search the configuration space using an algorithm that requires less than exponential time.

The Linear Scheduling Algorithm is very simple yet complete and meets most of the above criteria. In this algorithm, for each process flow graph (corresponding to an initial process flow graph or a production), it has a scheduler. Each scheduler is a separate thread with a *Task Schedule List* (TSL) representing the order in which tasks are to be executed. The tasks in a scheduler's TSL are called its children tasks. A scheduler also has a *task pointer* to indicate the child task being executed in the TSL. The algorithm is recursive such that with each new instantiation of a production of a given task, a new scheduler is created to manage the flow graph representing the production selected. A liner scheduler creates a TSL by performing a topological sort of the initial process flow graph and executes its children tasks in order. If a child task is atomic, the scheduler executes the task without creating a new scheduler; otherwise, it selects a new alternative, creates a new child scheduler to manage the selected alternative, and waits for a signal from the child scheduler indicating success or failure. When a child task execution is successful, the scheduler increments the *task pointer* in its TSL and proceeds to execute the next task. If a scheduler reaches the end of its TSL, it signals success to its own parent, and awaits signals from its parent if it should terminate itself (all successful) or rollback (try another to find new configurations).

© 2003 by CRC Press LLC

If a child task fails, the scheduler tries another alternative for the task. If there is no alternatives left, it rolls back (by decrementing the task pointer) until it finds a logical task that has another alternative to try. If a scheduler rolls back to the beginning of the TSL and cannot find an alternative, then its flow has failed. In this case, it signals a failure to its parent and terminates itself.

In the linear scheduling algorithm, each scheduler can send or receive any of five signals: `PROCEED`, `ROLLBACK`, `CHILD-SUCCESS`, `CHILD-FAILURE`, and `DIE`. These signals comprise scheduler-to-scheduler communication, including self-signaling. Each of the five signals is discussed next.

- **PROCEED:** This signal tells the scheduler to execute the next task in the `TSL`. It can be self-sent or received from a parent scheduler. For example, a scheduler increments its task pointer and sends itself a `PROCEED` signal when a child task succeeds, whereas it sends a `PROCEED` signal to its children to start its execution
- **ROLLBACK:** This is signaled when a task execution has failed. This signal may be self-sent or received from a parent scheduler. Scheduler self-signals `ROLLBACK` whenever a child task fails. A Rollback can result in either trying the next alternative of a logical task, or decrementing the task pointer and trying the previous task in the TSL. If rollback results in decrementing the task pointer to point to a child task node which has received a success-signal, the parent scheduler will send a rollback signal to that child task scheduler.
- **CHILD-SUCCESS:** A child scheduler sends a `CHILD-SUCCESS` to its parent scheduler if it has successfully completed the execution of all of the tasks in its `TSL`. After sending the child-success signal, the scheduler remains active, listening for possible rollback signals from the parent. After receiving a child-success signal, parent schedulers self-send a proceed signal.
- **CHILD-FAILURE:** A child-failure signal is sent from a child scheduler to its parent in the event that the child's managed flow fails. After sending a child-failure signal, children schedulers terminate. Upon receiving child-failure signals, parent scheduler self-send a rollback signal.
- **DIE:** This signal may be either self-sent, or sent from parent schedulers to their children schedulers.

63.6 Implementation

In this section, a high level description of the major components of IMEDA and their organization and functionality will be presented. Detailed explanations of the key concepts involved in the architecture of the process management framework will also be discussed, including external tool integration, the tool invocation process, the Java File System, and state properties.

The System Cockpit

The system cockpit, as its name suggests, is where nearly all user interaction with the framework takes place. It is here that users create, modify, save, load, and simulate process flow graphs representing design processes. This system component has been implemented as a Java applet. As such, it is possible to run the cockpit in any Java-enabled Web browser such as Netscape's Navigator or Microsoft's Internet Explorer. It is also possible to run the cockpit in some Java-enabled operating systems such as IBM's OS/2.

Each cockpit component also has the following components:

- **Root Flow.** Every cockpit has a Root Flow. The Root Flow is the flow currently being edited in the Cockpit's Flow Edit Panel. Notice that the Root Flow may change as a result of applying a production to a flow graph, in which case the Root Flow becomes a derivation of itself.
- **Flow Edit Panel.** The Flow Edit Panel is the interactive Graphical User Interface (GUI) for creating and editing process flow graphs. This component also acts as a display for animating process simulations performed by various schedulers such as the manual or automode linear scheduler.
- **Class Directory.** The Cockpit has two Class Directories: Task Directory and the Specification Directory. These directories provide the "browser" capabilities of the framework, allowing users to create reusable general-to-specific hierarchies of task classes. Class Directories are implemented using a *tree* structure.

© 2003 by CRC Press LLC

- **Production Database.** The Production Database acts as a warehouse for logical task productions. These productions document the alternative methods available for completing a logical task. Each Production Database has a list of Productions. The Production Database is implemented as a tree-like structure, with Productions being on the root trunk, and Alternatives being leaves.
- **Browser**. Browsers provide the tree-like graphical user interface for users to edit both Class Directories and Databases. There are three Browsers: Database Browser for accessing the Production Database, Directory Browser for accessing the Task Directory, and Directory Browser for accessing the Spec Browser. Both Database Browsers and Directory Browsers inherit properties from object Browser, and offer the user nearly identical editing environments and visual representations. This deliberate consolidation of Browser interfaces allows us to provide designers with an interface that was consistent and easier to learn.
- **Menu.** A user typically performs and accesses most of the system's key function from the cockpit's Menu.
- **Scheduler.** The cockpit has one or more schedulers. Schedulers are responsible for searching the configuration space of a design process for configurations that meet user specified design constraints. The Scheduler animates its process simulations by displaying them in the Flow Edit Panel of the Cockpit.

External Tools

External Tools are the concrete entities to which atomic tasks from a production flow are bound. When a flow task object is expanded in the Cockpit Applet (during process simulation), the corresponding external tool is invoked. The external tool uses a series of inputs and produces a series of outputs (contained in files). These inputs and outputs are similarly bound to specifications in a production flow. Outputs from one tool are typically used as inputs for another. IMEDA can handle the transfer of input and output files between remote sites. The site proxy servers, in conjunction with a remote file server (also running at each site) automatically handle the transfer of files from one system to another. External tools may be implemented using any language, and on any platform that has the capability of running a site server. While performing benchmark tests of IMEDA, we used external tools written in C, Fortran, Perl, csh (a Unix shell script), Java applications, and Mathematica scripts.

External Tool Integration

One of the primary functionality of IMEDA is the integration of user-defined external tools into an abstract process flow. IMEDA then uses these tools both in simulating the process flow to find a flow configuration that meets specific constraints, and in managing selected flow configurations during actual design execution.

Two steps are used for integrating tools with a process flow defined in IMEDA: *association* and *execution*. Association involves "linking" or "binding" an abstract flow item (e.g., an atomic task) to an external tool. Execution describes the various steps that IMEDA takes to actually invoke the external tool and process the results.

Binding Tools

External tools may be bound to three types of flow objects: Atomic Tasks, Selectors, and Multiple Version Selectors. Binding an external tool to a flow object is a simple and straightforward job, involving simply defining certain properties in the flow object.

The following properties must be defined in an object that is to be bound to an external tool:

- **`SITE`.** Due to the fact that IMEDA can execute tools on remote systems, it is necessary to specify the site where the tool is located on. Typically, a default SITE will be specified in the system defaults, and making it unnecessary to define the site property unless the default is to be overridden. Note that the actual site ID specified by the SITE property must refer to a site that is running a Site Proxy Server listening on that ID. See the "Executing External Tools" section next for more details.

© 2003 by CRC Press LLC

- **CMDLINE.** The CMDLINE property specifies the command to be executed at the specified remote site. The CMDLINE property should include any switches or arguments that will always be sent to the external tool. Basically, the CMDLINE argument should be in the same format that would be used if the command were executed from a shell/DOS prompt.
- **WORKDIR.** The working directory of the tool is specified by the WORKDIR property. This is the directory in which IMEDA will actually execute the external tool, create temporary files, etc. This property is also quite often defined in the global system defaults, and thus may not necessarily have to be defined for every tool.
- **WRAPPERPATH.** The JDK 1.0.2 does not allow Java Applications to execute a tool in an arbitrary directory. To handle remote tool execution, a wrapper is provided. It is a "go-between" program that would simply change directories and then execute the external tool. This program can be as simple as a DOS/NT batch file, a shell script, or a Perl program. The external tool is wrapped in this simple script, and executed. Since IMEDA can execute tools at remote and heterogeneous sites, it was very difficult to create a single wrapper that would work on all platforms (WIN32, Unix, etc.). Therefor, the wrapper program may be specified for each tool, defined as global default, or a combination of the two.

Once the properties above have been defined for a flow object, the object is said to be "bound" to an external tool. If no site, directory, or filename is specified for the outputs of the flow object, IMEDA automatically creates unique file names, and stores the files in the working directory of the tool on the site that the tool was run. If a tool uses as inputs data items that are not specified by any other task, then the data items must be bound to static files on some site.

Executing External Tools

Once flow objects have been bound to the appropriate external tools, IMEDA can be used to perform process simulation or process management. IMEDA actually has several "layers" that lie between the Cockpit (a Java applet) and the external tool that is bound to a flow being viewed by a user in the Cockpit. A description of each of IMEDA components for tool invocations is listed below.

- **Tool Proxy.** The tool proxy component acts as a liaison between flow objects defined in Cockpits and the Site Proxy Server. All communication is done transparently through the communication server utilizing TCP/IP sockets. The tool proxy "packages" information from Cockpit objects (atomic tasks, selectors, etc.) into string messages that the Proxy Server will recognize. It also listens for and processes messages from the Proxy Server (through the communications server) and relays the information back to the Cockpit object that instantiated the tool proxy originally.
- **Communications Server.** Due to various security restrictions in the 1.0.2 version of Sun Microsystems' Java Development Kit (JDK), it is impossible to create TCP/IP socket connections between a Java applet and any IP address other than the address from which the applet was loaded. Therefore, it was necessary to create a "relay server" in order to allow cockpit applets to communicate with remote site proxy servers. The sole purpose of the communications server is to receive messages from one source and then to rebroadcast them to all parties that are connected and listening on the same channel.
- **Site Proxy Server.** Site Proxy Servers are responsible for receiving and processing invocation requests from tool proxies. When an invocation request is received, the site proxy server checks to see that the request is formatted correctly, starts a tool monitor to manage the external tool invocation, and returns the exit status of the external tool after it has completed.
- **Tool Monitors.** When the site proxy server receives an invocation request and invokes an external tool, it may take a significant amount of time for the tool to complete. If the proxy server had to delay the handling of other requests while waiting for each external tool to complete, IMEDA would become very inefficient. For this reason, the proxy server spawns a tool monitor for each external tool that is to be executed. The tool monitor runs as a separate thread, waiting on the tool, storing its stdout and stderr, and moving any input or output files that need moving to their appropriate

© 2003 by CRC Press LLC

site locations, and notifying the calling site proxy server when the tool has completed. This allows the site proxy server to continue receiving and processing invocation requests in a timely manner.

- **Tool Wrapper.** Tool wrapper changes directories into the specified `WORKDIR`, and then executes the `CMDLINE`.
- **External Tool.** External tools are the actual executable programs that run during a tool invocation. There is very little restriction on the nature of the external tools.

Communications Model

The Communications Model of IMEDA is perhaps the most complex portion of the system in some respects. This is where truly *distributed* communications come into play. One system component is communicating with another via network messages rather than function calls.

The heart of the communications model is the Communications Server. This server is implemented as a broadcast server. All incoming messages to the server are simply broadcast to all other connected parties. FlowObjects communicate with the Communications Server via ToolProxys. A ToolProxy allows a FlowObject to abstract all network communications and focus on the functionality of invoking tasks. A ToolProxy takes care of constructing a network message to invoke an external tool. That message is then sent to the Communications Server via a Communications Client. The Communication Client takes care of the low-level socket based communication complexities. Finally, the Communications Client sends the message to the Communications Server, which broadcasts the message to all connected clients. The client for which the message was intended (typically a Site Proxy Server) decodes the message and, depending on its type, creates either a ToolMonitor (for an Invocation Message) or an External Redraw Monitor (for a Redraw Request).

The Site Proxy Server creates these monitors to track the execution of external programs, rather than monitoring them itself. In this way, the Proxy Server can focus on its primary job — receiving and decoding network messages. When the Monitors invoke an external tool, they must do so within a Wrapper. Once the Monitors have observed the termination of an external program, they gather any output on *stdout* or *stderr* and return these along with the exit code of the program to the Site Proxy Server. The Proxy Server returns the results to the Communications Server, then the Communications Client, then the ToolProxy, and finally to the original calling FlowObject.

User Interface

The Cockpit provides both the user interface and core functionality of IMEDA. Figure 63.14 shows the system initial cockpit. While multiple users may use different instances of the Cockpit simultaneously, there is currently no provision for direct collaboration between multiple users. Developing efficient means of real-time interaction between IMEDA users is one of the major thrusts of the next development cycle.

Currently the GUI of the cockpit provides the following functionality:

- **Flow editing.** Users may create and edit process flows using the flow editor module of the Cockpit. The flow editor provides the user with a simple graphical interface that allows the use of a template of tools for "drawing" a flow. Flows can be optimally organized via services provided by a remote Layout Server written in Perl.
- **Production Library Maintenance.** The Cockpit provides functionality for user maintenance of collections of logical task productions, called libraries. Users may organize productions, modify input/output sets, or create/edit individual productions using flow editors.
- **Class Library Maintenance.** Users are provided with libraries of task and specification classes that are organized into a generalization–specialization hierarchy. Figure 63.15 shows an example of a task browser. Users can instantiate a class into an actual task, specification, selector, or database when creating a flow by simply dragging the appropriate class from a class browser and dropping

© 2003 by CRC Press LLC

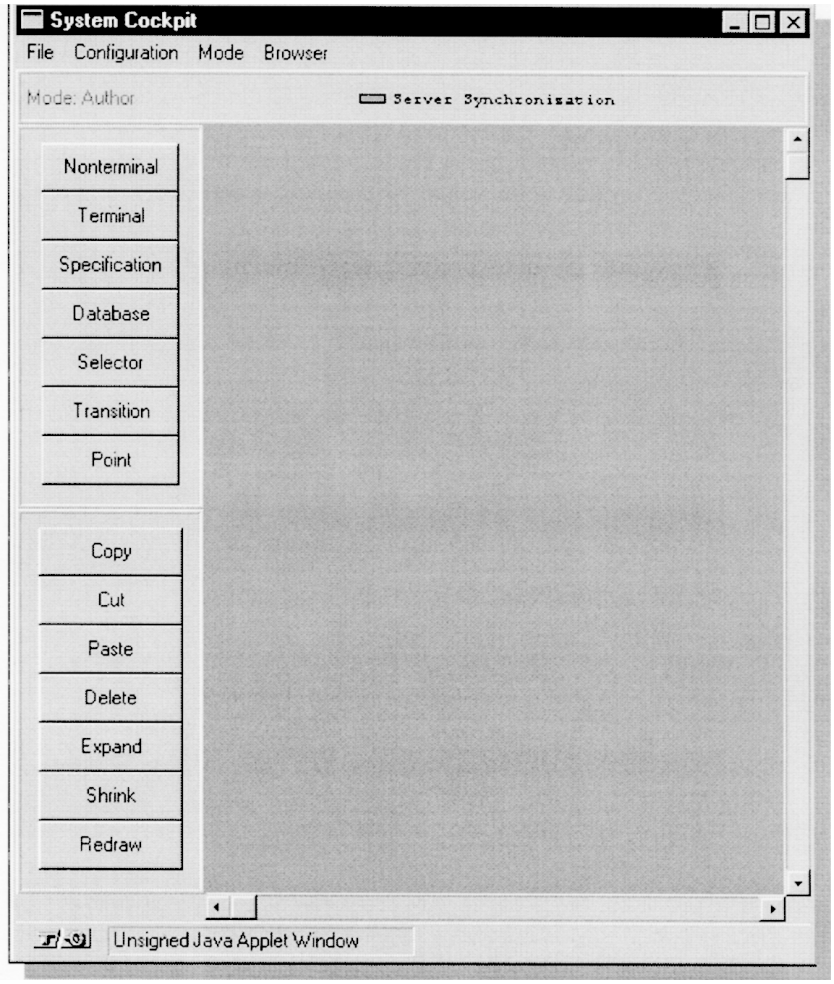

FIGURE 63.14 A system cockpit window.

it onto a flow editor's canvas. The Cockpit provides the user with a simple tree structure interface to facilitate the creation and maintenance of class libraries.

- **Process Simulation.** Processes may be simulated using the Cockpit. The Cockpit provides the user with several scheduler modules that determine how the process configuration space will be explored. The schedulers control the execution of external tools (through the appropriate site proxy servers) and simulation display (flow animation for user monitoring of simulation progress). There are multiple schedulers for the user to choose from when simulating a process, including the manual scheduler, comprehensive linear scheduler, etc.
- **Process Archival.** The Cockpit allows processes to be archived on a remote server using the Java File System (JFS). The Cockpit is enabled by a JFS client interface to connect to a remote JFS server where process files are saved and loaded. While the JFS system has its clear advantages, it is also awkward to not allow users to save process files, libraries, etc. on their local systems. Until version 1.1 of the Java Development Kit, local storage by a Java applet was simply not an option — the browser JVM definition did not allow access to most local resources. With version 1.1 of the JDK, however, comes the ability to electronically sign an applet. Once this has been done, users can grant privileged resource access to specific applets after a signature has been verified.

Design Flow Graph Properties

Initially, a flow graph created by a user using GUI is not associated with any system-specific information. For example, when a designer creates an atomic task node in a flow graph, there is initially no association with any external tool. The framework must provide a mechanism for users to bind flow graph entities to the external tools or activities that they represent.

We have used the concept of *properties* to allow users to bind flow graph objects to external entities. In an attempt to maintain flexibility, properties have been implemented in a very generic fashion. Users can define any number of properties for flow object. There are a number of key properties that the framework recognizes for each type of flow object. The user defines these properties to communicate needed configuration data to the framework.

A property consists of a *property label* and *property contents.* The label identifies the property, and consists of an alpha–numeric string with no white space. The contents of a property is any string. Currently, users define properties using a freeform text input dialog, with each line defining a property. The first word on a line represents the property label, and the remainder of the line constitutes the property contents.

Property Inheritance

To further extend the flexibility of flow object properties, the framework requires that each flow object be associated with a *flow object class.* Classes allow designers to define properties that are common to all flow objects that inherit from that flow object class. Furthermore, classes are organized into a general-to-specific hierarchy, with children classes inheriting properties from parent classes.

Therefore, the properties of a particular class consist of any properties defined locally for that object, in addition to properties defined in the object's inherited class hierarchy. If a property is defined in both the flow object and one of its parent classes, the property definition in the flow object takes precedence. If a property is defined in more than one class in a class hierarchy, the "youngest" class (e.g., the child in a parent–child relationship) takes precedence.

Classes are defined in the Class Browsers of IMEDA. Designers that have identified a clear general-to-specific hierarchy of flow object classes can quickly create design flow graphs by dragging and dropping from class browsers onto flow design canvases. The user would then need only to overload those properties in the flow objects that are different from their respective parent classes.

For example, consider a class hierarchy of classes that all invoke the same external sort tool, but pass different flags to the tool, based on the context. It is likely that all of these tools will have properties in common,

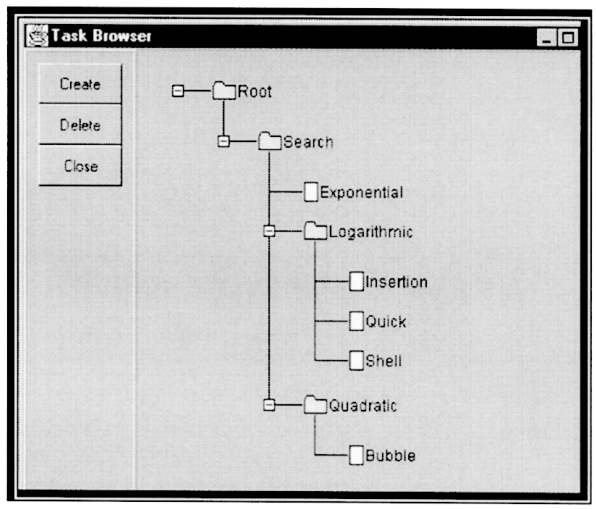

FIGURE 63.15 A task browser.

© 2003 by CRC Press LLC

such as a common working directory and tool site. By defining these common properties in a common ancestor of all of the classes, such as *Search*, it is unnecessary to redefine the properties in the children classes. Figure 63.16 shows an example of such a property window.

Of course, children classes can define new properties that are not contained in the parent classes, and may also overload property definitions provided by ancestors. Following these rules, class *Insertion* would have the following properties defined: `WORKDIR`, `SITE`, `WRAPPERPATH`, and `CMDLINE`.

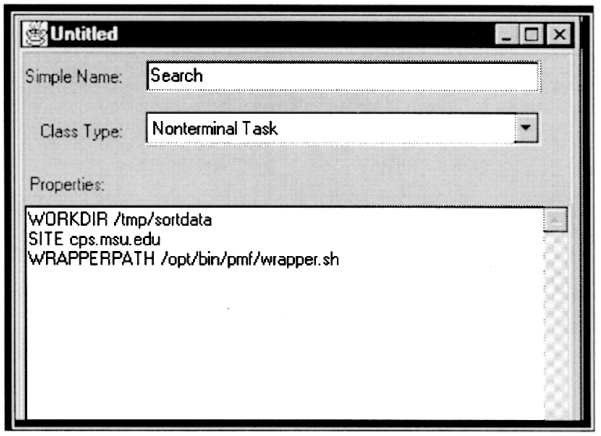

FIGURE 63.16 A property window and property inheritance.

Macro Substitution

While performing benchmarks on IMEDA, one cumbersome aspect of the framework that users often pointed out was the need to re-enter properties for tasks or specifications if, for example, a tool name or working directory changed. Finding every property that needed to be changed was a tedious job, and prone to errors.

In an attempt to deal with this problem, we came up with the idea of *property macros.* That is, a property macro is any macro that is not a key system macro. A macro is a textual substitution rule that can be created by users. By using macros in the property databases of flow objects, design flows can be made more flexible and more amiable to future changes.

As an example, consider a design flow that contains many atomic tasks bound to an external tool. Our previous example using searches is one possible scenario. On one system, the path to the external tool may be "/opt/bin/sort," while on another system the path is "`/user/keyesdav/public/bin/sort`." Making the flow object properties flexible is easy if a property macro named `SORTPATH` is defined in an ancestor of all affected flow objects. Children flow objects can then use that macro in place of a static path when specifying the flow object properties. As a further example, consider a modification to the previous "Search task hierarchy" where we define a macro `SORTPATH` in the Search class, and then use that macro in subsequent children classes, such as the Insertion class.

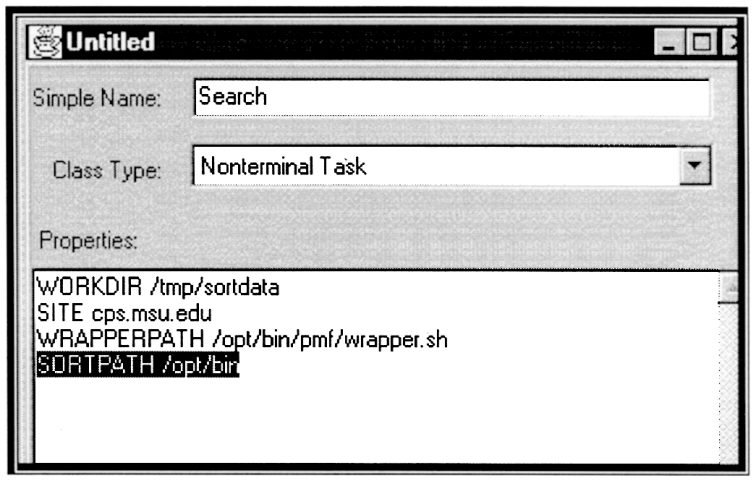

FIGURE 63.17
Macro definition.

© 2003 by CRC Press LLC

Figures 63.17 and 63.18 illustrate such a macro substitution. In the highlighted portion of the Property Database text area of Fig. 63.17, a macro called "SORTPATH" is defined. In subsequent class' Property Databases, this macro can be used in place of a static path as shown in Fig. 63.18. This makes it easy to change the path for all tools that use the SORTPATH property macro — just the property database dialog where SORTPATH is originally defined needs to be modified.

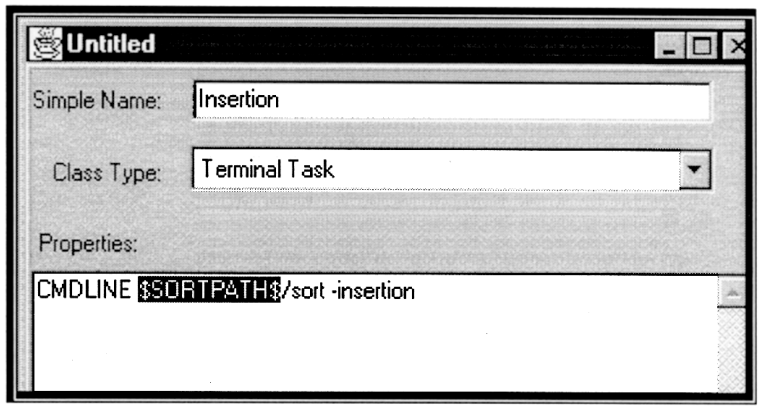

FIGURE 63.18 Macro substitution.

Key Framework Properties

In our current implementation of IMEDA, a number of key properties are defined. These properties allow users to communicate needed information to the framework in a flexible fashion. Most important, it allows system architects to define or modify system properties quickly. This is an important benefit when working with evolving software such as IMEDA.

63.7 Conclusion

Managing the design process is the key factor to improve the productivity in the micro-electronic industry. We have presented an **I**nternet-based **M**icro-**E**lectronic **D**esign **A**utomation (IMEDA) framework to manage the design process. IMEDA uses a powerful formalism, called design process grammars, for representing design processes. We have also proposed an execution environment that utilizes this formalism to assist designers in selecting and executing appropriate design processes. The proposed approach is applicable not only in rapid prototyping but also in any environment where a design is carried out hierarchically and many alternative processes are possible.

The primary advantages of our system are

- *Formalism*: A strong theoretical foundation enables us to analyze how our system will operate with different methodologies.
- *Parallelism*: In addition to performing independent tasks within a methodology in parallel, our system also allows multiple methodologies to be executed in parallel.
- *Extensibility*: New tools can be integrated easily by adding productions and manager programs.
- *Flexibility*: Many different control strategies can be used. They can even be mixed within the same design exercise.

The prototype of IMEDA is implemented using Java. We are integrating more tools into our prototype system and developing manager program templates that implement more sophisticated algorithms for pre-evaluation, logical task execution, and query handling. Our system will become more useful as CAD vendors to adapt open software systems and allow greater tool interoperability.

64.1 Introduction

The term **system**, when used in the digital design domain, implies many different entities. A system can consist of a processor, memory, and input/output, all on a single integrated circuit, or it can consist of a network of processors, geographically distributed, each performing a specific application. There can be a single clock, with modules communicating synchronously, multiple clocks with asynchronous communication, or an entirely asynchronous operation. The design can be general, or specific to a given application, i.e., application-specific. Together, the previously mentioned variations constitute the system style. To a great extent, system style selection is determined by the physical technologies used, the environment in which the system operates, designer experience, and corporate culture, and is not automated to any great extent.

System-level design covers a wide range of design activities and design situations. It includes the more specific activity system engineering, that involves the requirements development, test planning, subsystem interfacing, and end-to-end analysis of systems. System-level design is sometimes called system architecting, a term used widely in the aerospace industry.

General-purpose system-level design involves the design of programmable digital systems, including the basic modules containing storage, processors, input/output, and system controllers. At the system level, the design activities include determining the following:

© 2003 by CRC Press LLC

- Power budget (the amount of power allocated to each module in the system)
- Cost and performance budget allocated to each module in the system
- Interconnection strategy
- Selection of commercial off-the-shelf modules (COTS)
- Packaging of each module
- Overall packaging strategy
- Number of processors, storage units, and input/output interfaces required
- Overall characteristics of each processor, storage unit, and input/output interface

For example, memory system design focuses on the number of memory modules required, how they are organized, and the capacity of each module. A specific system-level issue in this domain can be the question of how to partition the memory between the processor chip and the off-chip memory. At a higher level, a similar issue might involve configuration of the complete storage hierarchy, including memory, disk drives, and archival storage.

For each general-purpose system designed, many systems are designed to perform specific applications. Application-specific system design involves the same activities as described previously, but can involve many more issues, since there are usually more custom logic modules involved. Specifications for application-specific systems contain not only requirements on general capabilities but also the functionality required in terms of specific tasks to be executed. Major application-specific, system-level design activities include not only the general-purpose system design activities, but the following activities as well:

- Partitioning an application into multiple functional modules
- Scheduling the application tasks on shared functional modules
- Allocating functional modules to perform the application tasks
- Allocating and scheduling storage modules to contain blocks of data as it is processed
- Determining the implementation styles of functional modules
- Determining the word lengths of data necessary to achieve a given accuracy of computation
- Predicting resulting system characteristics once the system design is complete

Each of the system design tasks given in the previous two lists will be described in subsequent detail. Since the majority of system design activities are application-specific, this section will focus on system-level design of application-specific systems. Related activities, hardware-software co-design, verification, and simulation are covered in other sections.

Design Philosophies and System-Level Design

Many design tools have been constructed with a top-down design philosophy. Top-down design represents a design process whereby the design becomes increasingly detailed until final implementation is complete. Considerable prediction of resulting system characteristics is required in order to make the higher-level decisions with some degree of success.

Bottom-up design, on the other hand, relies on designing a set of primitive elements and forming more complex modules from those elements. Ultimately, the modules are assembled into a system. At each stage of the design process there is complete knowledge of the parameters of the lower-level elements. However, the lower-level elements may be inappropriate for the tasks at hand.

Industry system designers describe the design process as being much less organized and considerably more complex than the top-down and bottom-up philosophies suggest. There is a mixture of top-down and bottom-up activities, with major bottlenecks of the system receiving detailed design consideration while other parts of the system still exist only as abstract specifications. For this reason, the system-level design activities presented in detail here support such a complex design situation. Modules, elements, and components used to design at the system level might exist or might only exist as abstract estimates along with requirements. The system can be designed after all modules have been designed and manufactured, prior to any detailed design, or with a mixture of existing and new modules.

The System Design Space

System design, like data path design, is quite straightforward as long as the constraints are not too severe. However, most modern system designs must solve harder problems than problems solved by existing systems; moreover, designers must race to produce working systems faster than competitors. More variations in design are possible than ever before, and such variations require that a large design space be explored. The dimensions of the design space (its axes) are system properties such as cost, power, design time, and performance. The design space contains a population of designs, each of which possesses different values of these system properties. There are literally millions of system designs for a given specification, each of which exhibits different cost, performance, power consumption, and design time. Straightforward solutions that do not attempt to optimize system properties are easy to obtain but may be inferior to designs that require use of system-level design tools and perhaps many iterations of design. The complexity of system design is not due to the fact that system design is an inherently difficult activity, but that so many variations in design are possible and time does not permit exploration of all of them.

64.2 System Specification

Complete system specifications contain a wide range of information including:

- Constraints on the system power, performance, cost, weight, size, and delivery time
- Required functionality of the system components
- Any required information about the system structure
- Required communication between system components
- The flow of data between components
- The flow of control in the system
- The specification of input precision and desired output precision

Most systems specifications that are reasonably complete exist first in a natural language. Such natural language interfaces are not currently available with commercial, system-level design tools.

More conventional system-specification methods, used to drive system-level design tools, include formal languages, graphs, or a mixture of the two. Each of the formal system-specification methods described here contains some of the information found in a complete specification, i.e., most specification methods are incomplete. The remaining information necessary for full system design can be provided interactively by the designer, can be entered later in the design process, or can be provided in other forms at the same time the specification is processed. The required design activities determine the specification method used for a given system design task.

There are no widely adopted formal languages for system-level hardware design although SLDL (system-level design language) is currently being developed by an industry group. Hardware descriptive languages such as VHDL[1] and Verilog[2] are used to describe the functionality of modules in an application-specific system. High-level synthesis tools can then synthesize such descriptions to produce register-transfer designs. Extensions of VHDL have been proposed to encompass more system-level design properties. Apart from system constraints, VHDL specifications can form complete system descriptions. However, the level of detail required in VHDL, and to some extent in Verilog, requires the designer to make some implementation decisions. In addition, some information explicit in more abstract specifications, such as the flow of control between tasks, is implicit in HDLs.

Graphical tools have been used for a number of years to describe system behavior and structure. Block diagrams are often used to describe system structure. Block diagrams assume that tasks have already been assigned to basic blocks and that their configuration in the system has been specified. They generally cannot represent the flow of data or control, or design constraints. The PMS (processor memory switch) notation invented by Bell and Newell was an early attempt to formalize the use of block diagrams for system specification.[3]

© 2003 by CRC Press LLC

Petri nets have been used for many years to describe system behavior using a token-flow model. A token-flow model represents the flow of control with tokens, which flow from one activity of the system to another. Many tokens can be active in a given model concurrently, representing asynchronous activity and parallelism, important in many system designs. Timed Petri nets have been used to model system performance, but Petri nets cannot easily be used to model other system constraints, system behavior, or any structural information.

State diagrams and graphical tools such as State Charts[4] provide alternative methods for describing systems. Such tools provide mechanisms to describe the flow of control, but they do not describe system constraints, system structure, data flow, or functionality.

Task-flow graphs, an outgrowth from the control/data-flow graphs (CDFG) used in high-level synthesis, are often used for system specification. These graphs describe the flow of control and data between tasks. When used in a hierarchical fashion, task nodes in the task-flow graph can contain detailed functional information about each task, often in the form of a CDFG. Task flow graphs contain no mechanisms for describing system constraints or system structure.

Spec Charts[5] incorporate VHDL descriptions into State-Chart-like notation, overcoming the lack of functional information found in State Charts.

Figure 64.1 illustrates the use of block diagrams, Petri nets, task flow graphs, and spec charts.

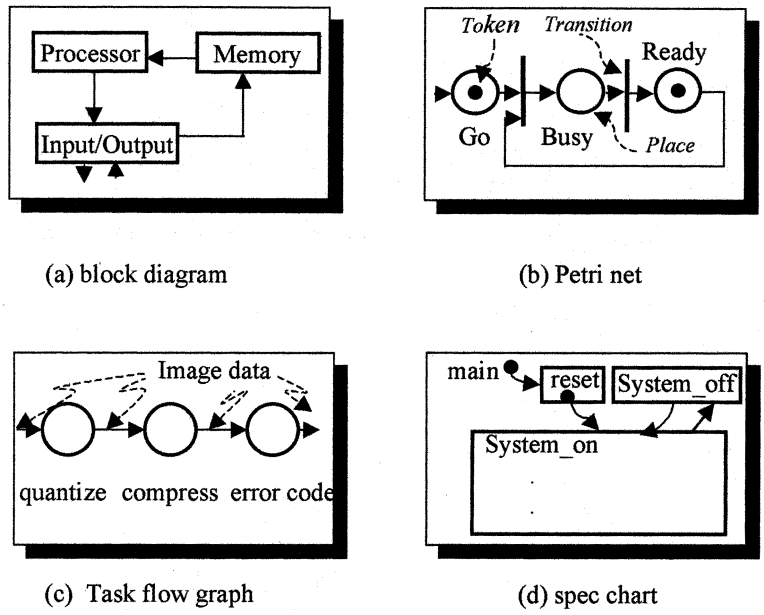

FIGURE 64.1 The use of block diagrams, Petri nets, task flow graphs, and spec charts, shown in simplified form.

64.3 System Partitioning

Most systems are too large to fit on a single substrate. If the complexity of the system tasks and the capacity of the system modules are of the same order, then partitioning is not required. All other systems must be partitioned so that they fit into the allowed substrates, packages, boards, multi-chip modules, and cases. Partitioning determines the functions, tasks, or operations in each partition of a system. Each partition can represent a substrate, package, multi-chip module, or larger component. Partitioning is performed with respect to a number of goals, including minimizing cost, design time, or power, or maximizing performance. Any of these goals can be reformulated as specific constraints, like meeting given power requirements.

© 2003 by CRC Press LLC

When systems are partitioned, resulting communication delays must be taken into account, affecting performance. Limitations on interconnection size must be taken into account, affecting performance as well. Pin and interconnection limitations force the multiplexing of inputs and outputs, reducing performance, and sometimes affecting cost. Power consumption must also be taken into account. Power balancing between partitions and total power consumption might both be considerations. In order to meet market windows, system partitions can facilitate the use of COTS, programmable components, or easily fabricated components such as gate arrays. In order to meet cost constraints, functions that are found in the same partition might share partition resources. Such functions or tasks cannot execute concurrently, affecting performance.

Partitioning is widely used at the logic level, as well as on physical designs. In these cases, much more information is known about the design properties, and the interconnection structure has been determined. System partitioning is performed when information about the specific components' properties might be uncertain, and the interconnection structure undetermined. For these reasons, techniques used at lower levels must be modified to include predictions of design properties not yet known and prediction of the possible interconnection structure as a result of the partitioning.

The exact partitioning method used depends on the type of specification available. If detailed CDFG or HDL specifications are used, the partitioning method might be concerned with which register-transfer functions (e.g., add, multiply, shift) are found in each partition. If the specification primitives are tasks, as in a task-flow graph specification, then the tasks must be assigned to partitions. Generally, the more detailed the specification, the larger the size of the partitioning problem. Powerful partitioning methods can be applied to problems of small size ($n < 100$). Weaker methods such as incremental improvement must be used when the problem size is larger.

Partitioning methods can be based on constructive partitioning or iterative improvement. Constructive partitioning involves taking an unpartitioned design and assigning operations or tasks to partitions. Basic constructive partitioning methods include bin packing using a first-fit decreasing heuristic, clustering operations into partitions by assigning nearest neighbors to the same partition until the partition is full, random placement into partitions, and integer programming approaches.

Constructive Partitioning Techniques

Bin packing involves creating a number of bins equal in number to the number of partitions desired and equal in size to the size of partitions desired. Then, the tasks or operations are sorted by size. The largest task in the list is placed in the first bin, and then the next largest is placed in the first bin, if it will fit, or if it does not fit, into the second bin. Each task is placed into the first bin in which it will fit, until all tasks have been placed in bins. More bins are added if necessary. This simple heuristic is useful to create an initial set of partitions to be improved iteratively later.

Clustering is a more powerful method to create partitions. Here is a simple clustering heuristic. Each task is ranked by the extent of "connections" to other tasks either due to control flow, data flow, or physical position limitations. The most connected task is placed in the first partition, and then the tasks connected to it are placed in the same partition, in order of the strength of their connections to the first task. Once the partition is full, the task with the most total connections remaining outside a partition is placed in a new partition, and other tasks are placed there in order of their connections to the first task. This heuristic continues until all tasks are placed.

Random partitioning places tasks into partitions in a greedy fashion until the partitions are full. Some randomization of the choice of tasks is useful in producing a family of systems, of which each member is partitioned randomly. This family of systems can be used successfully in iterative improvement techniques for partitioning, as described later in this section.

The most powerful technique for constructive partitioning is mathematical programming. Integer and mixed integer-linear programming techniques have been used frequently in the past for partitioning. Such powerful techniques are computationally very expensive, and they are successful only when the number of objects to be partitioned is small. The basic idea behind integer programming used for

© 2003 by CRC Press LLC

partitioning is the following: An integer, $TP(i,j)$, is used to represent the assignment of tasks to partitions. When $TP = 1$, task i is assigned to partition j. For each task in this problem, there would be an equation

$$\sum_{j=1}^{partition\ total} TP(i,j) = 1 \tag{64.1}$$

This equation more or less states that each task must be assigned to one and only one partition. There would be many constraints of this type in the integer program, some of which were inequalities. There would be one function representing cost, performance, or other design property, to be optimized. The simultaneous solution of all constraints, given some minimization or maximization goal, would yield the optimal partitioning.

Apart from the computational complexity of this technique, the formulation of the mathematical programming constraints is tedious and error prone if performed manually. The most important advantage of mathematical programming formulations is the discipline it imposes on the computer-aided design (CAD) programmer in formulating an exact definition of the CAD problem to be solved. Such problem formulations can prove useful when applied in a more practical environment, as described below in the next section, "Iterative Partitioning Techniques."

Iterative Partitioning Techniques

Of the many iterative partitioning techniques available, two have been applied most successfully at the system level. These techniques are min-cut partitioning, first proposed by Kernigan and Lin, and genetic algorithms.

Min-cut partitioning involves exchanging tasks or operations between partitions in order to minimize the total amount of "interconnections" cut. The interconnections can be computed as the sum of data flowing between partitions, or as the sum of an estimate of the actual interconnections that will be required in the system. The advantage of summing the data flowing is that it provides a quick computation, since the numbers are contained in the task flow graph. Better partitions can be obtained if the required physical interconnections are taken into account, since they are related more directly to cost and performance than to the amount of data flowing. If a partial structure exists for the design, predicting the unknown interconnections allows partitioning to be performed on a mixed design, one that contains existing parts as well as parts under design.

Genetic algorithms, highly popular for many engineering optimization problems, are especially suited to the partitioning problem. The problem formulation is similar in some ways to mathematical programming formulations. A simple genetic algorithm for partitioning is described here. In this example, a chromosome represents each partitioned system design, and each chromosome contains genes, representing information about the system. A particular gene, $TP(i,j)$, might represent the fact that task i is contained in partition j when it is equal to 1, and is set to 0 otherwise. A family of designs created by some constructive partitioning technique then undergoes mutation and crossover as new designs evolve. A fitness function is used to check the quality of the design, and the evolution is halted when the design is considered fit, or when no improvement has occurred after some time. In the case of partitioning, the fitness function might include the estimated volume of interconnections, the predicted cost or performance of the system, or other system properties.

The reader might note some similarity between the mathematical programming formulation of the partitioning problem presented here and the genetic algorithm formulation. This similarity allows the CAD developer to create a mathematical programming model of the problem to be solved, find optimal solutions to small problems, and create a genetic algorithm version. The genetic algorithm version can be checked against the optimal solutions found by the mathematical program. However, genetic

© 2003 by CRC Press LLC

algorithms can take into account many more details than can mathematical program formulations, can handle nonlinear relationships better, and can even handle stochastic parameters.[1]

Partitioning is most valuable when a mismatch exists between the sizes of system tasks and the capacities of system modules. When the system tasks and system modules are more closely matched, then the system design can proceed directly to scheduling and allocating tasks to processing modules.

64.4 Scheduling and Allocating Tasks to Processing Modules

Scheduling and allocating tasks to processing modules involve the determination of how many processing modules are required, which modules execute which tasks, and the order in which tasks are processed by the system. In the special case where only a single task is processed by each module, the scheduling becomes trivial. Otherwise, if the tasks share modules, the order in which the tasks are processed by the modules can affect system performance or cost. If the tasks are ordered inappropriately, some tasks might wait too long for input data, and performance might be affected. Or, in order to meet performance constraints, additional modules must be added to perform more tasks in parallel, increasing system cost.

A variety of modules might be available to carry out each task, with differing cost and performance parameters. As each task is allocated to a module, that module is selected from a set of modules available to execute the task. This is analogous to the task module selection, which occurs as part of high-level synthesis. For the system design problem considered here, the modules can be either general-purpose processors, special-purpose processors (e.g., signal processing processors), or special-purpose hardware. If all (or most) modules used are general-purpose, the systems synthesized are known as heterogeneous application-specific multiprocessors.

A variety of techniques can be used for the scheduling and allocation of system tasks to modules. Just as with partitioning, these techniques can be constructive or iterative. Constructive scheduling techniques for system tasks include greedy techniques such as ASAP (as soon as possible) and ALAP (as late as possible). In ASAP scheduling, the tasks are scheduled as early as possible on a free processing module. The tasks scheduled first are the ones with the longest paths from their outputs to final system outputs or system completion. Such techniques, with variations, can be used to provide starting populations of system designs to be further improved iteratively. The use of such greedy techniques for system synthesis differs from the conventional use in high-level synthesis, where the system is assumed to be synchronous, with tasks scheduled into time steps. System task scheduling assumes no central clock, and tasks take a wide range of times to complete. Some tasks could even complete stochastically, with completion time a random variable. Other tasks could complete basic calculations in a set time, but could perform a finer grain (more accurate) of computations if more time were available. A simple task-flow graph is shown in Fig. 64.2, along with a Gantt chart illustrating the ASAP scheduling of tasks onto two processors. Note that two lengthy tasks are performed in parallel with three shorter tasks, and that no two tasks take the same amount of time.

Similar to partitioning, scheduling and allocation, along with module selection, can be performed using mathematical programming. In this case, since the scheduling is asynchronous, time becomes a linear rather than integer quantity. Therefore, mixed integer-linear programming (MILP) is employed to model system-level scheduling and allocation. A typical MILP timing constraint is the following:

$$T_{OA}\left(i\right) + Cdelay \le T_{IR}\left(j\right) \tag{64.2}$$

[1]Stochastic parameters represent values that are uncertain. There is a finite probability of a parameter taking a specific value that varies with time, but that in general, probability is less than one.

© 2003 by CRC Press LLC

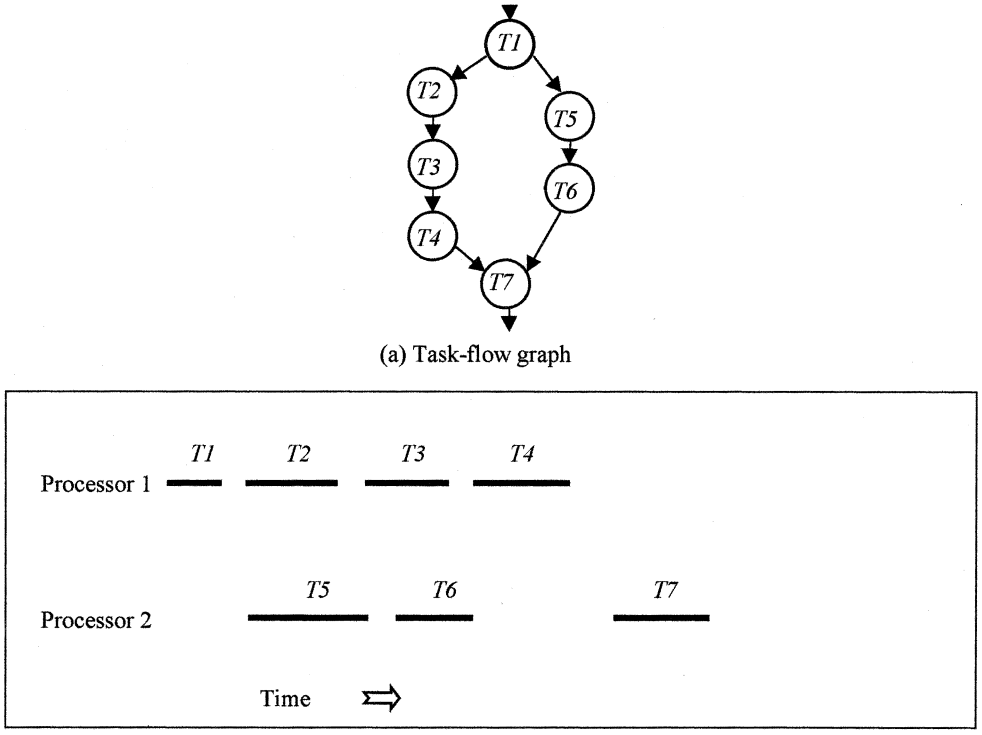

FIGURE 64.2 An example task-flow graph and schedule.

where $T_{OA}(i)$ is the time the output is available from task *i*, *Cdelay* is the communication delay, and $T_{IR}(j)$ is the time the input is required by task *j*. Unfortunately, the actual constraints used in scheduling and allocation are mostly more complex than this, because the design choices have yet to be made. Here is another example:

$$T_{OA}(i) \geq T_{IR}(i) + \sum_{k} \left[Pdelay(k) * M(i,k) \right] \tag{64.3}$$

This constraint states that the time an output from task *i* is available is greater than or equal to the time necessary inputs are received by task *i*, and a processing delay (*Pdelay*) has occurred. $M(i,k)$ indicates that task *i* is allocated to module *k*. *Pdelay* can take on a range of values, depending on which of k modules is being used to implement task *i*. The summation is actually a linearized select function that picks the value of *Pdelay* to use depending on which value of $M(i,k)$ is set to 1.

As with partitioning, mathematical programming for scheduling and allocation is computationally intensive and impractical for all but the smallest designs, but it does provide a baseline model of design that can be incorporated in other tools.

The most frequent technique used for iterative improvement in scheduling and allocation at the system level is a genetic algorithm. The genes can be used to represent task allocation and scheduling. In order to represent asynchronous scheduling accurately, time is generally represented as a linear quantity in such genes, rather than an integer quantity.

© 2003 by CRC Press LLC

64.5 Allocating and Scheduling Storage Modules

In digital systems, all data requires some form of temporary or permanent storage. If the storage is shared by several data sets, the use of the storage by each data set must be scheduled. The importance of this task in system design has been overlooked in the past, but it has now become an important system-level task.

Modern digital systems usually contain some multimedia tasks and data. The storage requirements for multimedia tasks sometimes result in systems where processing costs are dwarfed by storage costs, particularly caching costs. For such systems, storage must be scheduled and allocated either during or after task scheduling and allocation. If storage is scheduled and allocated concurrently with task scheduling and allocation, the total system costs are easier to determine, and functional module sharing can be increased if necessary in order to control total costs. On the other hand, if storage allocation and scheduling are performed after task scheduling and allocation, then both programs are simpler, but the result may not be as close to optimal.

Techniques similar to those used for task scheduling and allocation can be used for storage scheduling and allocation.

64.6 Selecting Implementation and Packaging Styles for System Modules

Packaging styles can range from single-chip dual-in-line packages (DIPs) to multi-chip modules (MCMs), boards, racks, and cases. Implementation styles include general-purpose processor, special-purpose programmable processor (e.g., signal processor), COTS modules, field programmable gate arrays (FPGAs), gate array, standard cell, and custom integrated circuits. For many system designs, system cost, performance, power, and design time constraints determine selection of implementation and packaging styles. Tight performance constraints favor custom integrated circuits, packaged in multi-chip modules. Tight cost constraints favor off-the-shelf processors and gate array implementations, with small substrates and inexpensive packaging. Tight power constraints favor custom circuits. Tight design time constraints favor COTS modules and FPGAs. If a single design property has high priority, the designer can select the appropriate implementation style and packaging technology. If, however, design time is crucial, but the system to be designed must process video signals in real time, then tradeoffs in packaging and implementation style must be made. The optimality of system cost and power consumption might be sacrificed: The entire design might be built with FPGAs, with much parallel processing and at great cost and large size. Because time-to-market is so important, early market entry systems may sacrifice the optimality of many system parameters initially and then improve them in the next version of the product.

Selection of implementation styles and packaging can be accomplished by adding some design parameters to the scheduling and allocation program, if that program is not already computationally intensive. The parameters added would include:

- A variable indicating that a particular functional module was assigned a certain implementation style
- A variable indicating that a particular storage module was assigned a certain implementation style
- A variable indicating that a particular functional module was assigned a certain packaging style
- A variable indicating that a particular storage module was assigned a certain packaging style

Some economy of processing could be obtained if certain implementation styles precluded certain packaging styles.

64.7 The Interconnection Strategy

Modules in a digital system are usually interconnected in some carefully architected, consistent manner. If point-to-point interconnections are used, they are used throughout the system, or in a subsystem. In the

© 2003 by CRC Press LLC

same manner, buses are not broken arbitrarily to insert point-to-point connections or rings. For this reason, digital system design programs usually assume an interconnection style and determine the system performance relative to that style. The most common interconnection styles are bus, point-to-point, and ring.

64.8 Word Length Determination

Functional specifications for system tasks are frequently detailed enough to contain the algorithm to be implemented. In order to determine the implementation costs of each system task, knowledge of the word widths to be used is important, as system cost varies almost quadratically with word width.

Tools to automatically select task word width are currently experimental, but the potential for future commercial tools exists.

In typical hardware implementations of an arithmetic-intensive algorithm, designers must determine the word lengths of resources such as adders, multipliers, and registers. In a recent publication,[6] Wadekar and Parker presented algorithm-level optimization techniques to select distinct word lengths for each computation which meet the desired accuracy and minimize the design cost for the given performance constraints. The cost reduction is possible by avoiding unnecessary bit-level computations that do not contribute significantly to the accuracy of the final results. At the algorithm level, determining the necessary and sufficient precision of an individual computation is a difficult task, since the precision of various predecessor/successor operations can be traded off to achieve the same desired precision in the final result. This is achieved using a mathematical model[7] and a genetic selection mechanism.[6] There is a distinct advantage to word-length optimization at the algorithmic level. The optimized operation word lengths can be used to guide high-level synthesis or designers to achieve an efficient utilization of resources of distinct word lengths and costs. Specifically, only a few resources of larger word lengths and high cost may be needed for operations requiring high precision to meet the final accuracy requirement. Other relatively low-precision operations may be executed by resources of smaller word lengths. If there is no timing conflict, a large word length resource can also execute a small word length operation, thus improving the overall resource utilization further. These high-level design decisions cannot be made without the knowledge of word lengths prior to synthesis.

64.9 Predicting System Characteristics

In system-level design, early prediction gives designers the freedom to make numerous high-level choices (such as die size, package type, and latency of the pipeline) with confidence that the final implementation will meet power and energy as well as cost and performance constraints. These predictions can guide power budgeting and subsequent synthesis of various system components, which is critical in synthesizing systems that have low power dissipation, or long battery life. The use by synthesis programs of performance and cost lower bounds allows smaller solution spaces to be searched, which leads to faster computation of the optimal solution.

System cost, performance, power consumption, and design time can be computed if the properties of each system module are known. System design using existing modules requires little prediction. However, if system design is performed prior to design of any of the contained system modules, their properties must be predicted or estimated. Due to the complexities of prediction techniques, describing these techniques is a subject worthy of an entire chapter. A brief survey of related readings is found in the next section.

The register-transfer and subsequent lower level power prediction techniques such as gate- and transistor-level techniques are essential for validation before fabricating the circuit. However, these techniques are less efficient for system-level design process, as a design must be generated before prediction can be done.

64.10 A Survey of Research in System Design

Many researchers have investigated the problem of system design, dating back to the early 1970s. This section highlights work that is distinctive, along with tutorial articles covering relevant topics. Much

© 2003 by CRC Press LLC

good research is not referenced here, and the reader is reminded that the field is dynamic, with new techniques and tools appearing almost daily.

Issues in top-down vs. bottom-up design approaches were highlighted in the design experiment reported by Gupta et al.[8]

System Specification

System specification has received little attention historically except in the specific area of software specifications. Several researchers have proposed natural language interfaces capable of processing system specifications and creating internal representations of the systems that are considerably more structured. Of note is the work by Granacki and Parker[9] and Cyre et al.[10] One noteworthy approach is the Design Specification Language (DSL), found in the Design Analysis and Synthesis Environment.[11] One of the few books on the subject concerns the design of embedded systems — systems with hardware and software designed for a particular application set.[12] In one particular effort, Petri nets were used to specify the interface requirements in a system of communicating modules, which were then synthesized.[13] The SIERA system designed by Srivastava, Richards, and Broderson[14] supports specification, simulation, and interactive design of systems.

Partitioning

Partitioning research covers a wide range of system design situations. Many early partitioning techniques dealt with assigning register-level operations to partitions. APARTY, a partitioner designed by Lagnese and Thomas, partitions CDFG designs for single-chip implementation in order to obtain efficient layouts.[15] Vahid[16] performed a detailed survey of techniques for assigning operations to partitions. CHOP assigns CDFG operations to partitions for multi-chip design of synchronous, common clocked systems.[17] Vahid and Gajski developed an early partitioner, SpecPart, which assigns processes to partitions.[18] Chen and Parker reported on a process-to-partition technique called ProPart.[19]

Non-Pipelined Design

Although research on **system design** spans more than two decades, most of the earlier works focus on single aspects of design like task assignment, and not on the entire design problem. We cite some representative works here. These include graph theoretical approaches to task assignment,[20,21] analytical modeling approaches for task assignment,[22] and probabilistic modeling approaches for task partitioning,[23,24] scheduling,[25] and synthesis.[26] Two publications of note cover application of heuristics to system design.[27,28]

Other noteworthy publications include mathematical programming formulations for task partitioning[29] and communication channel assignment.[30] Early efforts include those done by soviet researchers since the beginning of the 1970s such as Linsky and Kornev[31] and others, where each model only included a subset of the entire synthesis problem. Chu et al.[32] published one of the first mixed integer-linear programming (MILP) models for a sub-problem of system-level design, scheduling. Recently the program SOS (Synthesis of Systems), including a compiler for MILP models[33,34] was developed, based on a comprehensive MILP model for system synthesis. SOS takes a description of a system described using a task-flow graph, a processor library and some cost and performance constraints, and generates an MILP model to be optimized by an MILP solver. The SOS tool generates MILP models for the design of non-periodic (non-pipelined) heterogeneous multiprocessors. The models share a common structure, which is an extension of the previous work by Hafer and Parker for high-level synthesis of digital systems.[35]

Performance bounds of solutions found by algorithms or heuristics for system-level design are proposed in many papers, including the landmark papers by Fernandez and Bussel[36] and Garey and Graham[37] and more recent publications.[38]

© 2003 by CRC Press LLC

The recent work of Gupta et al.[8] reported the successful use of system-level design tools in the development of an application-specific heterogeneous multiprocessor for image processing. Gupta and Zorian[39] describe the design of systems using cores, silicon cells with at least 5000 gates. The same issue of Design and Test contains a number of useful articles on design of embedded core-based systems. Li and Wolf[40] report on a model of hierarchical memory and a multiprocessor synthesis algorithm which takes into account the hierarchical memory structure.

A major project, RASSP, is a rapid-prototyping approach whose development is funded by the U.S. Department of Defense.[41] RASSP addresses the integrated design of hardware and software for signal processing applications.

An early work on board-level design, MICON, is of particular interest.[42] Newer research results solving similar problems with more degrees of design freedom include the research by Chen[43] and Heo.[44] GARDEN, written by Heo, finds the design with the shortest estimated time to market, which meets cost and performance constraints.

All the MILP synthesis works cited to this point address only the nonperiodic case.

Synthesis of application-specific heterogeneous multiprocessors is a major activity in the general area of system synthesis. One of the most significant system-level design efforts is Lee's Ptolemy project at the University of California, Berkeley. Representative publications include papers by Lee and Bier describing a simulation environment for signal processing[45] and the paper by Kalavade et al.[46] Another prominant effort is the SpecSyn project,[47] which is a system-level design methodology and framework.

Macro-Pipelined Design

Macro-pipelined (periodic) multiprocessors execute tasks in a pipelined fashion, with tasks executing concurrently on different sets of data. Most research work on design of macro-pipelined multiprocessors has been restricted to homogeneous multiprocessors having negligible communication costs. This survey divides the past contributions according to the execution mode: preemptive or nonpreemptive.

Nonpreemptive Mode

The nonpreemptive mode of execution assumes that each task is executed without interruption. It is used quite often in low-cost implementations. Much research has been performed on system scheduling for the nonpreemptive mode. A method to compute the minimum possible value for the initiation interval for a task-flow graph given an unlimited number of processors and no communication costs was found by Renfors and Neuvo.[48]

Wang and Hu[49] use heuristics for the allocation and full static scheduling (meaning that each task is executed on the same processor for all iterations) of generalized perfect-rate task-flow graphs on homogeneous multiprocessors. Wang and Hu apply planning, an artificial intelligence method, to the task scheduling problem. The processor allocation problem is solved using a conflict-graph approach.

Gelabert and Barnwell[50] developed an optimal method to design macro-pipelined homogeneous multiprocessors using cyclic-static scheduling, where the task-to-processor mapping is not time-invariant as in the full static case, but is periodic, i.e., the tasks are successively executed by all processors. Gelabert and Barnwell assume that the delays for intra-processor and inter-processor communications are the same, which is an idealistic scenario. Their approach is able to find an optimal implementation (minimal iteration interval) in exponential time in the worst case.

In his doctoral thesis, Tirat-Gefen[51] extended the SOS MILP model to solve for optimal macro-pipelined, application-specific heterogeneous multiprocessors. He also proposed an integer-linear programming (ILP) model allowing simultaneous optimal retiming and processor/module selection in high and system-level synthesis.[52]

Verhaegh[53] addresses the problem of periodic multidimensional scheduling. His thesis uses an ILP model to handle the design of homogeneous multiprocessors without communication costs implementing data-flow programs with nested loops. His work evaluates the complexity of the scheduling and

© 2003 by CRC Press LLC

allocation problems for the multidimensional case, which were both found to be NP-complete. Verhaegh proposes a set of heuristics to handle both problems.

Passos and Sha[54] evaluate the use of multi-dimensional retiming for synchronous data-flow graphs. However, their formalism can only be applied to homogeneous multiprocessors without communication costs.

The Preemptive Mode of Execution

Feng and Shin[55] address the optimal static allocation of periodic tasks with precedence constraints and preemption on a homogeneous multiprocessor. Their approach has an exponential time complexity. Ramamrithan[56] developed a heuristic method that has a more reasonable computational cost. Rate-monotonic scheduling (RMS) is a commonly used method for allocating periodic real-time tasks in distributed systems.[57] The same method can be used in homogeneous multiprocessors.

Genetic Algorithms

Genetic algorithms are becoming an important tool for solving the highly non-linear problems related to system-level synthesis. The use of genetic algorithms in optimization is well discussed by Michalewicz[58] where formulations for problems such as bin packing, processor scheduling, traveling salesman, and system partitioning are outlined.

Research works involving the use of genetic algorithms to system-level synthesis problems are starting to be published, for example, as are the results of the following:

- Hou et al.[59] — scheduling of tasks in a homogeneous multiprocessor without communication costs
- Wang et al.[60] — scheduling of tasks in heterogeneous multiprocessors with communication costs but not allowing cost vs. performance tradeoff, i.e., all processors have the same cost
- Ravikumar and Gupta[61] — mapping of tasks into a reconfigurable homogeneous array processor without communication costs
- Tirat-Gefen and Parker[62] — a genetic algorithm for design of application-specific heterogeneous multiprocessors (ASHM) with nonnegligible communications costs specified by a nonperiodic task-flow graph representing both control and data flow
- Tirat-Gefen[51] — introduced a full-set of genetic algorithms for system-level design of ASHMs incorporating new design features such as imprecise computation and probabilistic design

Imprecise Computation

The main results in imprecise computation theory are due to Liu et al.[63] who developed polynomial time algorithms for optimal scheduling of preemptive tasks on homogeneous multiprocessors without communications costs. Ho et al.[64] proposed an approach to minimize the total error, where the error of a task being imprecisely executed is proportional to the amount of time that its optional part was not allowed to execute, i.e., the time still needed for its full completion. Polynomial time-optimal algorithms were derived for some instances of the problem.[63]

Tirat-Gefen et al.[65] presented a new approach for application-specific, heterogeneous multiprocessor design that allows trade-offs between cost, performance, and data quality through incorporation of imprecise computation into the system-level design cycle.

Probabilistic Models and Stochastic Simulation

Many probabilistic models for solving different subproblems in digital design have been proposed recently. The problem of task and data-transfer scheduling on a multiprocessor when some tasks (data transfers) have nondeterministic execution times, (communication-times) can be modeled by PERT networks, which were introduced by Malcolm et al.[66] along with the critical path method (CPM) analysis methodology.

© 2003 by CRC Press LLC

A survey on PERT networks and their generalization to conditional PERT networks is done by Elmaghraby.[67] In system-level design, the completion time of a PERT network corresponds to the system latency, whose cumulative distribution is a nonlinear function of the probability density distributions of the computation times of the tasks and the communication times of the data transfers in the task-flow graph.

The exact computation of the cumulative probability distribution function (c.d.f.) of the completion time is computationally expensive for large PERT networks, therefore it is important to find approaches that approximate the value of the expected time of the completion time and its c.d.f. One of the first of these approaches was due to Fulkerson,[68] who derived an algorithm to find a tight estimate (lower bound) of the expected value of the completion time. Robillard and Trahan[69] proposed a different method using the characteristic function of the completion time in approximating the c.d.f. of the completion time.

Mehrotra et al.[70] proposed a heuristic for estimating the moments of the probabilistic distribution of the system latency t_c. Kulkarni and Adlakha[71] developed an approach based on Markov processes for the same problem. Hagstrom[72] introduced an exact solution for the problem when the random variables modeling the computation and communication times are finite discrete random variables. Kamburowski[73] developed a tight upper bound on the expected completion time of a PERT network.

An approach using random graphs to model distributed computations was introduced by Indurkhya et al.,[23] whose theoretical results were improved by Nicol.[24] Purushotaman and Subrahmanyam[74] proposed formal methods applied to concurrent systems with a probabilistic behavior. An example of modeling using queueing networks instead of PERT networks is given by Thomasian and Bay.[75] Estimating errors due to the use of PERT assumptions in scheduling problems is discussed by Lukaszewicz.[76]

Tirat-Gefen developed a set of genetic algorithms using stratified stochastic sampling allowing simultaneous probabilistic optimization of the scheduling and allocation of tasks and communications on application-specific heterogeneous multiprocessor with nonnegligible communication costs.[51]

Performance Bounds Theory and Prediction

Sastry[77] developed a stochastic approach for estimation of wireability (routability) for gate arrays. Kurdahi[78] created a discrete probabilistic model for area estimation of VLSI chips designed according to a standard cell methodology. Küçükçakar[79] introduced a method for partitioning of behavioral specifications onto multiple VLSI chips using probabilistic area/performance predictors integrated into a package called BEST (Behavioral ESTimation). BEST provides a range of prediction techniques that can be applied at the algorithm level and includes references to prior research. These predictors provide information required by Tirat-Gefen's system-level probabilistic optimization methods.[51]

Lower bounds on the performance and execution time of task-flow graphs mapped to a set of available processors and communication links were developed by Liu and Liu[80] for the case of heterogeneous processors but no communication costs and by Hwang et al.[81] for homogeneous processors with communication costs. Tight lower bounds on the number of processors and execution time for the case of homogeneous processors in the presence of communication costs were developed by Al-Mouhamed.[82] Yen and Wolf[83] provide a technique for performance estimation for real-time distributed systems.

At the system and register-transfer level, estimating power consumption by the interconnect is important.[84] Wadekar et al.[85] reported "Freedom," a tool to estimate system energy and power that accounts for functional-resource, register, multiplexer, memory, input/output pads, and interconnect power. This tool employees a statistical estimation technique to associate low-level, technology-dependent, physical and electrical parameters with expected circuit resources and interconnection. At the system level, "Freedom" generates predictions with high accuracy by deriving an accurate model of the load capacitance for the given target technology — a task reported as critical in high level power prediction by Brand and Visweswariah.[86] Methods to estimate power consumption prior to high-level synthesis were also investigated by Mehra and Rabaey.[87] Liu and Svensson[88] reported a technique to estimate power consumption in CMOS VLSI chips. The reader is referred to an example publication that reports power prediction and optimization techniques at the register transfer level.[89]

Word Length Selection

Many researchers studied word-length optimization techniques at the register-transfer level. A few example publications are cited here. These technique can be classified as statistical techniques applied to digital filters,[90] simulated annealing-based optimization of filters,[91] and simulation-based optimization of filters, digital communication, and signal processing systems.[92] Sung and Kum reported a simulation-based word-length optimization technique for fixed-point digital signal processing systems.[93] The objective of these particular architecture-level techniques is to minimize the number of bits in the design which is related to, but not the same as the overall hardware cost.

65.1 Introduction

This chapter provides an overview of register transfer level synthesis and behavioral synthesis, contrasting the two with examples. Examples are written using VHDL and Verilog HDL, the two dominant hardware description languages (HDL) in the industry today.

The chapter intends to be more of a tutorial. It first describes the distinguishing characteristics of register transfer level (RTL) modeling as opposed to behavioral level modeling. It then uses both HDLs to illustrate how RTL models are mapped to hardware. Both combinational logic synthesis and sequential logic synthesis are presented. This includes how flip-flops, latches, and three-state gates are inferred from the RTL model. A finite-state machine modeling example is also described. The later part of the chapter shows the behavioral synthesis methodology with examples to illustrate the flow of transformations that occur during the synthesis process. Many scheduling and resource allocation algorithms exist today. In this chapter, we illustrate the basic ideas behind the algorithms. Examples are used to show the architectural exploration that can be performed with behavioral synthesis, something that is not possible with register transfer level synthesis.

Synthesis is here! It has become an integral part of every design process. Once upon a time, all circuits were designed by hand and logic gates and their interconnections were entered into a system using a schematic capture tool. This is no longer the norm. More and more designers are resorting to synthesis because of the tremendous advantages that it provides, for example, describing the design at a higher level of abstraction. To this end, a language is needed to describe the design. This is where a hardware description language comes in. A hardware programming language is a formal language designed with the intent of describing hardware. Additionally, each language construct has a functional semantic

© 2003 by CRC Press LLC

associated with it that can be used to verify a design described in HDL (a design described in a HDL is often called a "model"). The model also serves as a means of documenting the design.

65.2 The Two HDLs

The two dominant hardware description languages in use today are:

1. VHDL
2. Verilog HDL

VHDL originated from the Department of Defense through its VHSIC program and became a public domain standard in 1987, whereas Verilog HDL originated from a private company and became a public domain standard in 1995. Both languages are targeted at describing digital hardware. A design can be expressed structurally, in a dataflow style or in a sequential behavior style. The key difference between the two languages is that VHDL extends the modeling to higher levels of data abstraction, provides for strong type checking, and supports the delta delay mechanism.

An excellent introduction to both languages can be found in (Bhasker, 1995) and (Bhasker, 1997). The complete descriptions of languages can be found in their respective language reference manuals (LRMs), (IEEE, 1993) and (IEEE, 1995).

Here is an example of a simple arithmetic logic unit described using both languages. The design is described using a mixed style — it contains structural components, dataflow, and sequential behavior.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all, IEEE.NUMERIC_STD.all;
entity ALU is
  port (A, B: in UNSIGNED(3 downto 0);
        SEL: in STD_LOGIC_VECTOR(0 to 1);
        Z: out UNSIGNED(7 downto 0);
        ZComp: out BOOLEAN);
end;
architecture MIXED_STYLE of ALU is
  component MULTIPLIER
    port (PortA, PortB: in UNSIGNED (3 downto 0);
          PortC: out UNSIGNED (7 downto 0));
  end component;
  signal MulZ: UNSIGNED (7 downto 0);
begin
  ZComp <= A < B when SEL = "11" else FALSE;
  M1: MULTIPLIER port map (PortA => A, PortB => B,
                           PortC => MulZ);
  process (A, B, SEL, MulZ)
  begin
    Z <= (others => '0');
    case SEL is
      when "00" => Z(3 downto 0) <= A + B;
      when "01" => Z(3 downto 0) <= A - B;
      when "10" => Z <= MulZ;
      when others => Z <= (others => 'Z');
    end case;
  end process;
end;
```

© 2003 by CRC Press LLC

```
//Verilog:
module ALU (A, B, SEL, Z, ZComp);
  input [3:0] A, B;
  input [0:1] SEL;
  output [7:0] Z;
  reg [7:0] Z;
  output ZComp;
  assign ZComp = (SEL == 2'b11) ? A < B: b0;
  MULTIPLIER M1 (.PortA(A), .PortB(B), .PortC(MulZ));
  always @(A or B or SEL)
  begin
    case (SEL)
      2'b00: Z = A + B;
      2'b01: Z = A – B;
      2'b10: Z = MulZ;
      default: Z = bz;
    endcase
  end
endmodule
```

In VHDL, the interface of the design (entity declaration) is separate from the description of the design (architecture body). Note that each signal is declared as a specific type (UNSIGNED). This type is declared in the package NUMERIC_STD, which in turn is included in the design using the context clauses (library and use clause). The structural part is described using a component instantiation statement — a component declaration is required to specify the interface for the component. The dataflow part is specified using a concurrent signal assignment. The sequential part is specified using a process statement; this contains a case statement that switches to an appropriate branch based on the value of the case expression.

In the Verilog model, each variable can have at most four values: 0, 1, x, and z. The model shows the two main data types in Verilog: net and register (a wire is a net data type, while a reg is a register data type). The structural part is described using a module instantiation statement. Notice that named association is used to specify the connection between the ports of the module and its external nets to which they are connected. Dataflow part is modeled using the continuous assignment statement, while the sequential part is represented using the always statement.

In this chapter, we use both languages to illustrate the examples when describing synthesis.

65.3 The Three Different Domains of Synthesis

There are three distinct domains in synthesis:

1. Logic synthesis
2. RTL synthesis
3. Behavioral synthesis

But first, the definition (at least the author's) of synthesis: Synthesis is the process of transforming an HDL description of a design into logic gates. The synthesis process itself, starting from HDL, involves a number of tasks that need to be performed. These tasks may or may not be distinct in synthesis tools (Fig. 65.1).

Starting from an HDL description, synthesis generates a technology-independent RTL level netlist (RTL blocks interconnected by nets). Based on the target technology and design constraints, such as area and delay, the module builder generates a technology-specific gate level netlist. A logic optimizer further optimizes the logic to match the design constraints and goals such as area and delay. The synthesis process may bypass the module build phase and directly generate a gate level netlist if there are no RTL blocks in the design.

© 2003 by CRC Press LLC

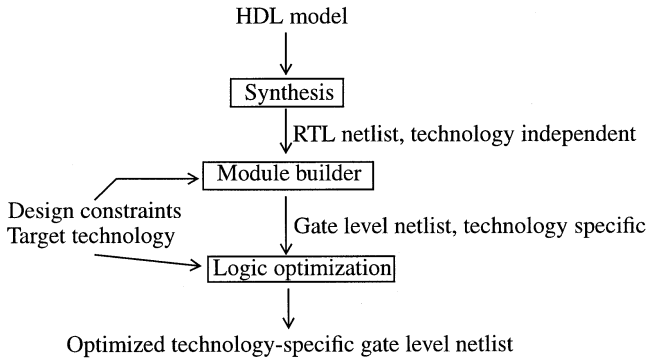

FIGURE 65.1 The tasks involved in synthesis process.

In this chapter, we will not discuss logic optimization and module building. One source that describes the algorithms behind logic optimization is (DeMicheli, 1994).

Coming back to the three different synthesis domains, let us briefly explore them. The level of abstraction increases as we go from the logic level to the behavioral level. Inversely, the structural inference reduces as we go from the logic level to the behavioral level (Fig. 65.2).

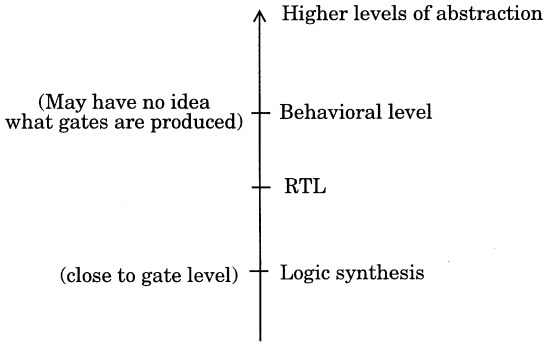

FIGURE 65.2 Varying levels of abstraction.

In the logic synthesis domain, a design is described in terms of Boolean equations. Components may be instantiated to describe hierarchy or may lower level primitives such as flip-flops. Here is a logic synthesis model for an incrementor whose output is latched.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
use IEEE.NUMERIC_STD.all;
entity INCREMENT is
  port (A: in UNSIGNED(0 to 2); CLOCK: in STD_LOGIC;
        Z: out UNSIGNED(0 to 2));
end;

architecture LOGIC_LEVEL of INCREMENT is
  component FD1S3AX
    port (DATA, CLK: in STD_LOGIC; Q: out STD_LOGIC);
  end component;
  signal DZ1, DZ2, DZ0, S429, A1BAR: STD_LOGIC;
```

© 2003 by CRC Press LLC

```
begin
  DZ1 <= not ((A(1) or DZ2) and (A(2) or A1BAR));
  DZ2 <= not A(2);
  DZ0 <= not ((A(0) or DZ2) and (A1BAR or S429));
  A1BAR <= not A(1);
  S429 <= not ((DZ2 or A1BAR) and A(0));

  S0: FD1S3AX port map (DZ2, CLOCK, Z(2));
  S1: FD1S3AX port map (DZ1, CLOCK, Z(1));
  S2: FD1S3AX port map (DZ0, CLOCK, Z(0));
end;

//Verilog:
module INCREMENT (A, CLOCK, Z);
  input [0:2] A;
  input CLOCK;
  output [0:2] Z;

  wire A1BAR, S429, DZ0, DZ1, DZ2;

  assign DZ1 = ! ((A[1] || DZ2) && (A[2] || A1BAR));
  assign DZ2 = ! A[2];
  assign DZ0 = ! ((A[0] || DZ2) && (A1BAR || S429));
  assign A1BAR = ! A[1];
  assign S429 = ! ((DZ2 || A1BAR) && A[0]);

  FD1S3AX    S0 (DZ2, CLOCK, Z[2]),
             S1 (DZ1, CLOCK, Z[1]),
             S2 (DZ0, CLOCK, Z[0]);
endmodule
```

Notice that all operators are logical operators; these implicitly specify the structure of the synthesized netlist (Fig. 65.3). For example, the `and` operator produces an `and` gate, the `or` operator produces an `or` gate, and so on. The component instantiations (module instantiations in Verilog) instantiate three flip-flops.

In the register transfer level synthesis domain, the arithmetic operations are modeled using language operators and the behavior is described using the language behavioral constructs. The design is described in terms of data transfers between arithmetic logic units and registers, possibly at explicitly defined clock edges. Moreover, registers may be inferred implicitly from the design. In addition, hierarchy can be described by instantiating other RTL descriptions. RTL blocks, such as a custom-built multiplier, may be directly instantiated.

The key difference from logic synthesis is that in the register transfer level case, the behavior is described using higher level operators such as + and –, and constructs such as if and case, that are provided by the hardware description language. In addition, for sequential circuits, the behavior of the design at each clock edge is explicitly described. Here is the same example of the incrementor, this time at the register transfer level:

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
use IEEE.NUMERIC_STD.all;
entity INCREMENT is
  port (A: in UNSIGNED(0 to 2); CLOCK: in STD_LOGIC;
        Z: out UNSIGNED(0 to 2));
end INCREMENT;
```

© 2003 by CRC Press LLC

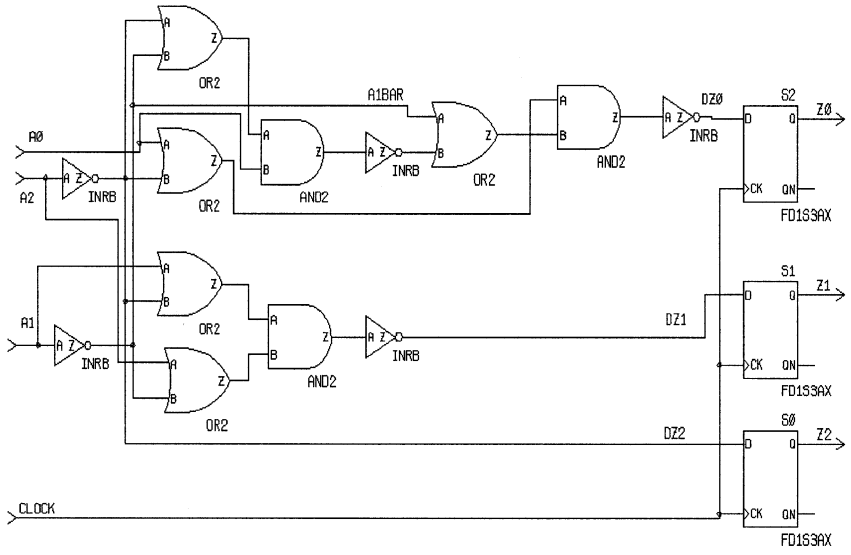

FIGURE 65.3 The synthesized netlist.

```
//The above entity declaration is identical to the
//logic level case.

architecture REGISTER_TRANSFER_LEVEL of INCREMENT is
  PZ: process
  begin
    wait until CLOCK = '1';
    Z <= A + 1;
  end process PZ;
end REGISTER_TRANSFER_LEVEL;

//Verilog:
module INCREMENT (A, CLOCK, Z);
  input [0:2] A;
  input CLOCK;
  output [0:2] Z;
  reg [0:2] Z;

    always @(posedge CLOCK)
      Z <= A + 1;
endmodule
```

Notice that flip-flops are not explicitly instantiated but are inferred. Inference rules are used to infer flip-flops. One such rule is that if any variable or signal (a reg in Verilog HDL) is assigned a value under the control of a clock edge (as shown using a wait on a clock edge in a process statement for VHDL and using a posedge event in an always statement for Verilog), then the variable or signal is inferred as a flip-flop. Also note that in the RTL description, the behavior of the design at every clock edge is explicitly specified. In the behavioral synthesis domain, this is one level above register transfer level synthesis, no clocking information is specified in the model (this is not completely true as we will see later when we talk about partially scheduled and fully scheduled models). Inference rules are not used to infer registers. The behavior of the design is described as a sequential program, and the synthesis tool's job is to figure

© 2003 by CRC Press LLC

out which operations are to be done in which clock cycle based on the design constraints that are specified. Any variable whose value needs to be saved between clock cycles will have to be stored in a register.

Here is a simple example used to illustrate behavioral synthesis:

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all, IEEE.NUMERIC_STD.all;
entity SIMPLE_TREE is
  port (InData: in UNSIGNED(0 to 3);
        OutData: out UNSIGNED(0 to 3));
end SIMPLE_TREE;

architecture ONLY_TO_EXPLAIN of SIMPLE_TREE is
begin
  P1: process (InData)
    variable Tree: UNSIGNED (0 to 3);
  begin
    Tree: = InData + 1;
    Tree: = Tree + 1;
    OutData <= Tree + 1;
  end process P1;
end ONLY_TO_EXPLAIN;

//Verilog:
module SIMPLE_TREE (InData, OutData);
  input [0:3] InData;
  output [0:3] OutData;
  reg [0:3] OutData;
  reg [0:3] Tree;

  always @(InData)
  begin
    Tree = InData + 1;
    Tree = Tree + 1;
    OutData <= Tree + 1;
  end
endmodule
```

Notice that no clocking information, such as clock edges, is explicitly present in the model. Now, if we assume that an adder (the addition operator) takes 5 ns to compute and assume a clock period of 6 ns, we can see that it will take three clock cycles to completely execute the behavior. In addition, all the three "+" operators can be shared using only one adder. Also, only one register *Tree* is required to save the intermediate values (the value between clock cycles). Figure 65.4 shows one architecture (RTL netlist) generated under the given assumptions. The controller sequencing is shown in Fig. 65.5.

If a clock period of 11 ns is specified, then only two clock cycles are required to complete execution. See Fig. 65.6 for the controller sequencing. This time two adders are required. Figure 65.7 shows the new architecture.

By changing the constraints, different architectures for the same behavior are produced — this is called "architectural exploration." Such generation of different architectures is not possible with RTL synthesis, since the architecture of the design is explicitly specified in the RTL model.

We describe register transfer level synthesis and behavioral synthesis in further detail in the next two sections.

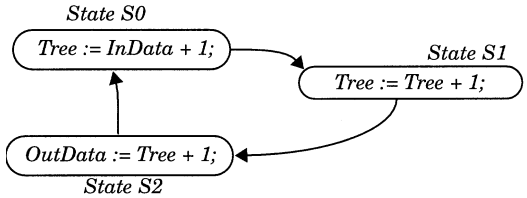

FIGURE 65.5 Controller sequencing.

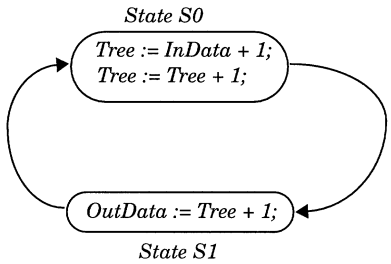

FIGURE 65.6 Controller sequencing with new specification.

65.4 RTL Synthesis

In describing an RTL model, different design styles are used for modeling combinational logic and for modeling sequential logic.

Combinational Logic

Combinational logic can be described using:

1. concurrent signal assignment (continuous assignment in Verilog)
2. process statement with no clock edges (always statement with no edge event in event list for Verilog).

Language operators such as + and –, and behavioral constructs such as if, case, and loop statements, may be used to model the design. Here is an example of a BCD to seven-segment decoder:

© 2003 by CRC Press LLC

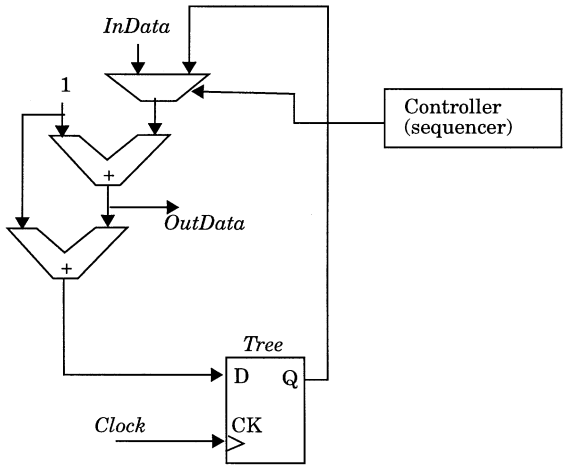

FIGURE 65.7 Another architecture with a clock period of 11 ns.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
entity BCD_TO_7 is
  port (D: in STD_LOGIC_VECTOR(0 to 3);
        Q: out STD_LOGIC_VECTOR(0 to 6));
end BCD_TO_7;

architecture RTL_MODEL of BCD_TO_7 is
begin
  P1: process (D)
  begin
    case D is
      when "0000" => Q <= "1111110";
      when "0001" => Q <= "0001100";
      when "0010" => Q <= "1011011";
      when "0011" => Q <= "0011111";
      when "0100" => Q <= "0101101";
      when "0101" => Q <= "0110111";
      when "0110" => Q <= "1100111";
      when "0111" => Q <= "0011100";
      when "1000" => Q <= "1111111";
      when "1001" => Q <= "0111101";
      when others => Q <= "--------";
    end case;
  end process P1;
end RTL_MODEL;

//Verilog:
module BCD_TO_7 (D, Q);
  input [0:3] D;
  output [0:6] Q;
  reg [0:6] Q;
```

© 2003 by CRC Press LLC

```
  always @(D)
    case (D)
      4'd0: Q = 7'b1111110;
      4'd1: Q = 7'b0001100;
      4'd2: Q = 7'b1011011;
      4'd3: Q = 7'b0011111;
      4'd4: Q = 7'b0101101;
      4'd5: Q = 7'b0110111;
      4'd6: Q = 7'b1100111;
      4'd7: Q = 7'b0011100;
      4'd8: Q = 7'b1111111;
      4'd9: Q = 7'b0111101;
      default: Q = 7'bx;
    endcase
endmodule
```

It is required that all signals (variables in Verilog) read within the process statement (always statement) must appear in the sensitivity list (event list for Verilog), or else there may be a possibility for a functional mismatch between the RTL model and its synthesized netlist. Some synthesis tools issue a warning about such missing signals.

Sequential Logic

Edge-sensitive storage elements (flip-flops) are modeled differently from level-sensitive storage elements (latches). First, let us take a look at how level-sensitive storage devices are modeled.

Modeling a Level-Sensitive Storage Element

When a variable or a signal is not explicitly assigned a value in every iteration of a process statement (or an always statement in Verilog), a level-sensitive storage element is inferred. For example, this can happen if a variable is not assigned a value in all branches of an if statement.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
entity LSSE is
  port (D, Clock: in STD_LOGIC; Q: out STD_LOGIC);
end LSSE;

architecture LATCH_INFERENCE of LSSE is
begin
  process (Clock, D)
  begin
    if (Clock = '1') then
      Q <= D;
    end if;
  end process;
end LATCH_INFERENCE;

//Verilog:
module LSSE (D, Clock, Q);
  input D, Clock;
  output Q;
  reg Q;
```

© 2003 by CRC Press LLC

```
  always @(D or Clock)
    if (Clock)
      Q = D;
endmodule
```

Based on the language semantics, *Q* needs to retain its value during the period when *Clock* is 0. This is achieved by implementing a level-sensitive storage element for *Q*. This is shown in Fig. 65.8, which shows the synthesized netlist (FD1S1A is a latch).

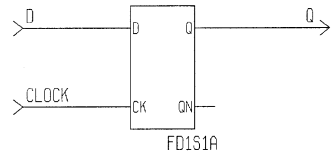

FIGURE 65.8 Synthesizing a level-sensitive storage element.

Modeling an Edge-Sensitive Storage Element

A signal or a variable assigned a value under the control of a clock edge is inferred as a flip-flop.

In VHDL: Here is a template of a process statement that has to be used to infer edge-sensitive storage elements.

```
process
  declarations, if any
begin
  wait until <clock_edge>
  <sequential_statements>
end process;
-- <clock_edge> can be either of:
--  Signal = '1' for a rising edge
--  Signal = '0' for a falling edge.
```

In Verilog: Here is a template of the always statement.

```
always @(<edge_event>)
  <statement>
//<edge_event> is:
//  "posedge VariableName" for positive edge,
//  "negedge VariableName" for negative edge.
```

Here is an example.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all, IEEE.NUMERIC_STD.all;
entity ESSE is
  port (Clk: in STD_LOGIC; D: in UNSIGNED (0 to 2);
        Q: out UNSIGNED(0 to 2));
end ESSE;

architecture FF_INFERENCE of ESSE is
begin
  process
  begin
    wait until Clk = '0';
    Q <= D + 1;
  end process;
end FF_INFERENCE;

//Verilog:
module ESSE (Clk, D, Q);
```

© 2003 by CRC Press LLC

```
  input Clk;
  input [0:2] D;
  output [0:2] Q;
  reg [0:2] Q;

  always @(negedge Clk)
    Q <= D + 1;
endmodule
```

Since *Q* is assigned a value under the control of a clock edge, an edge-sensitive storage element is inferred for *Q*. This is shown in the synthesized netlist (Fig. 65.9).

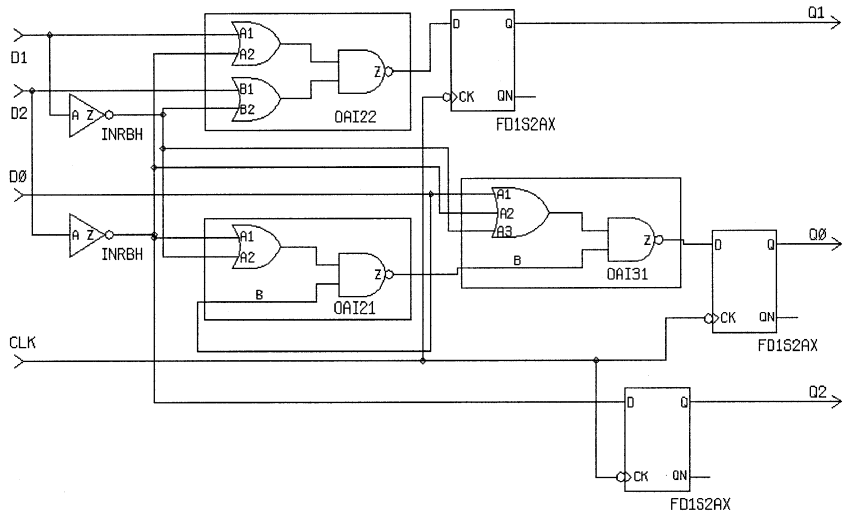

FIGURE 65.9 Inferring a flip-flop.

65.5 Modeling a Three-State Gate

A three-state gate is modeled at the register transfer level by assigning the high-impedance value to a signal or variable under the control of a condition.

```
-- VHDL:
library IEEE;
use IEEE.STD_LOGIC_1164.all;
entity THREE_STATE is
  generic (NBITS: POSITIVE:= 3);
  port (Enable: in STD_LOGIC;
        MemDataReg: in STD_LOGIC_VECTOR(1 to NBITS);
        ReadBus: out STD_LOGIC_VECTOR (1 to NBITS));
end THREE_STATE;

architecture INFERENCE of THREE_STATE is
begin
  process (Enable, MemDataReg)
  begin
    if (Enable = '0') then
      ReadBus <= (others => 'Z');
    else
      ReadBus <= MemDataReg;
```

© 2003 by CRC Press LLC

```
    end if;
  end process;
end INFERENCE;

//Verilog:
module THREE_STATE (Enable, MemDataReg, ReadBus);
  parameter NBITS = 3;
  input Enable;
  input [1:NBITS] MemDataReg;
  output [1:NBITS] ReadBus;
  reg [1:NBITS] ReadBus;

  always @(Enable or MemDataReg)
    if (! Enable)
      ReadBus = bz;
    else
      ReadBus = MemDataReg;
endmodule
```

The target *ReadBus* is assigned the high impedance value under the control of the condition "*Enable* = 0". The synthesized netlist contains three three-state gates with the condition "*Enable* = 0" controlling the three-state behavior of the gate and *MemDataReg* as the input to the three-state gate (see Fig. 65.10 for the synthesized netlist).

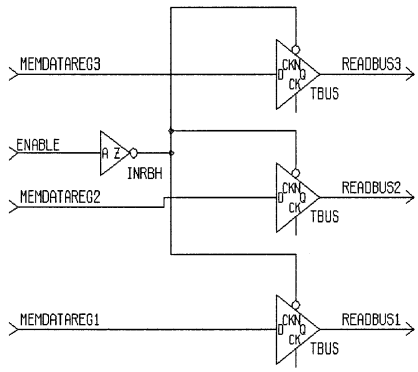

FIGURE 65.10 Synthesizing a three-state gate.

65.6 An Example

Here is an example of a synthesis model. There exists a mango juice dispenser that dispenses mango juice cartons for 25¢ each. The machine accepts only coins (quarters, dimes, and nickels), and appropriate change is to be returned. All state transitions are synchronized to the positive edge of a clock. The state transition diagram is shown as shown in Fig. 65.11.

```
-- VHDL:
entity MANGO_JUICE is
  port (CoinIn: in POSITIVE; Clock, Reset: in BIT;
        DispenseJuice: out BOOLEAN;
        NickelOut, DimeOut: out NATURAL);
end MANGO_JUICE;
```

The finite-state machine is modeled using two processes (two always statements in Verilog). The first process is used to model the sequential logic, while the second process models the combinational logic. A case statement switches between the different states based on *CurrentState* and goes to the next state, depending on the value of the coin read in. Three asynchronous, clear flip-flops are synthesized from this model: these flip-flops hold the state of the mango juice dispenser.

For further reading on these topics of register transfer level synthesis, see (Bhasker, 1998). Since the modeling style enforces certain restrictions on what features of the language can be used, an IEEE standard for such a register transfer level synthesis subset is just evolving. The one for VHDL synthesis, IEEE PAR 1076.6, will be an IEEE standard by the end of this year, while the one for Verilog synthesis, IEEE PAR 1364.1, is expected to be an IEEE standard by the end of 1999. The VHDL synthesis subset standard is being developed by the VHDL synthesis interoperability working group, whereas the Verilog standard is being developed by the Verilog synthesis interoperability working group. The author is the chair for both working groups.

65.7 Behavioral Synthesis

As mentioned in an earlier section, behavioral synthesis differs from register transfer level synthesis due to the fact that clocking information may not exist in the model, that is, the behavior of the design at every clock edge is not explicitly described in the model. This is the task of the behavioral synthesis tool to determine.

Behavioral synthesis is often referred to as "high-level synthesis." In its basic form, an input to such a program is a sequential program, that is, a program that contains a sequence of statements that describes the behavior. This program is analyzed by a behavioral synthesis tool that then performs three major tasks:

- Scheduling — this is the task of determining the clock boundaries or assigning operations to clock cycles.
- ALU allocation — this is the task of determining which types of ALUs and how many ALUs are required.
- Register allocation — this task is to determine the required registers.

These tasks may be performed in any order by a behavioral synthesis tool. The fact is that these three problems need to be addressed. We shall explore each of these tasks in greater detail using the algorithm of a differential equation solver (see Paulin et al., 1985).

```
//Solve the differential equation:
//y'' + 5 x y' + 3y = 0

-- VHDL:
entity DIFF_EQ is
  port (A, DX: in INTEGER; X, U, Y: inout INTEGER);
end DIFF_EQ;

architecture HIGH_LEVEL of DIFF_EQ is
begin
  process
  begin
    while X < A loop
      X < = X + DX;
      U < = U – 5 * U * X * DX – 3 * Y * DX;
      Y < = Y + U * DX;
      wait for 0 ns;//Just so signal values settle.
    end loop;
  end process;
end HIGH_LEVEL;

//Verilog:
module DIFF_EQ (A, DX, X, U, Y);
  input [0:31] A, DX;
  output [0:31] X, U, Y;
  reg [0:31] X, U, Y;

  always @ (A or DX or X or U or )
    while (X < A)
    begin
      X < = X + DX;
      U < = U – 5 * U * X * DX – 3 * Y * DX;
      Y < = Y + U * DX;
```

© 2003 by CRC Press LLC

```
        #0;
    end
endmodule
```

As you can see from the model, there is no mention of a clock, just the behavior of the differential equation solver is described. To ease the explanation of the following tasks that occur in a behavioral synthesis tool, we will use just one of the assignments (the second assignment) to explain the techniques and issues behind these tasks. The line is:

```
U <= U - 5 * U * X * DX - 3 * Y * DX;
```

Quite often, it is useful to construct a data flow graph (DeMicheli, 1994) of such a behavior. This is shown in Fig. 65.12. Five multipliers and two subtractors are used. The arrows show the flow of data from one operation to another.

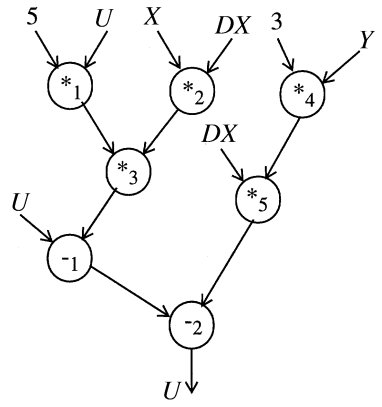

FIGURE 65.12 Data flow graph of assignment statement.

Scheduling

Given the previous model, we can see that there is no information about what operations are to be done in which clock cycle. The behavior would be performed in a number of clock cycles. Note that each clock cycle represents one state of the behavior. More or less, the behavior is broken up into a number of clock cycles based on the clock period. To determine the scheduling, additional data needs to be provided. In the previous case, the path delay of the subtractor and the multiplication operator needs to be known. This information can be derived from a technology library. In this instance, let us assume that a subtractor has a delay of 5 ns and a multiplier has a delay of 12 ns.

The number of operations that can be done in one control step is dependent on the clock period — this also needs to be known. Let us say, a clock period of 14 ns is specified. In such a case, Fig. 65.13 and Fig. 65.14 shows two possible ways of scheduling the operations. In the first schedule, operations $*_1$, $*_2$, $*_3$ are performed in the first clock cycle, operations $*_3$, $*_5$ are performed in the second clock cycle, operation $-_1$ is performed in the third clock cycle, and the operation $-_2$ is performed in the fourth clock cycle. With this schedule, the behavior takes four clock cycles to complete execution. In the second schedule, operators $*_1$ is performed in the first clock cycle, $*_2$ and $*_4$ are performed in the second clock cycle, $*_3$ is done in the third clock cycle, $-_1$ and $*_5$ in the fourth, and $-_2$ in the fifth. Which schedule is better depends on how the other tasks (ALU allocation and register allocation) perform in achieving the user constraints (typically area and speed).

If the clock period is changed to 25 ns, a different set of schedules can occur. One such example is shown in Fig. 65.15. Notice that the clock period is large enough to support two or more operations that are performed in sequence to be done in a single clock cycle. With this schedule, it takes only three clock cycles to complete execution.

Another constraint that could have been provided is the number of clock cycles.

Thus, by controlling the clock period and the number of clock cycles, different schedules (and different architectures) for the same behavior can be produced. This is called "exploration of architectural design space." The output of a scheduling task is typically an equivalent RTL model. An RTL model for the last schedule is shown next.

```
-- VHDL:
architecture RTL of EXAMPLE is
  type STATES is (CLOCK_CYCLE_1, CLOCK_CYCLE_2,
                  CLOCK_CYCLE_3);
```

ALU Allocation

Once a schedule is known, the knowledge about which operations are mutually exclusive is also known. Two operations that are mutually exclusive, that is, are not used in the same clock cycle, may be shared using just one ALU. For example, in the schedule of Fig. 65.15, operations $*_2$ and $*_4$ are mutually exclusive; therefore, these two operations can be performed using a single multiplier (ALU that just does multiplication): in clock cycle 1, the multiplier performs the $*_2$ operation while in clock cycle 2, the multiplier performs the $*_4$ operation. However, sharing has a cost. Extra multiplexers may be needed at the input of the multiplier to multiplex the inputs in. This introduces extra delay and could be in the critical path of the circuit. So, a behavioral synthesis tool has to make a judicious choice when sharing.

Here are the various possibilities that can occur when sharing an ALU:

1. Same operator, same operands: definitely must share. Example: $A + B$, $A + B$
2. Same operator, one different operand: trade-off, since one multiplexer is introduced. Example: $A + B$, $A + C$
3. Same operator, different operands: trade-off, since two multiplexers are introduced. Example: $A + B$, $C + D$
4. Different operators, same operands: useful to share. Example: $A + B$, $A - B$
5. Different operators, one different operand: trade-off, since one multiplexer is introduced. Example: $A + B$, $A - C$
6. Different operators, different operands: trade-off, since two multiplexers are introduced. Example: $A + B$, $C - D$

Possibility i is the best case to share followed by iv, ii, v, iii, and vi.

Consider the schedule in Fig. 65.13. Sharing to its maximum, to reduce area, yields us just one subtractor and three multipliers. One possible way to share is:

- Operation $*_1$, $*_3$: ALU1 (multiplier)
- Operation $*_4$, $*_5$: ALU2 (multiplier)
- Operation $*_2$: ALU3 (multiplier)
- Operation $-_1$, $-_2$: ALU4 (subtractor)

The block diagram of the architecture is shown in Fig. 65.16. Notice that there are values that need to be saved in registers; these are shown as circles in the figure; more on this is in the next section.

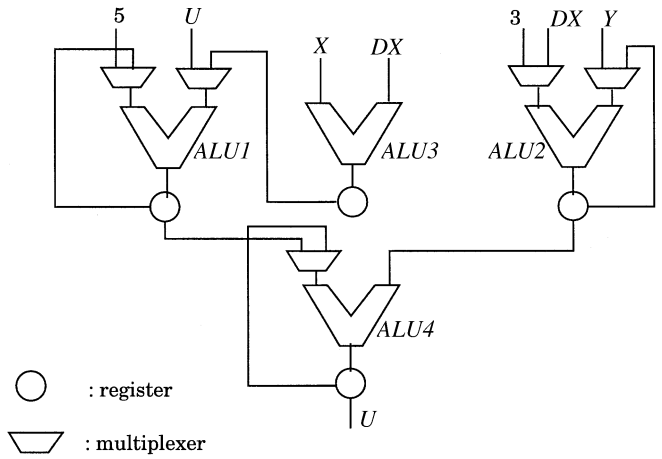

FIGURE 65.16 The ALU architecture of the first schedule.

© 2003 by CRC Press LLC

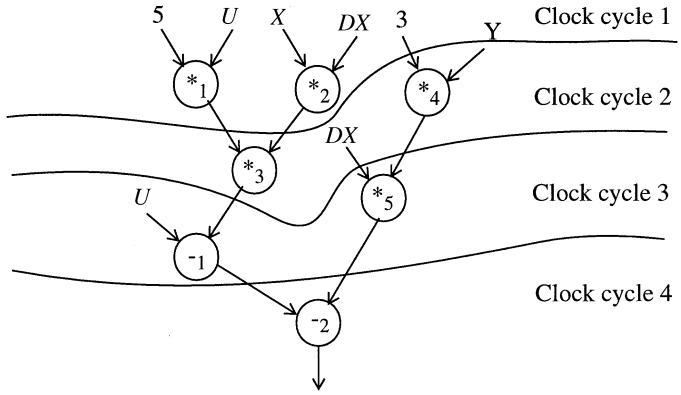

FIGURE 65.17 A schedule subject to resource constraints.

If a different kind of constraint, called resource constraints, is placed on the behavioral synthesis tool, for example, only two multipliers and one subtractor are available, then a different schedule and different sharing will occur. Figure 65.17 shows a possible schedule. Notice that in each clock cycle, two multiplications at most and one subtraction at most are performed. A possible sharing strategy is

- $*_1$, $*_3$: ALU1 (multiplier)
- $*_2$, $*_4$, $*_5$: ALU2 (multiplier)
- $-_1$, $-_2$: ALU3 (subtractor)

The architecture produced with this sharing is shown in Fig. 65.18. Another possible sharing strategy is

- $*_1$, $*_4$, $*_5$: ALU1 (multiplier)
- $*_2$, $*_3$: ALU2 (multiplier)
- $-_1$, $-_2$: ALU3 (subtractor)

Notice that even within the same schedule, different kinds of sharing can produce architectures that have different total area and speed.

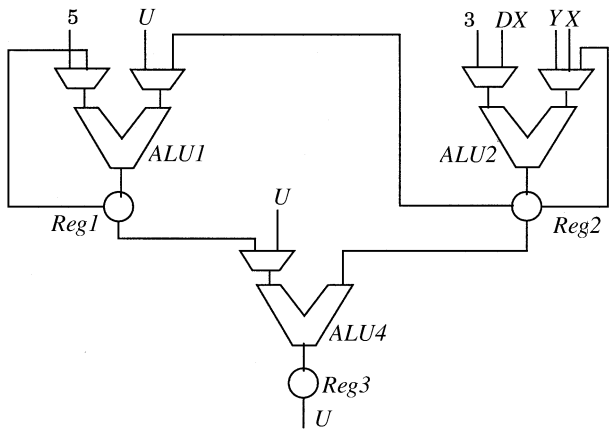

FIGURE 65.18 Architecture with resource constraints specified.

© 2003 by CRC Press LLC

Register Allocation

The input to a behavioral synthesis tool is a behavioral model in which no registers are explicitly specified. But once a schedule has been determined, registers can be identified. A register is needed for any variable whose value has to be saved from one clock cycle to the next. For example, in Fig. 65.17, the output of $*_1$ has to be saved, since its value is defined in clock cycle 1 and used by $*_3$ in clock cycle 2. Similarly, the output of $*_4$ has to be saved as a register, since it is defined in clock cycle 2 and the value used in clock cycle 3.

The problem of register allocation is minimizing the number of such registers. If we do not apply any minimization, from the schedule shown in Fig. 65.17, we see that we will need six registers:

- R1: output of $*_1$
- R2: output of $*_2$
- R3: output of $*_3$
- R4: output of $*_4$
- R5: output of $*_5$
- R6: output of $-_1$

By optimizing the number of registers, this number can be reduced significantly. Such an analysis is performed by looking at the lifetimes of the potential registers. A lifetime is defined as the period from the clock cycle;it is defined to the clock cycle in which its value ceases to be not required. For example, here are the lifetimes of the above identified registers:

- R1: clock cycle 1 to 2
- R2: clock cycle 1 to 2
- R3: clock cycle 2 to 3
- R4: clock cycle 2 to 3
- R5: clock cycle 3 to 4
- R6: clock cycle 3 to 4

Two or more registers whose lifetimes are nonoverlapping can share the same register — basically once a register use is over, another register can reuse the same register for its lifetime, after which another register can use the register and so on. A possible register allocation may produce the following:

- Reg1: R1, R3
- Reg2: R2, R4, R5
- Reg3: R6

This allocation is shown in Fig. 65.18.

A different register allocation scheme may produce the following:

- Reg1: R1, R3, R6
- Reg2: R2, R4, R5

Notice that sharing of registers may also introduce multiplexers at the inputs of registers, as in the previous specified register allocation scheme. This is shown in Fig. 65.19. Selecting an appropriate register allocation is once again based on user-specified constraints such as area and speed.

Other variations are possible with the input HDL model:

1. Zero scheduled
2. Partially scheduled
3. Fully scheduled

The example we have seen so far follows the "zero scheduled" model, since no explicit clock boundaries were defined. In a "fully scheduled" model, all the scheduling information is explicitly specified by the user. In a "partially scheduled" model, some points in the model are explicitly demarcated as clock

© 2003 by CRC Press LLC

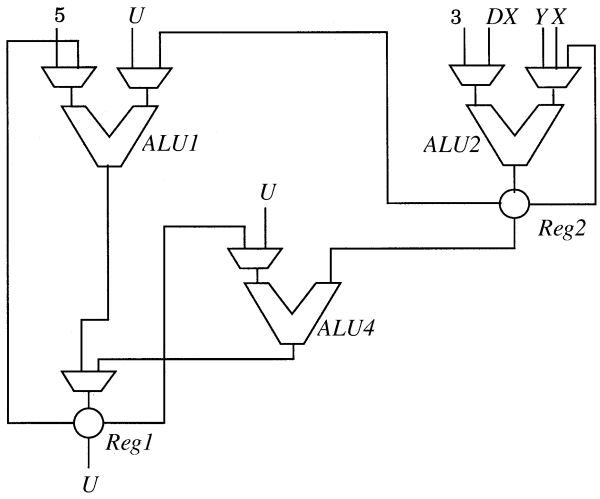

FIGURE 65.19 A register allocation may introduce extra multiplexers.

boundaries — for example, when a user knows exactly where a clock boundary must be but the behavioral synthesis tool is free to schedule the remaining parts of the behavior. We will break up our assignment statement that we have been using as an example to illustrate the various scheduling options.

```
-- Zero scheduled:
T1:= 5 * U;              -- *1
T2:= X * DX;             -- *2
T3:= T1 * T2;            -- *3
T4:= 3 * Y;              -- *4
T5:= DX * T4;            -- *5
T6:= U - T3;             -- -1
U <= T6 - T5;            -- -2

-- Partially scheduled:
T1:= 5 * U;              -- *1
T2:= X * DX;             -- *2
T3 = T1 * T2;            -- *3
T4:= 3 * Y;              -- *4
wait until CLOCK = '1';
T5:= DX * T4;            -- *5
T6:= U - T3;             -- -1
U <= T6 - T5;            -- -2

-- Fully scheduled:
T1 = 5 * U;              -- *1
T2:= X * DX;             -- *2
wait until CLOCK = '1';
T3:= T1 * T2;            -- *3
T4:= 3 * Y;              -- *4
wait until CLOCK = '1';
T5:= DX * T4;            -- *5
T6:= U - T3;             -- -1
wait until CLOCK = '1';
U <= T6 - T5;            -- -2
```

© 2003 by CRC Press LLC

Scheduling information is explicitly specified in the model by placing the clock edges — the demarcation points are "**wait until** *CLOCK* = '1'; ". In Verilog HDL, "@(**posedge** *CLOCK*);" can be used. In the partially scheduled and fully scheduled cases, architectural exploration is limited but still can be achieved by controlling the ALU sharing and register sharing.

An additional factor that may be considered in behavioral synthesis is scheduling with a clock period less than the maximum delay of an operator, for example, if a multiplier has a delay of 12 ns, then having a clock period of 5 ns.

Due to lack of space, we have skipped talking about controller synthesis which is an important aspect of behavioral synthesis. A good starting point on this topic is the reference (Nagle, 1982).

Verification of a behavioral synthesis model is a little more tricky than verification of an RTL model. This is due to lack of clocking information in the behavioral model. (See Bhasker, 1991) for further details of an example of how verification can be performed.)

Two references for reading on the topic of logic synthesis are (Devadas et al., 1994) and (DeMicheli, 1994). Detailed algorithms are also described in these references. Further readings on behavioral synthesis can be found in (DeMicheli, 1994), (Camposano and Wolf, 1991), and (Gajski, 1992).

For behavioral synthesis, it is usually not possible to support the entire set of language constructs supported by Verilog HDL and VHDL. However, at present, there is no publicly available standard subset.

65.8 Conclusion

The purpose of this chapter was to give an overview of synthesis in the register transfer level domain and the behavioral synthesis domain and to elaborate on the differences between the two. VHDL and Verilog HDL examples were used to illustrate these differences.

Behavioral synthesis is still a well-studied research topic. If you are interested in learning more about the latest state-of-the-art advances in this technology, a good starting point would be the Design Automation Conference proceedings, which usually contain a good one or two full sessions devoted to the topic of behavioral (high-level) synthesis.

Embedded Computing Systems and Hardware/Software Co-Design

66.1 Introduction
66.2 Uses of Microprocessors
66.3 Embedded System Architectures
66.4 Hardware/Software Co-Design
Models • Co-Simulation • Performance Analysis • Hardware/Software Co-Synthesis • Design Methodologies

Wayne Wolf
Princeton University

66.1 Introduction

This chapter describes embedded computing systems that make use of microprocessors to implement part of the system's function. It also describes hardware/software co-design, which is the process of designing embedded systems while simultaneously considering the design of its hardware and software elements.

66.2 Uses of Microprocessors

An embedded computing system (or more simply an embedded system) is any system which uses a programmable processor but itself is not a general purpose computer. Thus, a personal computer is not an embedded computing system (though PCs are often used as platforms for building embedded systems), but a telephone or automobile that includes a CPU is an embedded system. Embedded systems may offer some amount of user programmability — 3Com's PalmPilot, for example, allows users to write and download programs even though it is not a general-purpose computer — but embedded systems generally run limited sets of programs. The fact that we know the software that we will run on the hardware allows us to optimize both the software and hardware in ways that are not possible in general-purpose computing systems.

Microprocessors are generally categorized by their word size, since word size is associated both with maximum program size and data resolution. Commercial microprocessors come in many sizes; the term microcontroller is used to denote a microprocessor which comes with some basic on-chip peripheral devices, such as serial input/output (I/O) ports. Four-bit microcontrollers are extremely simple but capable of some basic functions. Eight-bit microcontrollers are workhorse low-end microprocessors. Sixteen- and 32-bit microprocessors provide significantly more functionality. A 16/32-bit microprocessor

© 2003 by CRC Press LLC

may be in the same architectural family as the CPUs used in computer workstations, but microprocessors destined for embedded computing often do not provide memory management hardware. A digital signal processor (DSP) is a microprocessor tuned for signal processing applications. DSPs are often Harvard architectures, meaning that they provide separate data and program memories; Harvard architectures provide higher performance for DSP applications. DSPs may provide integer or floating-point arithmetic.

Microprocessors are used in an incredible variety of products. Furthermore, many products contain multiple microprocessors. Four- and eight-bit microprocessors are often used in appliances: for example, a thermostat may use a microcontroller to provide timed control of room temperature. Automatic cameras often use several eight-bit microprocessors, each responsible for a different aspect of the camera's functionality: exposure, shutter control, etc. High-end microprocessors are used in laser and ink-jet printers to control the rendering of the page. Many printers use two or three microprocessors to handle generation of pixels, control of the print engine, and so forth. Modern automobiles may use close to 100 microprocessors, and even inexpensive automobiles generally contain several. High-end microprocessors are used to control the engine's ignition system — automobiles use sophisticated control algorithms to simultaneously achieve low emissions, high fuel economy, and good performance. Low-end microcontrollers are used in a number of places in the automobile to increase functionality: for example, four-bit microcontrollers are often used to sense whether seat belts are fastened and turn on the seat belt light when necessary.

Microprocessors may replace analog components to provide similar functions, or they may add totally new functionality to a system. They are used in several different ways in embedded systems. One broad application category is signal conditioning, in which the microprocessor or DSP performs some filtering or control function on a digitized input. The conditioned signal may be sent to some other microprocessor for final use. Signal conditioning allows systems to use less-expensive sensors with the application of a relatively inexpensive microprocessor. Beyond signal conditioning, microprocessors may be used for more sophisticated control applications. For example, microprocessors are often used in telephone systems to control signaling functions, such as determining what action to take based on the reception of dial tones, etc. Microprocessors may implement user interfaces; this requires sensing when buttons, knobs, etc. are used, taking appropriate actions, and updating displays. Finally, microprocessors may perform data processing, such as managing the calendar in a personal digital assistant.

Microprocessors make good design components in such a wide variety of application areas for several reasons. First, digital systems often provide more complex functionality than can be created using analog components. A good example is the user interface of a home audio/video system, which provides more information and is easier use than older, non-microprocessor-controlled systems. Microprocessors also allow related products much more cost-effectively. An entire product family, including models at various price and feature points, can be built around a single microprocessor-based platform. The platform includes both hardware components common to all the family members and software running on the microprocessor to provide functionality. Software elements can easily be turned on or off in various family members. Economies of scale often mean that it is cheaper to put the same hardware in both expensive and cheap models and to turn off features in the inexpensive models rather than to try to optimize the hardware and software configurations of each model separately. Microprocessors also allow design changes to be made much more quickly. Many changes may be possible simply by reprogramming; other features may be made possible by adding memory or other simple hardware changes along with some additional programming. Finally, microprocessors aid in concurrent engineering. After some initial design decisions have been made, hardware and software can be designed in parallel, reducing total design time.

While embedded computing systems traditionally have been fabricated at the board level out of multiple chips, embedded computing systems will play an increasing role in integrated circuit design as well. As VLSI technology moves toward the ability to fabricate chips with billions of transistors, integrated circuits will increasingly incorporate one or several microprocessors executing embedded software. Using microprocessors as components in integrated circuits increases design productivity, since CPUs can be used as large components which implement a significant part of the system functionality. Single-chip

© 2003 by CRC Press LLC

embedded systems can provide much higher performance than board-level equivalents, since chip-to-chip delays are eliminated.

66.3 Embedded System Architectures

Although embedded computing spans a wide range of application areas, from automotive to medical, there are some common principles of design for embedded systems. The application-specific embedded software runs on a hardware platform. An example hardware platform is shown in Fig. 66.1. It contains a microprocessor, memory, and I/O devices. When designing on a general-purpose system such as a PC, the hardware platform would be predetermined, but in hardware/software co-design the software and hardware can be designed together to better meet cost and performance requirements.

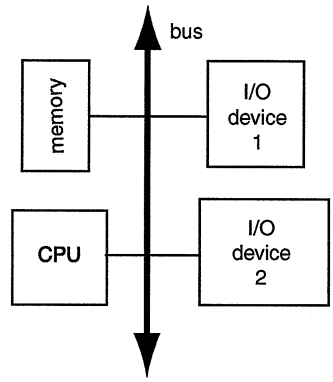

FIGURE 66.1 Hardware structure of a microprocessor system.

Depending on the application, various combinations of criteria may be important goals for the system design. Two typical criteria are speed and manufacturing cost. The speed at which computations are made often contributes to the general usability of the system, just as in general-purpose computing. However, performance is also often associated with the satisfaction of deadlines — times at which computations must be completed to ensure the proper operation of the system. If failure to meet a deadline causes a major error, it is termed a hard deadline. And missed deadlines, which result in tolerable but unsatisfactory degradations are called soft deadlines. Hard deadlines are often (though not always) associated with safety-critical systems. Designing for deadlines is one of the most challenging tasks in embedded system design. Manufacturing cost is often an important criteria for embedded systems. Although the hardware components ultimately determine manufacturing cost, software plays an important role as well. First, the size of the program determines the amount of memory required, and memory is often a significant component of the total component cost. Furthermore, the improper design of software can cause one to require higher-performance, more-expensive hardware components than are really necessary. Efficient utilization of hardware resources requires careful software design. Power consumption is becoming an increasingly important design metric. Power is certainly important in battery-operated devices, but it can be important in wall socket-powered systems as well — lower power consumption means smaller, less-expensive power supplies and cooling and may result in environmental ratings that are advantageous in the marketplace. Once again, power consumption is ultimately determined by the hardware, but software plays a significant role in power characteristics. For example, more efficient use of on-chip caches can reduce the need for off-chip memory access, which consumes much more power than on-chip cache references

Figure 66.1 shows the hardware architecture of a basic microprocessor system. The system includes the CPU, memory, and some I/O devices, all connected by a bus. This system may consist of multiple chips for high-end microprocessors or a single-chip microcontroller. Typical I/O devices include analog/digital (ADC) and digital/analog (DAC) converters, serial and parallel communication devices, network and bus interfaces, buttons and switches, and various types of display devices. This configuration is a complete, basic, embedded computing hardware platform on which application software can execute.

The embedded application software includes components for managing I/O devices and for performing the core computational tasks. The basic software techniques for communicating with I/O devices are polling and interrupt-driven. In a polled system, the program checks each device's status register to determine if it is ready to perform I/O. Polling allows the CPU to determine the order in which I/O operations are completed, which may be important for ensuring that certain device requests are satisfied at the proper rate. However, polling also means that a device may not be serviced in time if the CPU's program does not check it frequently enough. Interrupt-driven I/O allows a device to change the flow

© 2003 by CRC Press LLC

of control on the CPU and call a device driver to handle the pending I/O operation. An interrupt system may provide both prioritized interrupts to allow some devices to take precedence over others and vectored interrupts to allow devices to specify which driver should handle their request.

Device drivers, whether polled or interrupt-driven, will typically perform basic device-specific functions and hand-off data to the core routines for processing. Those routines may perform relatively simple tasks, such as transducing data from one device to another, or may perform more sophisticated algorithms such as control. Those core routines often will initiate output operations based on their computations on the input operations.

Input and output may occur either periodically or aperiodically. Sampled data is a common example of periodic I/O, while user interfaces provide a common source of aperiodic I/O events. The nature of the I/O transactions affects both the device drivers and the core computational code. Code which operates on periodic data is generally driven by a timer which initiates the code at the start of the period. Periodic operations are often characterized by their periods and the deadline for each period. Aperiodic I/O may be detected either by an interrupt or by polling the devices. Aperiodic operations may have deadlines, which are generally measured from the initiating I/O event. Periodic operations can often be thought of as being executed within an infinite loop. Aperiodic operations tend to use more event-driven code, in which various sections of the program are exercised by different aperiodic events, since there is often more than one aperiodic event which can occur.

Embedded computing systems exhibit a great deal of parallelism which can be used to speed up computation. As a result, they often use multiple microprocessors which communicate with each other to perform the required function. In addition to microprocessors, application-specific ICs (ASICs) may be added to accelerate certain critical functions. CPUs and ASICs in general are called processing elements (PEs). An example multiprocessor system built from several PEs along with I/O devices and memory is shown in Fig. 66.2.

The choice of several small microprocessors or ASICs rather than one large CPU is primarily determined by cost. Microprocessor cost is a nonlinear function of performance, even within a microprocessor family. Vendors generally supply several versions of a microprocessor which run at different clock rates; chips which run at varying speeds are a natural consequence of the variations in the VLSI manufacturing process. The slowest microprocessors are significantly less expensive than the fastest ones, and the cost increment is larger at the high end of the speed range than at the low end. As a result, it is often cheaper to use several smaller microprocessors to implement a function.

When several microprocessors work together in a system, they may communicate with each other in several different ways. If slow data rates are sufficient, serial data links are commonly used for their low hardware cost. The I^2C bus is a well-known example of a serial bus used to build multi-microprocessor embedded systems; the CAN bus is widely used in automobiles. High-speed serial links can achieve

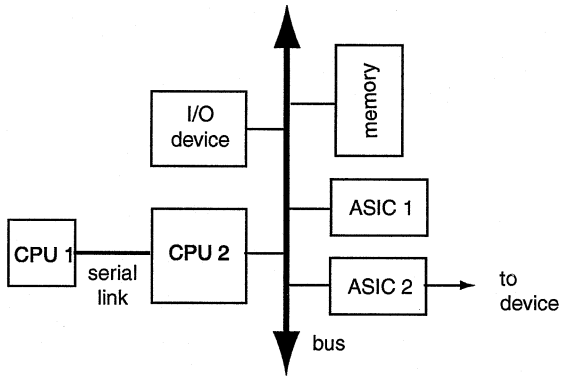

FIGURE 66.2 A heterogeneous embedded multiprocessor.

© 2003 by CRC Press LLC

moderately high performance and are often used to link multiple DSPs in high-speed signal processing systems. Parallel data links provide the highest performance thanks to their sheer data width. High-speed busses such as PCI can be used to link several processors.

The software for an embedded multiprocessing system is often built around processes. A process, as in a general-purpose computing system, is an instantiation of a program with its own state. Since problems complex enough to require multiprocessors often run sophisticated algorithms and I/O systems, dividing the system into processes helps manage design complexity. A real-time operating system (RTOS) is an operating system specifically designed for embedded, and specifically real-time applications. The RTOS manages the processes and device drivers in the system, determining when each executes on the CPU. This function is termed scheduling. The partitioning of the software between application code which executes core algorithms and an RTOS which schedules the times to which those core algorithms are executed is a fundamental design principle in computing systems in general and is especially important for real-time operation.

A number of techniques can be used to schedule processes in an embedded system — that is, to determine which process runs next on a particular CPU. Most RTOSs use process priorities in some form to determine the schedule. A process may be in any one of three states: currently executing (there can obviously be only one executing process on each CPU); ready to execute; or waiting. A process may not be able to execute until, for example, its data has arrived. Once its data arrives, it moves from waiting to ready. The scheduler chooses among the ready processes to determine which process runs next. In general, the RTOS's scheduler chooses the highest-priority ready process to run next; variations between scheduling methods depend in large part on the ways in which priorities are determined. Unlike general-purpose operating systems, RTOSs generally allow a process to run until it is preempted by a higher-priority process. General-purpose operating systems often perform time-slicing operations to maintain fair access of all the users on the system, but time-slicing does not allow the control required for meeting deadlines.

A fundamental result in real-time scheduling is known as rate-monotonic scheduling. This technique schedules a set of processes which run independently on a single CPU. Each process has its own period, with the deadline happening at the end of each period. There can be arbitrary relationships between the periods of the processes. It is assumed that data does not in general arrive at the beginning of the period, so there are no assumptions about when a process goes from waiting to ready within a period. This scheduling policy uses static priorities — the priorities for the processes are assigned before execution begins and do not change. It can be shown that the optimal priority assignment is based on period — the shorter the period, the higher the priority. This priority assignment ensures that all processes will meet their deadlines on every period. It can also be shown that at most, 69% of the CPU is used by this scheduling policy. The remaining cycles are spent waiting for activities to happen — since data arrival times are not known, it is not possible to utilize 100% of the CPU cycles.

Another well-known, real-time scheduling technique is earliest deadline first (EDF). This is a dynamic priority scheme — process priorities change during execution. EDF sets priorities based on the impending deadlines, with the process whose deadline is closest in the future having the highest priority. Clearly, the rate of change of process priorities depends on the periods and deadlines. EDF can be shown to be able to utilize 100% of the CPU, but it does not guarantee that all deadlines will be met. Since priorities are dynamic, it is not possible in general to analyze whether the system will be overloaded at some point.

Processes may be specified with data dependencies, as shown in Fig. 66.3, to create a task graph. An arc in the data dependency graph specifies that one process feeds data to another. The sink process cannot become ready until all the source processes have delivered their data. Processes which have no data dependency path between them are in separate tasks. Each task can run at its own rate. Data dependencies allow schedulers to make more efficient use of CPU resources. Since the source and sink processes of a data dependency cannot execute simultaneously, we can use that information to eliminate some combinations of processes which may want to run at the same time. Narrowing the scope of process conflicts allows us to more accurately predict how the CPU will be used.

© 2003 by CRC Press LLC

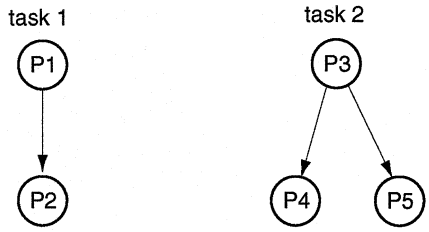

FIGURE 66.3 A task graph with two tasks and data dependencies between processes.

A real-time operating system is often designed to have a small memory footprint, since embedded systems are more cost-sensitive than general-purpose computers. RTOSs are also designed to be more responsive in two different ways. First, they allow greater control over the order of execution of processes, which is critical for ensuring that deadlines are met. Second, they are designed to have lower context-switching overhead, since that overhead eats into the time available for meeting deadlines. The kernel of an RTOS is the basic set of functions that is always resident in memory. A basic RTOS may have an extremely small kernel of only a few hundred instructions. Such microkernels often provide only basic context-switching and scheduling facilities. More complex RTOSs may provide high-end operating system functions such as file systems and network support; many high-end RTOSs are POSIX (a Unix standard) compliant. While running such a high-end operating system requires more hardware resources, the extra features are useful in a number of situations. For example, a controller for a machine on a manufacturing line may use a network interface to talk to other machines on the factory floor or the factory coordination unit; it may also use the file system to access a database for the manufacturing process.

66.4 Hardware/Software Co-Design

Hardware/software co-design refers to any methodology which takes into account both hardware and software during the design of an embedded computing system. When the hardware and software are designed together, the designer has more opportunities to optimize the system by making tradeoffs between the hardware and software components. Good system designers intuitively perform co-design, but co-design methods are increasingly being embodied in computer-aided design (CAD) tools. We will discuss several aspects of co-design and co-design tools, including models of the design, co-simulation, performance analysis, and various methods for architectural co-synthesis. We will conclude with a look at design methodologies that make use of these phases of co-design.

Models

In designing embedded computing systems, we make use of several different types of models at different points in the design process. We need to model basic functionality. We must also capture nonfunctional requirements: speed, weight, power consumption, manufacturing cost, etc.

In the earliest stages of design, the task graph is an important modeling tool. The task graph does not capture all aspects of functionality, but it does describe the various rates at which computations must be performed and the expected degrees of parallelism available. This level of detail is often enough to make some important architectural decisions. A useful adjunct to the task graph are the technology description tables, which describe how processes can be implemented on the available components. One of the technology description tables describes basic properties of the processing elements, such as cost and basic power dissipation. A separate table describes how the processes may be implemented on the components, giving execution time (and perhaps other function-specific parameters like precise power consumption) on a processing element of that type. The technology description is more complex when ASICs can be used as processing elements, since many different ASICs at differing price/performance points can be designed for a given functionality, but the basic data still applies.

© 2003 by CRC Press LLC

A more detailed description is given by either high-level language code (C, etc.) for software or hardware description language code (VHDL, Verilog, etc.) for software components. These should not be viewed as specifications — they are, in fact, quite detailed implementations. However, they do provide a level of abstraction above assembly language and gates and so can be valuable for analyzing performance, size, etc. The control-data flow graph (CDFG) is a typical representation of a high-level language: a flowchart-like structure describes the program's control, while data flow graphs describe the behavior within expressions and basic blocks.

Co-Simulation

Simulation is an important tool for design verification. The simulation of a complete embedded system entails modeling both the underlying hardware platform and the software executing on the CPUs. Some of the hardware must be simulated at a very fine level of detail — for example, buses and I/O devices may require gate-level simulation. On the other hand, the software can and should be executed at a higher level of abstraction. While it would be possible to simulate software execution by running a gate-level simulation of the CPU and modeling the program as residing in the memory of the simulated CPU, this would be unacceptably slow.

We can gain significant performance advantages by running different parts of the simulation at different levels of detail: elements of the hardware can be simulated in great detail, while software execution can be modeled much more directly. Basic functionality aspects of a high-level language program can be simulated by compiling the software on the computer on which the simulation executes, allowing those parts of the program to run at the native computer speed. Aspects of the program which deal with the hardware platform must interface to the section of the simulator that deals with the hardware. Those sections of the program are replaced by stubs that interface to the simulator. This style of simulation is a multi-rate simulation system, since the hardware and software simulation sections run at different rates: a single instruction in the software simulation will correspond to several clock cycles in the hardware simulation. The main jobs of the simulator are to keep the various sections of the simulation synchronized and to manage communication between the hardware and software components of the simulation.

Performance Analysis

Since performance is an important design goal in most embedded systems, both for overall throughput and for meeting deadlines, the analysis of the system to determine its speed of operation is an important element of any co-design methodology. System performance — the time it takes to execute a particular aspect of the system's functionality — clearly depends both on the software being executed and the underlying hardware platform. While simulation is an important tool for performance analysis, it is not sufficient, since simulation does not determine the worst-case delays. Since the execution times of most programs are data-dependent, it is necessary to give the simulation of the program the proper set of inputs to observe worst-case delay. The number of possible input combinations makes it unlikely that one will find those worst-case inputs without the sort of analysis that is at the heart of performance analysis.

In general, performance analysis must be done at several different levels of abstraction. Given a single program, one can place an upper bound on the worst-case execution time of the program. However, since many embedded systems consist of multiple processes and device drivers, it is necessary to analyze how these programs interact with each other, a phase which makes use of the results of single-program performance analysis.

Determining the worst-case execution time of a single program can be broken into two subproblems: determining the longest execution path through the program and determining the execution time of that program. Since there is at least a rough correlation between the number of operations and the actual execution time, we can determine the longest execution path without detailed knowledge of the instructions being executed — the longest path depends primarily on the structure of conditionals and loops. One way to find the longest path through the program is to model the program as a control-flow graph and use network flow algorithms to solve the resulting system.

© 2003 by CRC Press LLC

Once the longest path has been found, we need to look at the instructions executed along that path to determine the actual execution time. A simple model of the processor would assume that each instruction has a fixed execution time, independent of other factors such as the data values being operated on, surrounding instructions, or the path of execution. In fact, such simple models do not give adequate results for modern high-speed microprocessors. One problem is that in pipelined processors, the execution time of an instruction may depend on the sequence of instructions executed before it. An even greater cause of performance variations is caching, since the same instruction sequence can have variable execution times, depending on whether the code is in the cache. Since cache miss penalties are often 5X or 10X, the cost of mischaracterizing cache performance is significant. Assuming that the cache is never present gives a conservative estimate of worst-case execution time, but one that is so over-conservative that it distorts the entire design. Since the performance penalty for ignoring the cache is so large, it results in using a much faster, more expensive processor than is really necessary. The effects of caching can be taken into account during the path analysis of the program — path analysis can determine bound how often an instruction present in the cache.

There are two major effects which must be taken into account when analyzing multiple-process systems. The first is the effect of scheduling multiple processes and device drivers on a single CPU. This analysis is performed by a scheduling algorithm, which determines bounds on when programs can execute. Ratemonotonic analysis is the simplest form of scheduling analysis — the utilization factor given by ratemonotonic analysis tells one an upper limit on the amount of active CPU time. However, if data dependencies between processes are known, or some knowledge of the arrival times of data is known, then a more accurate performance estimate can be computed. If the system includes multiple processing elements, more sophisticated scheduling algorithms must be used, since the data arrival time for a process on one processing element may be determined by the time at which that datum is computed on another processing element.

The second effect which must be taken into account is interactions between processes in the cache. When several programs on a CPU share a cache, or when several processing elements share a second-level cache, the cache state depends on the behavior of all the programs. For example, when one process is suspended by the operating system and another process starts running, that process may knock the first program out of the cache. When the first process resumes execution, it will initially run more slowly, an effect which cannot be taken into account by analyzing the programs independently. This analysis clearly depends in part on the system schedule, since the interactions between processes depends on the order in which the processes execute. But the system scheduling analysis must also keep track of the cache state — which parts of which programs are in the cache at the start of execution of each process. Good accuracy can be obtained with a simple model which assumes that a program is either in the cache or out of it, without considering individual instructions; higher accuracy comes from breaking a process into several sub-processes for analysis, each of which can have its own cache state.

Hardware/Software Co-Synthesis

Hardware/software co-synthesis tries to simultaneously design the hardware and software for an embedded computing system, given design requirements such as performance as well as a description of the functionality. Co-synthesis generally concentrates on architectural design rather than detailed component design — it concentrates on determining such major factors as the number and types of processing elements required and the ways in which software processes interact.

The most basic style of co-synthesis is known as hardware/software partitioning. As shown in Fig. 66.4, this algorithm maps the given functionality onto a template architecture consisting of a CPU and one or more ASICs communicating via the microprocessor bus. The functionality is usually specified as a single program. The partitioning algorithm breaks that program into pieces and allocates pieces either to the CPU or ASICs for execution. Hardware/software partitioning assumes that total system performance is dominated by a relatively small part of the application, so that implementing a small fraction of the application in the ASIC leads to large performance gains. Less performance-critical sections of the application are relegated to the CPU.

© 2003 by CRC Press LLC

The first problem to be solved is how to break the application program into pieces; common techniques include determining where I/O operations occur and concentrating on the basic blocks of inner loops. Once the application code is partitioned, various allocations of those components must be evaluated. Given an allocation of program components to the CPU or ASICs, performance analysis techniques can be used to determine the total system performance; performance analysis should take into account the time required to transfer necessary data into the ASIC and to extract the results of the computation from the ASIC. Since the total number of allocations is large, heuristics must be used to search the design space. In addition, the cost of the implementation must be determined. Since the CPU's cost is known in advance, that cost is determined by the ASIC cost, which varies as to the amount of hardware required to implement the desired function. High-level synthesis can be used to estimate both the performance and hardware cost of an ASIC that will be synthesized from a portion of the application program.

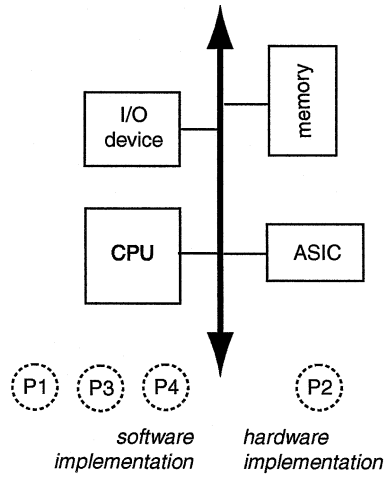

FIGURE 66.4 Hardware/software partitioning.

Basic, co-synthesis heuristics start from extreme initial solutions: We can either put all program components into the CPU, creating an implementation which is minimal cost but probably does not meet performance requirements, or put all program elements in the ASIC, which gives a maximal-performance, maximal-expense implementation. Given this initial solution, heuristics select which program component to move to the other side of the partition to either reduce hardware cost or increase performance, as desired. More sophisticated heuristics try to construct a solution by estimating how critical a component will be to overall system performance and choosing a CPU or ASIC implementation accordingly. Iterative improvement strategies may move components across the partition boundary to improve the design.

However, many embedded systems do not strictly follow the one CPU, one bus, n ASIC architectural template. These more general architectures are known as distributed embedded systems. Techniques for designing distributed embedded systems rest on the foundations of hardware/software partitioning, but they are generally more complicated, since there are more free variables. For example, since the number and types of CPUs is not known in advance, the co-synthesis algorithm must select them. If the number of busses or other communication links is not known in advance, those must be selected as well. Unfortunately, these decisions are all closely related. For example, the number of CPUs and ASICs required depends on the system schedule. The system schedule, in turn, depends on the execution time of each of the components on the available hardware elements; but those execution times depend on the processing elements available, which is what we are trying to determine in the first place. Co-synthesis algorithms generally try to fix several designs and vary only one or a few, then check the results of a design decision on the other parameters. For example, the algorithm may fix the hardware architecture and try to move processes to other processing elements to make more efficient use of the available hardware. Given that new configuration of processes, it may then try to reduce the cost of the hardware by eliminating unused processing elements or replacing a faster, more expensive processing element with a slower, cheaper one.

Since the memory hierarchy is a significant contributor to overall system performance, the design of the caching system is an important aspect of distributed system co-synthesis. In a board-level system with existing microprocessors, the sizes of second-level caches is under designer control, even if the first-level cache is incorporated on the microprocessor and therefore fixed in size. In a single-chip embedded system, the designer has control over the sizes of all the caches. Co-synthesis can determine hardware elements such as the placement of caches in the hardware architecture and the size of each cache. It can

© 2003 by CRC Press LLC

also determine software attributes such as the placement of each program in the cache. The placement of a program in the cache is determined by the addresses used by the program — by relocating the program, the cache behavior of the program can be changed. Memory system design requires calculating the cache state when constructing the system schedule and using the cache state as one of the factors to determine how to modify the design.

Design Methodologies

A co-design methodology tries to take into account aspects of hardware and software during all phases of design. At some point in the design process, the hardware and software components are well-specified and can be designed relatively independently. But it is important to consider the characteristics of both the hardware and software components early in design. It is also important to properly test the system once the hardware and software components are assembled into a complete system.

Co-synthesis can be used as a design planning tool, even if it is not used to generate a complete system architectural design. Because co-synthesis can evaluate a large number of designs very quickly, it can determine the feasibility of a proposed system much faster than a human designer. This allows the designer to experiment with what-if scenarios, such as adding new features or speculating on the effects of lower component costs in the future. Many co-synthesis algorithms can be applied without having a complete program to use as a specification. If the system can be specified to the level of processes with some estimate of the computation time required for each process, then useful information about architectural feasibility can be generated by co-synthesis.

Co-simulation plays a major role once subsystem designs are available. It does not have to wait until all components are complete, since stubs may be created to provide minimal functionality for incomplete components. The ability to simulate the software before completing the hardware is a major boon to software development and can substantially reduce development time.

Don Cottrell
Si2, Inc.

67.1 Introduction

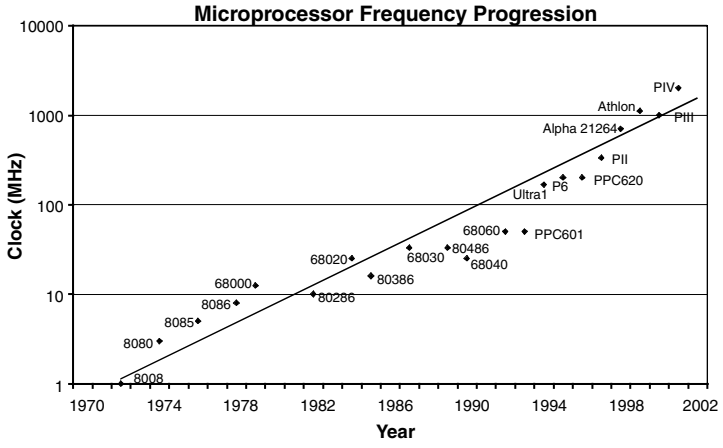
No invention in the modern age has been as pervasive as the semiconductor and nothing has been more important to its technological advancement than has electronic design automation (EDA). EDA was born in the 1960s both for and because of the electronic computer. It was the advent of the computer that allowed for the development of specialized programs that perform the complex management, design, and analysis operations associated with semiconductors and electronic systems. At the same time, it was the design, management, and manufacture of the thousands (now tens of millions) of devices that make up a single electronic assembly that made EDA an absolute requirement to fuel the semiconductor progression. Today, EDA programs are used on electronic packages for all business markets from computers to games, telephones to aerospace guidance systems, toasters to automobiles. Across these markets, EDA supports many different package types such as integrated circuit (IC) chips, multi-chip modules (MCM), printed circuit boards (PCB), and entire electronic assemblies of several different packages.

No electronic circuit package is as challenging to those EDA as the IC. The growth in complexity in ICs has placed tremendous demands on EDA. Mainstream EDA applications such as simulation, layout, and test generation have had to improve their speed and capacity characteristics with this ever-increasing growth in the number of circuits to be processed. New types of design and analysis applications, new methodologies, and new design rules have been necessary to keep pace. Yet, even with the technological breakthroughs that have been made in EDA across the past three decades, it is still having difficulty keeping up with the breakthroughs being made in the electronic technologies that it supports. The increase in the chip's die size coupled with the decrease in size of the features on the chip is causing the number of design elements per IC to increase at a tremendous rate. The decrease in feature size and spacing coupled with the increase in operating frequency is causing additional levels of complexity to be approximated in the models used by design and analysis programs.

In the period from 1970 to the present the following semiconductor advances occurred:

- IC integration has grown from tens of transistors on a chip to over 10,000,000.
- The feature size on production ICs has shrunk from 10 microns to 0.13 microns and smaller.

© 2003 by CRC Press LLC



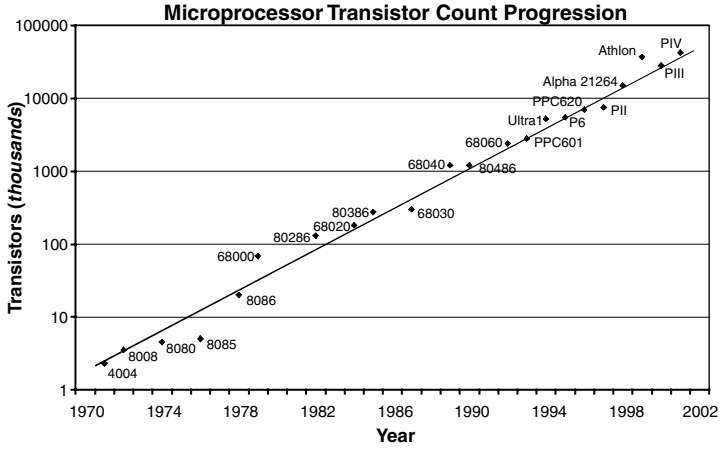


FIGURE 67.1 Microprocessor development.

- On-chip clock frequency has increased from a few MHz, to over 2 GHz.
- Die sizes have increased from less than 20 mm^2 to over 500 mm^2.

Playing an essential part in the advancement of EDA have been advances in computer architectures that run the EDA applications. These advances include the following:

- Computer CPU speed: from less than 1 million instructions per second (MIPS) of shared mainframe to hundreds of MIPS on a dedicated workstation.
- Computer memory: from less than 32 KB, to over 500 GB.
- Data archive: from voluminous reels of (rather) slow speed tape to virtually limitless amounts of high-speed electronic storage devices.

However, these major improvements in computing power alone would not have been sufficient to meet the EDA needs of the even more significant advances in semiconductors. Major advances also had to be made in fundamental algorithms used by EDA programs, and entirely new design techniques and design paradigms had to be invented and established for the technology advances to be supportable. This chapter traces the more notable advancements made in EDA across the past three decades. From there, it discusses the technology trends predicted across the next decade along with the impact they will have

© 2003 by CRC Press LLC

on EDA of the future. It is important to understand these trends and projections because if the EDA systems cannot keep pace with the semiconductor projections, then these projections will never be realized. Although it may be possible to build manufacturing processes that can produce ultra-deep submicron and find the billions of dollars of capital required, without the necessary EDA support these factories will never be fully utilized. SEMATECH reports that chip design productivity has increased at a compounded rate somewhere between 21 to 30%, while Moore's Law predicts the number of transistors on a chip to increase at a compound rate of 56%. This means that at some time building manufacturing plants that can produce smaller denser chips will reach a point of diminishing returns, because the ability to design chips with that many transistors will not be possible.

67.2 Design Automation — Historical Perspective

The 1960s — The Beginnings of Design Automation

Early entries into design automation were made in the areas of design records, PCB wiring, and manufacturing test generation. A commercial EDA industry did not exist and developments were made within companies with the need, such as IBM[1] and Bell Labs, on mainframe computers such as the IBM 7090. The 7090 had addressable 36-bit words and a limit of 32,000 words of main storage (magnetic cores). By today's standard, this would be equivalent to the storage in a small electronic address book, far less than the typical 128+ MB of RAM on the average notebook PC, and certainly no match for a high-function RISC workstation with 512 MB of main store or more. Computer limitations continue to be the curse of EDA development, particularly when EDA support is targeted for design of the next generation computer. However, the limitation of the computers of the 1960s was particularly acute.

In retrospect though, the limit of computers in the 1960s was a blessing for the development of design automation. Because of these limitations, design automation developers were forced to invent highly creative algorithms that operated on very compact data structures. Many of the algorithms developed during this decade are still in use within commercial EDA systems today, with only minor differences in fundamental concepts. Notable advances during this period were:

- The fundamental "stuck-at" model for manufacturing test and a formal algebra for the generation of tests and diagnosis of faults
- Parallel fault simulation, which provided simulation of many fault conditions in parallel with the good-machine (non-faulty circuit) to reduce fault-simulation run-times
- A three-valued algebra for simulation which yields accurate results using simple delay models, even in the presence of race conditions within the design
- Development of fundamental algorithms for the placement and wiring of components

Also, there was development of fundamental heuristics for placement and wire routing, and for divide and conquer concepts. One such concept was the hierarchical division of a wiring image into cells, globally routing between cells, and then performing detailed routing within cells, possibly subdividing them further. Many of these fundamental concepts are still applied today, although the physical design of today's LSI is vastly more complex.

The 1960s represented the awakening of design automation and provided the proof of its value and need for electronic design. It would not be until the end of this decade when the explosion of the number of circuits designed on a chip would occur and the term LSI (large-scale integration) would by coined. EDA development in the 1960s was primarily focused on printed circuit assemblies, but the fundamental concepts developed for design entry, test generation, and physical design provided the basics for EDA in the LSI era.

Design Entry

Before the use of computers in electronic design, the design schematic was a drawing. This drawing was a draftsman's rendering of the notes and sketches provided by the designer. The drawings provided the

© 2003 by CRC Press LLC

basis for manufacturing or repair operations in the field. As automation developed, it became desirable to store these drawings on media usable by computers so that the creation of input to the automated processes could be automated. The need to record the design of electronic products and assemblies in computers was recognized in the late 1950s and early 1960s. In the early days of design automation, the electronic designer would develop the design using paper and pencil, and then transcribe it to a form suitable for keyed entry to a computer. Once keyed into the computer, the design could be rendered in a number of different formats to support the manufacturing and field support processes. It recognized further that these computerized representations of the circuit design drawing could also drive design processes, such as the routing of printed circuit traces or the generation of manufacturing test patterns. From there, it was but a short step to the use of computers to generate data in the form required to drive automated manufacturing and test equipment.

Early design entry methods involved the keying of the design into transcription records that were read into the computer and saved on a persistent storage device. This became known as the design's database, and is the start of the design automation **system**. From the database, schematic diagrams and logic diagrams were rendered for use in engineering, manufacturing, and field support. This was typically a two-step process, whereby the designer drew the schematic by hand and then submitted it to another for conversion to the transcription records, keypunch, and submission to the computer. Once in the computer, the formal automated drawings were generated, printed, and returned to the designer. Although this process seems archaic by today's standards, it did result in a permanent record of the design in computer readable format. This could be used for many forms of records management, engineering change history, and as input to design, analysis, and manufacturing automation that would soon follow.

With the introduction of the alphanumeric terminal, the keypunch was replaced as the window into the computer. With this, new design description languages were developed, and the role of the transcription operator dissolved. Although these description languages still represented the design at the device or gate level, they were free format and keyword oriented and engineers were willing to use them. The design engineer now had the tools to enter design descriptions directly into the computer, thus eliminating the inherent inefficiencies of the "middle-man". Thus, a paradigm shift began to evolve in the method by which design was entered into the EDA system. Introduction of the direct access storage devices (disks) in the late 1960s also improved the entry process as well as the entire design system by providing online, high-speed direct access to the entire design or any portion of it. This was also important to the acceptance of design entry by the designer, as the task was still viewed as a necessary overhead rather than a natural part of the design task. It was necessary to obtain access to the other evolving design automation tools, but typically, the real design thought process took place with pencil-and-paper techniques. Therefore, any change that made the entry process faster and easier was eagerly accepted.

With the evolution of design tools, new design description languages began to be introduced that were capable of representing the functional design intent, but without the implementation details. The design engineer was now able to represent his design ideas at a more abstract level with less detail. Register transfer level (RTL) design languages were introduced and with new simulators capable of simulation directly from these, the designer was able to verify design intent much earlier in the design cycle.

The next shift occurred in the later part of the 1970s with the introduction of graphics terminals. With these, the designer could enter design into the database in schematic form. This form of design entry was a novelty, but not a clear performance improvement. In fact, until the introduction of the workstation and dedicated graphics support, in many cases graphic entry was detrimental to design productivity. Negative effects such as less than effective transaction speed and time lost in making the schematic ascetically pleasing, and the low level of detail all added to less than obvious advances. On the other hand, use of the graphics display to view the design and make design change proved extremely effective and was a great improvement over the red-lined prints. For this reason alone, graphics represented a major advance. However, even with the negative virtues of graphic schematic entry, this style took off with the introduction of the workstation in the 1980s. In fact, the graphic editor glitz and capability often was a major decision point in the purchase of one commercial EDA system over another, and to be considered a commercially viable system, graphics entry was required. Nevertheless, as the density of

© 2003 by CRC Press LLC

ICs grew and grew, graphics entry of schematics would begin to yield to the advantages of alphanumeric entry languages. As EDA design and analysis tool technology advanced, entry of design at the RTL level would become commonplace. Today, design entry using RTL descriptions is the generally accepted approach for original design of standard cell design, although schematic entry is the accepted method for PCB design and many elements of custom ICs.

There is no doubt that the introduction of graphics into the design automation system represents a major advance and a major paradigm shift. Use of graphics to visualize design details, wiring congestion, timing diagrams, etc. is of major importance. Use of the graphics to perform certain edit functions is standard operating procedure. Large system design often entails control circuitry, dataflow, and functional modules. Classically, these systems span across several chips and boards and employ several styles of entry for the different physical packages. These may include:

- Schematics — graphic
- RTL and behavorial level languages — alphanumeric
- Timing diagrams — graphic
- State diagrams — alphanumeric
- Flowcharts — graphic

Today, these entry techniques can be found in different EDA tools, and each is particularly effective for different types of design problems. Schematics are effective for the design of "glue" logic that interconnects functional design elements, such as modules on a PCB. Behavorial languages are useful for all design, but particularly effective for dataflow behavior. Timing diagrams lend themselves well to describe the functional operations of "black-box" components at their I/Os without needing to describe their internal circuitry. State diagrams are a convenient way to express the logical operation of combinational circuits. Flowcharts are effective for describing the operations of control logic, much like use of flowcharts for specification of software program flow. With technology advances, the IC is engulfing more and more of the entire system and all of these forms of design are prevalent on a single chip. It is even expected that the design of "black-box" functions will be available from multiple sources to be embedded onto the chip similar to the use of modules on a PCB. Thus, it is likely that future EDA systems will support a mixture of design description forms to allow the designer to represent sections of the design in a manner most effective to each. After all, design is described in many forms by the designer outside the design system.

Test Generation

Testing of manufactured electronic subassemblies entails the use of special test hardware that can provide stimulus (test signals) to selected [input] pins of the part under test and measure for specified responses on selected [output] pins. If the measured response matches the specified response, then the part under test successfully passed that test. If some other response is measured, then the part failed that test and the presence of a defect is indicated. Manufacturing test is the successive application test patterns that cause some measurable point on the part under test to be sensitized to the presence of a manufacturing defect. That is, some measurable point on the part under test will result in a value if the fault is present that is different from what it would be if the fault were not present. The collection of test patterns causes all (or almost all) possible manufacturing failures to render a different output response than would the non-defective part. For static DC testers, each stimulus is applied and after the part under test settles to steady state, the specified outputs are measured and compared with the expected results for a non-defective part.

To bound the test generation problem, a model was developed to represent possible defects at the abstract gate level. This model characterizes the effects of defects as a stuck-at value. This model is fundamental to most of the development in test generation and is still in use today. It characterizes defects as causing either a stuck-at-one or a stuck-at-zero condition at pins on a gate. Additionally, it assumes that a fault is persistent and that only one fault occurs at a time. Thus, this model became known as the

© 2003 by CRC Press LLC

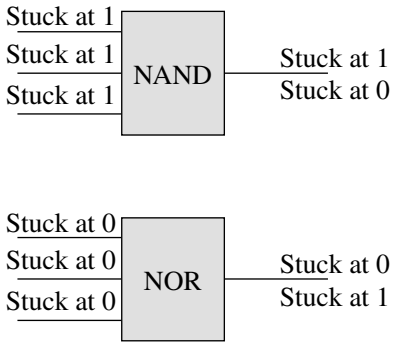

FIGURE 67.2 Stuck fault models.

single stuck-at fault model. Stuck-at fault testing assumes that the symptom of any manufacturing defect can be characterized by the presence of a stuck-at fault some place within the circuit. By testing for the presence of all possible stuck-at faults that can occur, all possible manufacturing defects can thus be tested.

The stuck-fault models for NAND and NOR gates are shown in Fig. 67.2. For the NAND gate, the presence of an input stuck-at-one defect can be sensitized (made detectable) at the gate's output pin by setting the good-machine state for that input to zero, and setting the other input values to 1. If a 0-state is observed at the gate's output node, then the fault is detected. A stuck-at-zero condition on any specific input to the NAND gate is not distinguishable from a stuck-at-zero on any other input to the gate; thus, it is not part of the model. However, a stuck-at-one is modeled at the gate's output to account for such a fault or a defect on the gate's output circuitry.

The fault model for the NOR gate is similar except that here the input condition is stuck-at-zero only, as the stuck-at-one defect cannot be isolated to a particular input.

Later in time, additional development would attack defects not detectable with this stuck-at fault model; for example, bridging faults where nodes are shorted together, and delay faults where the output response does not occur within the required time. The stuck-at fault model cannot detect these fault types and they became important as the development of CMOS progressed. Significant work was performed in both of these areas beginning in the 1970s, but it did not have the impact on test generation development that the stuck-at fault model did.

The creation of the fault model was very important to test generation, as it established a realistic set of objectives to be met by the test generator that could be achieved in a realistic amount of compute time. A formal algebra was developed by Roth[2] called the D-ALG, which formalized an approach to test generation and fault diagnosis.

The test generation programs could choose a fault based on the instances of gates within the design and the fault models for the gates. It could then trace back from that fault to the input pins of the design and, using the D-ALG calculus, find a set of input states that would sensitize the fault. Then, it could trace forward from that fault to the design's output pins, sensitizing the path (cause the good-machine value to be the opposite from the stuck-at-fault value along that path) to at least one observable pin.

Use of functional patterns as the test patterns in lieu of heuristic test generation was another approach for manufacturing test. However, this required an extreme number of tests to be applied and, worse, depended on the experience and skill of the designer to create quality tests. The use of fault models and automatic test generation produced a minimum set of tests and greatly reduced manually intensive labor.

The exhaustive method to assure coverage of all possibly detectable defects would be to apply all possible input states to the design under test and compare the measured output states with the simulated good-machine states. For a design with n input pins, however, the simulation of 2^n input patterns for combinatorial logic and at least 2^{n+m} for sequential logic (where m is the number of independent storage elements) was required. For even a relatively small number of input pins, this amount of simulation would not be possible even on today's computers, and the time to apply this number of patterns at the tester would be grossly prohibitive.

© 2003 by CRC Press LLC

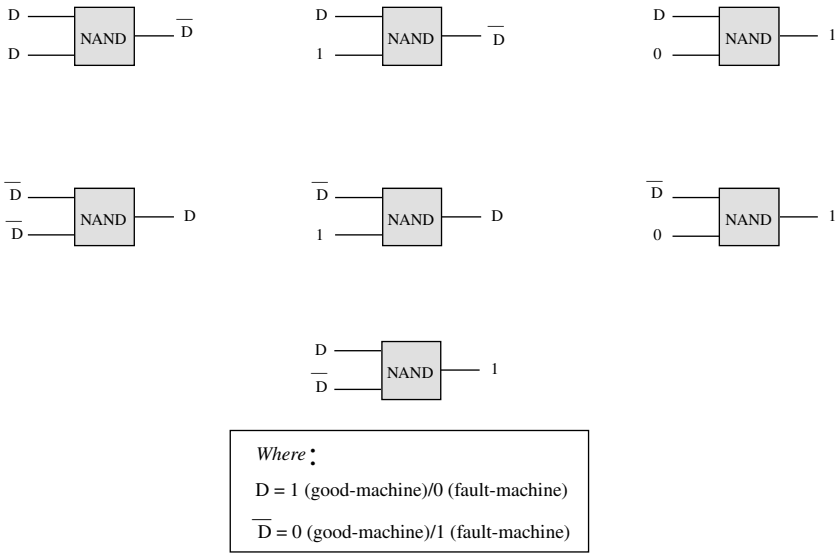

FIGURE 67.3 D-ALG calculus.

The amount of time that a part resides on the tester is critical in the semiconductor business, as it impacts the number of parts that can be produced in a given amount of time and the capital cost for testers. This implies that the number of test patterns that need to be applied at the tester should be keep to a minimum. Early work in test generation attacked this problem in two ways. First, when a test pattern was generated for a specific fault, it was simulated against all possible faults. In many cases, the application of a test pattern that is targeted for a specific fault will also detect several other faults at the same time. The test for the specific fault may be detectable on one output pin, for example, but additional faults may be observable at other output pins. The use of fault simulation detected these cases and provided a mechanism to mark as tested those faults that were "accidentally" covered. This meant that the test generation algorithm did not have to generate a specific test for those faults. Second, schemes were developed to merge input patterns together into a smaller number of test vectors to minimize the number of patterns that needed to be applied at the tester. This was possible when two adjacent test patterns required the application of specific stimulus values at different input pins, each allowing all other input pins to be at the "don't-care" state. In these cases, the patterns could be merged into a single test vector. With successive analysis in this way, all pairs of test patterns (pattern n with n+1, or the merger of m and m+1 with pattern m+2) were analyzed, and merged into a reduced set of patterns.

Sequential design elements severely complicate test generation, as they require the analysis of previous states and the application of sequences of patterns. Early work in test generation broke feedback nets, inserted a lumped delay on them, and analyzed the design using a Huffman model. Later work attempted to identify the memory elements within the design using sophisticated topological analysis and then use a Huffman model to analyze each. State tables for each sequential element were generated and saved for later use as lookup tables in the test generation process. Use of three-value simulation within the analysis both reduced the analysis time and guaranteed that the results were always accurate. Huffman analysis required 2^x simulations (where x is the number of feedback nets) to determine if critical hazards existed in the sequential elements. Using three-valued simulation[3] (all value transitions go through an X state), this was reduced to a maximum of $2x$ simulations.

This lumped delay model did not account for the distribution of delays in the actual design, thus it often caused pessimistic results. Often simulated results yielded don't-know (X-state) conditions when a more accurate model could yield a known state. This made it difficult to generate patterns that would detect all faults in the model. As the level of integration increased, the problems associated with automatic test generation for arbitrary sequential circuits became unwieldy. This necessitated that the designer be

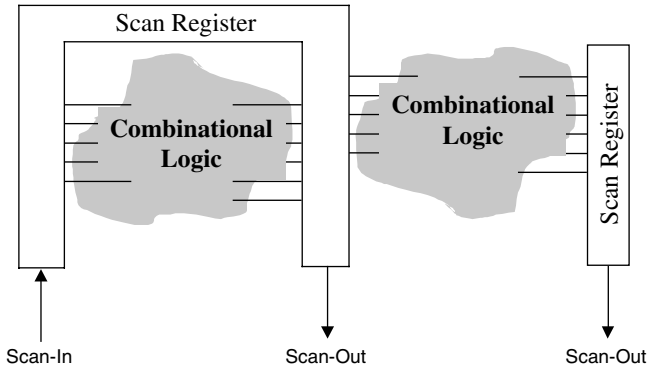

FIGURE 67.4 Scan design.

called back into the problem of test generation most often to develop tests that would detect those missed by the test generation program. New approaches were developed that ranged from random pattern generation to advanced algorithms and heuristics which used sequences of different approaches. However, by the mid-1970s the need to design-for-test was becoming evident to many companies.

During the mid 1970s the use of scan-design was developed.[4] Scan design provides external control and observability to points within a design that might otherwise be inaccessible. This is accomplished by inserting special scan registers into the design at the points to be controlled and observed. These registers are connected into a shift register chain that has its data input and output connected to an accessible pin. Under normal conditions, signals from the design are passed through individual registers. Under test conditions, test vectors can be scanned in from the input pin of the scan register and applied to the appropriate points within the design. Similarly, values on points within the design are captured in individual registers and scanned out to the output pin of the scan register.

The development of scan design was important for two reasons. First, level sensitive scan design (LSSD) allowed for external control and observability of sequential elements within the design. With specific design-for-test rules, this reduced the problem of test generation by allowing the design to be analyzed as a combinational circuit. In LSSD, rigid design-rules such as the following were developed and checking programs or scan generation algorithms were implemented to assure they were adhered to before entering test generation:

- All internal storage elements implemented in hazard-free polarity-hold latches
- Absence of any global feedback loops
- Latches may not be controlled by the same clock as latches feeding them
- Externally controllable clocks to shift register latches

Second, scan design allowed for external control and observability at otherwise non-probable points between modules on an MCM or PCB. During the 1980s, an industry standard for this was developed called Boundary Scan (IEEE 1149.1 Joint Test Action Group).[5] Use of a standard technique and shift register latches greatly improved the transfer of complex modules into a random design by simplifying the test problem. Each of these uses of scan techniques to provide additional control and observability have a price. They require additional real estate in the IC design and have a level of performance overhead. However, with the achievable transistor density levels on today's ICs and the test benefits accrued, these penalties are easily justified in all but the most performance critical designs. In fact, with today's IC densities and speeds, the use of circuitry on-chip is often used to generate test vectors.

During the 1980s, IC density allowed for the design of built in self-test (BIST) circuitry on the chip itself. Operating at hardware speed, it became feasible to generate complete exhaustive tests and large numbers of random tests never possible with software and stored program testers. BIST tests are generated on the tester by the device under test, reducing the management of data transfer from design to manufacturing.

© 2003 by CRC Press LLC

A binary-counter or linear feedback shift-registers (LFSR) are used to generate the patterns for exhaustive or random tests, respectively. In the latter case, a pseudo-random bit sequence is formed by the exclusive-OR of the bits on the LFSR and this result is then fed back into the LFSR input. Thus, a pseudo-random bit sequence can be generated whose sequence length is based on the number of LFSR stages and the initial LFSR state. The design can be simulated to determine the state conditions for the generated test patterns, and these simulated results compared with the actual device-under-test results observed at the tester.

Today, BIST techniques are becoming common for the test of on-chip RAM and ROS. BIST is also used for logic sections of chips either with fault simulated weighted random test patterns or good machine simulated exhaustive patterns. In the latter case, logic is partitioned into electrically isolated regions with a smaller number of inputs in order to reduce the number of test patterns. Partitioning of the design reduces the number of exhaustive tests from 2^n (where n is the total number of inputs) to:

$$\sum_{i=1}^{n=F/31} Patterns$$

where, m is the number of partitions and n^i $(n^i < n)$ is the number of inputs on each logic partition.

Since the use of BIST implies extremely large numbers of tests, the simulated data transfer and test measurement time is reduced greatly by the use of a compressed signature to represent the expected and actual test results. Thus, only a comparison of the simulated signatures for each BIST region needs to be made with the signatures derived by the on-chip hardware, rather than the results of each individual test pattern. This is accomplished by feeding the output bit sequence to a single input serial input LFSR after exclusive-OR with the pseudo-random pattern generated by that LFSR. In this way, a unique pattern can be observed for a sequence of test results, which is a function of the good-machine response and a pseudo-random number.

Today, testing of ICs typically consists of combinations of different test strategies. These may include stored program stuck fault tests, BIST tests, DC and delay tests (which test for signal arrival times in addition to state), and I_{DDQ} tests (direct drain quiescent current testing checks for CMOS defects that cause current leakage). These latter two test techniques are used to detect defect conditions not identified by stuck-at fault tests such as shorts (bridging faults) between signal nets or gate oxide defects which cause incorrect device operation. The progression of inventions in stuck-fault modeling and scan design that have taken place over the last 30 years have been key to the success in this field. Moreover, as will be seen later in this chapter, these techniques will continue to be essential ingredients for IC test in the future.

Fault Simulation

Fault simulation is used to predict the state of a design at observable points in the presence of a defect. This is used in manufacturing tests to detect faulty parts and for field diagnostics of entire assemblies. Early work in fault simulation relied on the stuck-fault model and performed successive simulations of the design with each single fault independent of any other fault; thus, a single stuck-at-fault model was assumed. Because even these early designs consisted of thousands of faults, it was too time consuming to simulate each fault serially, and it was necessary to create high-speed simulation algorithms.

For manufacturing test, fault simulation took advantage of three-valued zero-delay simulation. The simulation model of the design was levelized and compiled into an executable program. Levelization assured that driver-gates were simulated before the gates receiving the signals, thus allowing a state resolution in a single simulation pass. Feedback loops were cut and the X-transition of three-valued simulation resolved race conditions. The inherent instruction set of the host computer (such as AND, OR, XOR, etc.) allowed the use of a minimum set of instructions to simulate a gate's function.

The Parallel-Fault simulation algorithm was developed during the 1960s, which allowed many faults to be simulated in parallel. Using the 32-bit word length of the IBM 7090 computer architecture, for example, simulation of 31 faults in a single pass (using the last bit for the good-machine) was possible. For each gate in the design, two host machine words were assigned to represent its good-machine state and the state for 31 single stuck-at faults. A bit position in the first word was set to one or zero to represent the state of the node represented for the good or faulty machine, which that bit position represented. The corresponding bit position in the second word was set to zero if it was a known state and one if it was an X-state. The entire fault list was divided into *n* partitions of 31 faults, and each partition was then simulated against all input patterns. In this way, the run-time for simulation is a function of:

$$C_{gate} = \varepsilon_{ox}\left(W_{gate}L_{gate}\right)/T_{gox}\,\alpha\left(S_{feature}S_{feature}\right)/S_{feature} = S_{feature}$$

where *F* is the total number of single stuck-at faults in the design. Specific faults are injected within the word representing their location within the design, by the insertion of a mask that is AND'd or OR'd at the appropriate word. For stuck-at-one conditions, the mask contains a 1-bit in the position representing the fault (and 0-bits at others) and it is OR'd to the gate's memory location. For stuck-at-zero faults the mask contains a 0-bit at the positions representing the fault (and 1-bits at others) and it is AND'd with the gate's memory location.

As the level of integration increased, however, so did the number of faults. The simulation speed improvement realized from parallel-fault simulation is limited to the number of faults simulated in parallel and because of the algorithm overhead, it was typically less than that factor. Also, during the 1970s, the challenges to test became those of the IC, which was major because of the rapidly increasing circuit density. However, the IC also allowed relaxed goals in test.

When manufacturing test is performed on PCB packages, it is desirable to not only detect the presence of a fault, but also to isolate it to the faulty module, which can then be replaced. With IC's the notion of fixing faulty parts is not realistic. To isolate faults to a particular replaceable unit, it is necessary to simulate all generated tests against all faults exhaustively. When fault detection is the only goal, a fault-machine need only be simulated up to the point where it is detectable at an observable pin and need not be simulated against any other patterns. Parallel-fault simulation did not lend itself to be able to drop out simulation of detected faults because even when individual faults within a word were detected, others were not; thus, simulation of the entire set had to continue. Only when all faults in the word were detected could simulation of that parallel set cease. This, coupled with the limiting factor of a speedup of the number of parallel faults, led to the development of event-based fault simulation and improved algorithms.

Deductive-fault simulation was developed early in the 1970s and required only one simulation pass per test pattern. This is accomplished by simulating only the good-machine behavior and using deductive techniques to determine each fault that is detectable along the simulated paths. Because lists of faults detectable at every point along the simulated path need to be kept, this algorithm requires extensive

© 2003 by CRC Press LLC

memory, far more than the parallel algorithm. However, with increasing memory on host computers and the inherent increase in fault simulation speed, this technique won the favor of many fault simulators.

Concurrent-fault simulation refined the deductive algorithm by recognizing the fact that paths in the design quickly become insensitive to the presence of most faults, particularly after some initial set of test patterns is simulated. (An observation made in the 1970s was that a high percentage of faults was detected in a low percentage of the initial test patterns, even if those patterns are randomly generated.) The concurrent-fault simulation algorithm simulates the good-machine and "concurrently" simulates a number of fault-machines. Once it is determined that a particular fault-machine state is the same as the good-machine, simulation for that fault ceases. Because in logic paths most faults will become insensitive rather close to the point where the fault is located, the amount of simulation for these fault-machines was kept small. This algorithm required even more memory, particularly for the early test patterns; however, host machine architectures of the late 1970s were supporting what then appeared as massive amounts of addressable memory.

With the use of scan-design, all sequential elements were controllable from the tester. Therefore, the design could be simulated as a combinational circuit and its state was deterministic based on any single test pattern — and not dependent on previous patterns or states. Parallel-pattern fault simulation was developed in the late 1970s to take advantage of this, and simulate multiple test patterns in parallel against a single fault. A performance advantage was achieved because compiled simulation could again be utilized as opposed to the more general event-based approach. In addition, because faults not detected by the initial test patterns are typically only detectable by a few patterns, simulation of many sets of patterns does not require a complete pass across the design. In most cases, the required sensitized path to detect these faults disappears within a close proximity to the fault. Adjustment of the number of patterns to simulate in parallel, therefore, could effect the required simulation time.

Because of the increasing number of devices on chips, the test generation and fault simulation problem continued to face severe challenges. During the 1980s, BIST began to evolve as a method for manufacturing test. Use of circuitry on the IC itself to generate test vectors meant that exhaustive tests could be generated and exercised at the tester. With exhaustive tests, and no need to provide fault isolation diagnostics, fault simulation could be eliminated. With BIST approaches to testing, only the good machine behavior needed to be simulated and compared with the actual results at the tester. To decrease the amount of data passed from the simulation to the tester and the time on the tester, special hardware was designed on the chip to capture the results and compress them into a single value (signature). This signature was compared with the simulated signature only at the end of a sequence of tests, thus minimizing the number of comparisons required.

Physical Design

As with test generation, physical design (PD) has evolved from early work on PCBs. PD automation programs generate the physical routing (wiring) for the interconnections of the logical nets in a design. To accomplish this, the suite of PD programs must be capable of assigning physical package pins (pin assignment) to nets, placing logic functions (placement) on the package, and performing a myriad of electrical and topographical checks to assure the quality of the solution. The challenge for PD has become ever greater since the early days. It started with PCBs, where the goal was simply to route all the nets, typically with the shortest paths. Any nets that were not auto-routed were routed (embedded) manually, or with discrete wires as a last resort. As the problem moved to ICs, the ability to use discrete wires to finish routing was no more. For nets that could not be auto-routed, manual routing (embedding) was required. Now, wiring congestion in areas on the IC had to be considered by PD programs. Too much congestion in an area could block the passage of more wires through that area and complicate or negate a possible solution, and less than a 100% solution was unacceptable. As the IC densities increased, so did the number of nets. This necessitated the invention of smarter wiring programs and heuristics, for even a small number of incomplete (overflow) routes became too complex of a task for manual solutions.

Later, as IC device sizes shrank and the gate delays decreased, the delay imposed by interconnect wiring became an important factor. No longer was any wiring solution that connected the nodes on the nets

© 2003 by CRC Press LLC

necessarily a correct solution. Now, the wiring problem was complicated by the need to find wiring solutions that fell within acceptable timing limits. Thus, the wiring lengths and thickness needed to be considered. As IC features became packed closer together, cross-coupled capacitance (crosstalk) effects between them became an important consideration as well. For advanced ICs even today, effects of cross coupling have expanded into a 3-dimensional space.

If this challenge was not enough, the decrease in power supply (V_{dd}) voltage levels with smaller more closely spaced features has introduced a new problem with which physical design must contend. This is called noise — the unwanted introduction of voltage on a signal. Noise can cause both increases in signal delays and incorrect logical behavior. Noise is a function of both the physical layout of the design and the signal switching characteristics. It results from design factors such as signal termination, simultaneous switching of circuits, and crosstalk between adjacent lines. These conditions result from characteristics such as spacing between signal lines, switching frequency, rise times, cross-sectional area of wires, etc. Design tools for PCBs and multi-chip modules have had to contend with noise for some time. However, it is now becoming a significant factor in the design of ICs. Future PD solutions must consider these complex factors, and still achieve a 100% solution that meets the designer specified timing for IC designs that contain millions of nets.

Because of these increasing demands on PD, major paradigm changes have taken place in the design methodology. In the early days, there was a clear separation of logic design and physical design. The logic designer was responsible for creating a netlist that correctly represented the logic behavior desired. Timing was a function of the drive capability of the driving circuit and the number of receivers. Different power levels for drivers could be chosen by the logic designer to match the timing requirements, based on the driven circuits. The delay imposed by the time-of-flight along interconnects and due to the parasitics on the interconnect was insignificant. Therefore, the logic designer could hand-off the physical design to another, more adept at using the PD programs and manually embedding overflow wires. As the semiconductor technology progressed, however, there needed to be more interactions between the logic designer and the physical designer, as the interconnect delays became a more dominant factor across signal paths. The logic designer had to give certain timing constraints to the physical designer and if these could not be met, the design was often passed back to the logic designer. The logic designer, in-turn, then had to choose different driver gates or a different logical architecture to meet the design specification. In many cases, the pair had to become a team or there was a merger of the two previously distinct operations into one "IC designer".

This same progression of merging logic design and physical design into one operational responsibility has also begun at the EDA system architecture level. In the 1960s and 1970s, front-end (design) programs were separate from back-end (physical) programs. Most often they were developed by different EDA development teams and designs were transferred between them by means of data files. Beginning in the 1980s and continuing into today, the data transferred between front-end programs and back-end included specific design constraints that must be met by the PD programs — the most common being a specific amount of allowed delay across an interconnect or signal path. As the number of constraints that must be met by the PD programs increases, however, the likelihood that a 100% solution can be found becomes less and less. This results in additional design cycles between front-end and back-end programs coupled with longer processing times within any cycle. This will result in another necessary paradigm shift in the architecture and design of physical design systems and algorithms, which will be discussed in more detail later in this chapter.

Ignoring the complexities of checking and electrical constraints that modern-day physical design programs have to deal with, however, many of the fundamental wiring heuristics and algorithms spawned from work done in the 1960s for PCBs.

Before global routing is performed, placement of the modules, cells, or gates is performed. Early placement algorithms were developed to minimize the total length of the interconnect wiring using Steiner Trees and Manhattan wiring graphs. In addition, during these early years, algorithms were developed to analyze wiring congestion that would occur as a result of placement choices and minimize it to give routing a chance to succeed. Later work in the 1960s led to algorithms that performed a

© 2003 by CRC Press LLC

hierarchical division of the wiring image and performed global wiring between these subdivisions (then called cells) before routing within the cells.[6] This divide and conquer approach simplified the problem and led to quicker and more complete results. Min-cut placement algorithms often used today are a derivative of this divide and conquer approach. The image is divided into partitions and placement of these partitions is swapped to minimize interconnect length and congestion. Then, placement is performed within the partitions using the same objectives. Many current placement algorithms are based on these early techniques although they need to consider more constraints, such as crosstalk, timing requirements, and power dissipation.

Development of efficient maze routing algorithms also began in the 1960s and many of today's routers use enhanced derivatives of these early techniques. The Lee algorithm[7] finds a solution by emitting a "wave" out from both the source and target points to be wired. This wave is actually an ordered identification of available channel positions — where the available positions adjacent to the source or destination are numbered 1, and the available positions adjacent to them are numbered 2, etc. Successive moves and sequential identification are made (out in all directions as would a wave) until the source and destination moves meet (the waves collide). Then a backtrace is performed from the intersecting position in reverse sequential order along the numbered track positions back to the source and destination. At points where a choice is available (that is, there are two adjacent points with the same order number), the one that does not require a change in direction is chosen.

Other techniques, such as the Hightower Line-Probe technique,[8] were developed during this period and sped up maze routing by use of emanating lines rather than waves. This algorithm emanated a line out from both the source and destination points toward each other. When either line encountered an obstacle, then another line was emanated from a point just missing the edge of the obstacle on the original line at a right angle to the original line, and toward the target or source. Thus, the process is much like walking blindly in an orthogonal line toward the target and changing direction only after bumping into a wall. This process continues until the lines intersect at which time the path is complete.

In today's ICs, the challenge of completed wiring that meets all constraints is of crucial importance. Unlike test generation, which can be considered successful when a very high percentage of the faults are detected by the test patterns, 100% of the nets must be wired. Further, 100% of the wires must fall within the required electrical and physical design constraints. Nothing less than 100% is acceptable! Today these constraints include timing, power consumption, noise, and electromigration and this list will become more complex as IC feature sizes and spacing are reduced further.

The 1970s — The Awaking of Verification

Before the introduction of LSI components, it was common practice to build prototype hardware and then verify the design correctness. PCB packages containing small-scale integrated modules allowed for engineering rework of real hardware within the verification cycle. Prototype PCBs were built and engineering used drivers and oscilloscopes to determine whether the correct output conditions resulted from input stimuli. As design errors were detected, they were repaired on the PCB prototype, validated, and recorded for later engineering change (EC) into the production version of the design. Use of the wrong logic function within the design could easily be repaired by replacing the low cost component(s) in error with the correct one(s). Incorrect connections could easily be repaired by cutting a printed circuit and replacing it with a discrete wire (as opposed to a printed circuit). Using wire-wrap tools, these discrete wires could easily connect the desired pins of the modules on the PCB. Thus, design verification was a sort of trial and error process and the final rework of a PCB could contain hundreds of these wires.

The introduction of LSI drastically changed the design verification (DV) paradigm. Although use of software simulation to verify design correctness began during the 1960s, it was not until the advent of LSI that this concept became widely accepted. With large-scale integration, it became impossible to accurately model the design with a populated PCB, and it was not possible to rework gates and wires on the chip. Thus, the 1970s are best represented as a quantum leap into software DV and verification before manufacture. This represented a major paradigm shift in electronic design and it was a difficult change

© 2003 by CRC Press LLC

for some to accept. DV on hardware prototypes resulted in a tangible result that could be touched and held. It was a convenient tangible, which could be shown to management to represent real progress. Completed DV against a software model did not produce the same level of touch and feel. Further, because the use of computer models was a relatively new concept, it met with the distrust of many. However, the introduction of LSI demanded this change and today, software DV is a common accepted practice for all levels of electronic components, subassemblies, and systems.

Early DV simulators simulated gate-level models of the design with two-valued simulation. Since gates had nearly equal delays and the interconnect delay was insignificant by comparison, use of a unit delay value of each gate was common. Later simulators exploited the use of three-valued simulation to resolve race conditions and identify oscillations within the design more quickly. With the emergence of LSI, however, these simple models had to become more complex, and simulators had to become more flexible and much faster. In the first half of the 1970s, important advances were made to DV simulators that included:

- Use of abstract (with respect to the gate-level) models to improve simulation performance and allow for verification throughout the design cycle (not just at the end)
- More accurate representations of gate and interconnect delays to enhance the simulated accuracy

In the latter half of the decade, significant contributions began as a result of design constraints such as scan design, which reduced the problem to combinational circuits. During this period work began on separating functional characteristics from timing, and more formal approaches verification. However, the fundamental DV tool is simulation, and the challenge to make simulators faster and more flexible continues even today.

Simulation

Although some early DV simulators used compiled models, these quickly gave way to interpretative event-driven approaches. Compiled simulators have the advantage of higher speed simulation of individual gates because host machine instructions are compiled inline and are directly executed with minimum simulator overhead. Event-based simulators require more overhead to manage the simulation operations, but provide a level of flexibility and generality not possible with the compiled model. This flexibility was necessary to provide for simulation of timing characteristics as well as function, and to handle general sequential designs. Therefore, this approach was generally adopted for DV simulators over the compiled approach used by early fault simulators. An event-based simulator has four main concepts:

- The Netlist, which provides the list of blocks (gates at first, but any complex function later), connections between blocks, and delay characteristics of the blocks.
- Event Time Queues, which are lists of events that need to be executed (blocks that need to be simulated) at specific points in [simulation] time. Event queues contain two types of events — Update and Calculate. Update-events change the specified node to the specified value, then schedule calculate-events for the blocks driven from that node. Calculate-events call the simulation behavior of the specified block and, on return from the behavior routine, schedule update-events to change the states on the output nodes to the new values.
- Block Simulation Behavior (the instructions that when passed the block's input states will compute its output states — possibly also scheduling some portion of itself to be simulated at a later time).
- Value List — the current state of each node in the design.

Simulation begins with the stimulus generator, which schedules update-events in the time-zero queue. After all update-events are stored for all time-zero stimuli, the time-zero event queue is traversed and, one-by-one, each update-event in the queue is executed. Update events update the node in the Value List and, if the value new value is different from the current value, schedule calculate-events for blocks driven from the updated node. These calculate-events may be placed back in the time-zero queue or in other time queues based on delay specifications — which will be discussed later. After all update-events are

© 2003 by CRC Press LLC

executed and removed from the queue, the simulator traverses the queue, selects the next calculate-event, interprets its function, and passes control to the appropriate Block Simulation Behavior for calculation. Thus, event-based simulation is interpretative as opposed to the compiled simulator, which is ignorant of the function because it is compiled inline with host instructions.

Execution of a calculate-event causes simulation of a block to take place. This is accomplished by passing control to the simulation behavior of the block with pointers to the current state-values on its inputs (in the Value List). When complete, the simulation routine of the block will pass control back to the simulator with the new state condition for its output(s). The simulator then schedules the block output(s) value update by placing an update-event for it in the appropriate time queue. The decision of which time queue the update-events are scheduled within is based on what the delay value is for the block.

Once all calculate-events are executed and removed from the queue, the cycle begins again but first, the stimulus generator is again called. The stimulus generator may store new update-events in the next time queue, or (if required) insert a new time queue for a time between the present and that of the next existing queue. Then the process of executing update-events followed by calculate-events for the current time queue repeats. This cycle repeats until there are no more events or until some specified maximum simulation time. To keep update-events separated from calculate-events within the linked-list queues, it is common to add update-events at the top of the linked-list and calculate-events at the bottom, updating the chain-links accordingly.

Because it is not possible to predetermine how many events will reside in a queue at any time, it is common to create these as linked lists of dynamically allocated memory. Additionally, time queues are linked because the required number of time queues cannot be determined in advance and similar to events, new time queues can be inserted into that chained list as required.

A number of techniques have been developed to make queue management fast and efficient as it is the heart of the simulator. Because of its generality, the event-based algorithm was the clear choice for DV. One advantage of event-based simulation over the compiled approach is that it easily supports the simulation of delay. Delays can be assigned to blocks and they are simulated by choosing the appropriate time queue(s) in which to schedule the update event(s) for the block output(s) change. Delays can be assigned to nets and they are simulated by choosing the appropriate time queues in which to schedule calculate events for the fanout nodes. (Note that this allows different delays to be associated with each path in the net as receiver block calculation-events can be scheduled in different time queues.) Therefore,

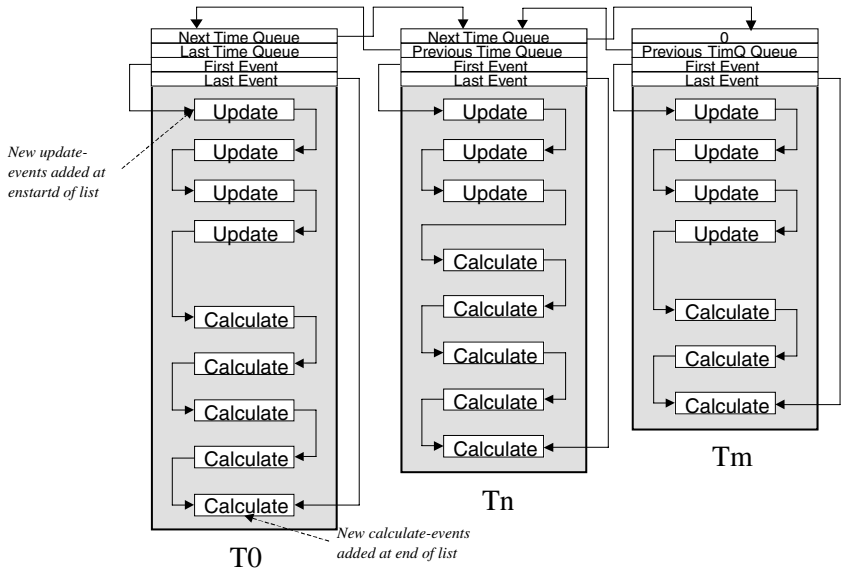

FIGURE 67.6 Event queues.

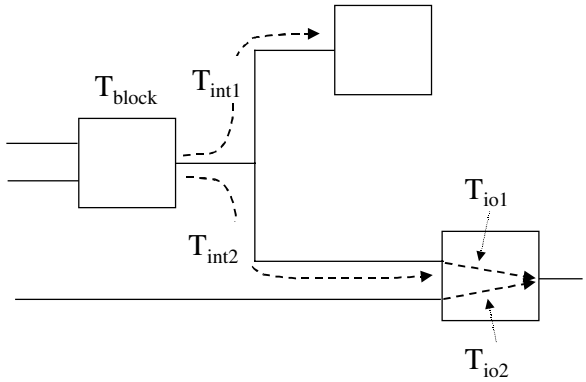

FIGURE 67.7 Simulation delay types.

early simulators typically supported a very complete delay model, even before sophisticated delay calculators were available to take advantage of it.

The delay model included:

- Intrinsic Block Delay (T_{block}) — the time required for the block output to change state relative to the time that a controlling input to that block changed state.
- Interconnect Delay (T_{int}) — the time required for a specific receiver pin in a net to change state relative to the time that the driver pin changed state.
- Input-Output Delay (T_{io}) — the time required for a specific block output to change state relative to the time the state changed on a specific input to that block.

Treatment of delay has had to evolve and expand since the beginnings of software DV. Unit delay was the first model used — where each gate in the design is assigned one unit of delay and interconnect delays are zero. This was a crude approximation but allowed for high-speed simulations because of the simplifying assumptions and it worked reasonably well. As the integrated circuit evolved, however, the unit delay model was replaced by a lumped delay model in which each gate could be assigned a unique value for delay — actually, a rise-delay and a fall-delay. This was assigned by the technologist based on some average load assumed. Also this time, the beginnings of development of delay calculators began. These early calculators used simple equations, adding the number of gates driven by the gate being calculated, and then adding the additional delay to the intrinsic delay values of that gate. As interconnect wiring became a factor in the timing of the circuit, the pin-to-pin delay came into use. At first, delay calculation for the interconnect contribution to delay was crude, associating a fixed value for pin-to-pin delay for very long interconnects. Today's ICs, however, require delay calculation based on very accurate distributed RC-models for interconnects, as these delays have become more significant with respect to gate delays. Tomorrow's ICs will require even more precise modeling for delays, as will be discussed later in this chapter, and consider inductance (L) in addition to the RC parasitics. Additionally, transmission line models will be necessary for the analysis of certain critical global interconnects. However, the delay model defined in the early years of DV and the capabilities of the event-based simulation algorithm stand ready to meet this challenge.

Another significant advantage of the event-based simulation algorithm commonly used today evolved from development that began in the early 1970s. This is the mixed level simulation model. Recall that one of the fundamental components of event simulation is the Block Simulation Behavior. A calculation-event for a block passes control to the sub-routine that simulates the behavior along with the block's input states. For gate-level simulation, these behavior subroutines are quite simple — AND, OR, NOR, etc. However, since the behavior is actually a program sub-routine, it can be arbitrarily complex as well. Realizing this, early work took place to generalize the interface between the simulator control program and the Block Simulation Behavior. A small number of functional level commands were formalized to

© 2003 by CRC Press LLC

access input states, schedule execution at a specific entry to the behavior for a later time, and update the block output states. Thus, a Block Simulation Behavior might look like the following:

```
FUNCTION (CNOR);
/* Complimentary output NOR function with 3 inputs. Input delay = 2,
    intrinsic delay for true output = 10, intrinsic delay for complement
    output = 12*/

INPUT (a,b,c);/*Declare for inputs a, b, c*/
OUTPUT (x,y);
DECLARE input1, input2, input3;    /*Declare storage for inputs*/
DECLARE out, cout;                 /*Declare storage for outputs*/

GET a,input1, b,input2, c,input3;
DELAY 2, Entry1;
      Entry1: out = input1|input2|input3;
      cout = ¬out;
      DELAY 10, (x = out);   /*Schedule this update-event for 10 time units
                               later */
      SELAY 12 (y = cout);   /*Schedule this update-event for 12 time units
                               later */
      END Entry1;
ENDCNOR;
```

Sophisticated use of these behavorial commands supported the direct representation not only for simple gates, but also for complex functions such as registers, MUXs, RAM, ROS, etc. In doing so, simulation performance was improved because what before was treated as a complex interconnection of gates could now be simulated as a single block.

By generalizing the simulator system, Block Simulation Routines could be loaded at simulation run-time if required (by the use of a block with that function in the netlist), and dynamically linked with the simulator control program. This meant that the Block Simulation Behaviors could be developed by anyone, compiled independently of the simulator, stored in a library of simulation behavioral models, and used as needed in simulation. This is common practice in DV simulators today, but this concept in the early 1970s represented a significant breakthrough and supported a major paradigm shift in design — namely, the concept of top-down design and verification.

With top-down design, the designer no longer had to design the gate level netlist before verification could take place. Now, high-level models could be written to represent the behavior of sections of the design not yet complete and they could be used in conjunction with gate-level descriptions of the completed parts to perform full system verification. Now, simulation performance could be improved by swapping in the use of gate-level models or behavior models for system elements based on what the verification goals were. Now, concurrent design and verification could take place across design teams. Now, there was a formal method to support design reuse of system elements without the need to expose internal design details for reusable elements. In the extreme case, the system designer could write a single functional model for the entire system and verify it with simulation. The design could then be partitioned into sub-system elements and each could be described with a behavorial model before being handed off for detailed design. During the detailed design phase, individual designers could verify their sub-system in the full system context even before the other sub-systems were completed. This was particularly valuable for generation of the functional patterns to be simulated as they could now be generated by the simulation of the other system components. Thus, verification of the design no longer had to wait until the end, it could now be a continuous process throughout the design.

Throughout the period, improvements were made to DV simulators to improve performance and in the formulation and capability of behavorial description languages. In addition, designers found more and more novel ways to use behavorial models to describe non-digital system elements such as card readers and analog assemblies. For analog devices, the digital-to-analog interface was modeled on entry

© 2003 by CRC Press LLC

to the behavior and the analog-to-digital interface when returning to the simulator, as well as the analog behavior within the modeled element. Punch-card reader behavior could be modeled with software that would access stored memory containing the data on the simulated cards and return the bit patterns back to the simulator — on the proper nodes and at the proper simulation times.

In the late 1970s and through the 1980s, this was formalized into:

- VHDL[9] (VHSIC [very high speed integrated circuit] high-level description language), sponsored by DARPA, and
- Verilog,[10] a commercially developed RTL-level description language.

These two languages are now both accepted industry standard hardware description languages. Simulator performance improved by means of creative queue algorithms and the use of compiled representations of standard functions, etc. Additionally, methodologies and tools were developed to compare simulated results of simulations against the high-level models with those of the detail-level designs at selected outputs, and top-down design verification using event-based simulation became common practice. This was a natural evolution for large system designers. It was, however, the introduction of Synthesis and the commercial ASIC, which evolved in the 1980s, that made its use the norm today.

With the advent of structured scan design, such as LSSD, the use of compiled simulation returned for verification of the combinational sections of the design between scan latches. A simulation technique, called cycle-simulation, was developed which yielded a major performance advantage over event-based simulation. Cycle-simulation treats the combinational sections of a scan-based design as compiled zero-delay models. The simulator executes each section at each simulated cycle by passing control to the compiled routine for it along with its input states. The resulting state values at the outputs of these sections are assumed to be correctly captured in their respective latch positions. That is, the clock circuitry and path delays are assumed correct, and are not simulated during this phase of verification. The (latched) output values are used as the input states to the sections they drive at the next cycle, and the process repeats for each simulated cycle. Each simulation pass across the compiled models represents one cycle of the design's system clock, starting with an input state and resulting in an output state. To assure only one pass is required, the gates or RTL-level statements for the combinational sections are levelized before compilation into the host-machine instructions. This assures that value updates occur before calculations and only one pass across a section of the model is required to achieve the correct state response at the outputs.

Simulation performance was greatly improved with cycle-simulation because of the compiled model and because the clock circuitry did not have to be simulated repeatably with each simulated-machine cycle. Early cycle-simulators were developed on mixed-level event simulators and by unique implementations. For cycle-simulation on top of event simulators, the design model consisted of a netlist containing an interconnected set of the combinational sections. Each of the combinational sections was described in an RTL-level language and treated as a general compiled behavorial model by the simulator. The event simulator operated as normal, except that the control program simulated state changes at the outputs of simulated models were not propagated to the inputs of the driven sections until the start of the next simulated clock cycle. Later implementations used look-up table models[11] in place of compiled inline host instructions, which provided additional speed improvements as they did not require the execution of compiled host-instructions for every element within a combinational logic section for each cycle.

Cycle-simulation did not completely replace event simulation, as the clock circuitry needs to be verified. Its use, however, was effective for control logic of synchronous computer designs. Cycle-simulation is less useful of dataflow circuitry and not useful for unstructured asynchronous designs. It requires use of structured design constraints so the design can be viewed as combinational. Thus, its use was limited to a few companies with designs large enough to justify the perceived overhead of the design constraints. However, early use of cycle-simulation was very effective for many large systems and these early developments provided the foundations for modern cycle-simulators that are now beginning to gain acceptance for complex ICs.

Simulation has some severe inherent problems. First, unlike test generation or physical design, there is no precise measure of completeness. Test generation has the stuck-fault model, and physical design

© 2003 by CRC Press LLC

has a finite list of nets that must be routed. However, no equivalent metrics are available to determine when verification of the design is complete, or when enough simulation is done. During the 1970s, research began to develop a metric for verification completeness, but to this day none has been generally accepted. Use is made of minimum criteria, such as all nets must switch in both directions, and statistical models using random patterns. Recent work in formal verification applies algorithmic approaches to validate coverage of paths and branches within the model. However, the generally accepted goal is to "do more". Second, it is a hard and time-consuming task to create effective simulation vectors to verify a complex design. DV simulators typically support a rich high-level language for the stimulus generator, but it still requires the thought, experience, and ingenuity of the design verification engineer to develop and debug these programs. Therefore, it is desirous to simulate the portion of the design being verified in as much of the total system environment as possible, and have the simulation create functional stimulus for the portion to be verified. Likewise, it is hard to validate the simulated results for correctness, making it desirable to use them in the full system environment where it is easier to validate them. Ideally, the owner of an ASIC chip being designed for a computer could simulate that chip within a model of all of the computer's hardware, the microcode, the operating system, and use example software programs as the ultimate simulation experiment. To even approach this goal, however, the simulators have to become faster.

During the 1980s, research and development took place on custom hardware simulators and accelerators. Special purpose hardware-simulators use massively parallel instruction processors with much customized instruction sets to simulate gates. These provide simulation speeds that are orders of magnitude faster than software simulation on general-purpose computers. However, they are expensive to build, lack the flexibility of software simulators, and the hardware technology they are built in soon becomes outdated (although general parallel architectures may allow the incremental addition of additional processors). Hardware accelerators use custom hardware to simulate portions of design in conjunction with the software simulator. These are more flexible, but still have the inherent problems that their big brothers have. Nonetheless, use of custom hardware to tackle the simulation performance demands has gained acceptance in many companies and they are commercially available today using both gate-level and HDL design descriptions.

Timing Analysis

The practice of divide and conquer in design verification started in the 1970s with the introduction of the behavorial model. Another divide and conquer style born in the 1970s, which became generally popular in the 1990s, is to separate verification of the design's function from its timing. With the invention of scan design, it became possible to verify logic as a combinational circuit using high-speed compiled cycle-simulators. Development of path tracing algorithms to verify timing resulted in a technique to verify timing without simulation, thus providing a complete solution rather than an experimental one. This became known as static timing analysis (TA). TA is used to analyze signal paths from primary inputs to latches, latches to latches, latches to primary outputs, and primary inputs to primary outputs. At each gate, the TA program computes the min-max time that gate will change in state based on the min-max arrival times of its input signals. TA tools do not simulate the gate function, they only add its contribution to the path delay, although the choice of using rise or fall times for the gate is based on whether or not it has a complimentary output. Because the circuitry between the latches is combinational, only one pass needs to be made across the design. The addition can be based on the minimum rise or fall delay for gates or both, providing a min-max analysis. The designer specifies the required arrival times for paths at the latches or primary outputs, and the TA program compares these with the actual arrival times. The difference between the required arrival and the actual arrival is defined as slack. The TA tool computes the slack at the termination of each path, sorts them numerically, and provides a report. The designer then verifies the design correctness by analysis of all negative slacks.

Engineering judgment is applied during the analysis including the elimination of false-path conditions. A false-path is a signal transition that will never occur in the real operation of the design. Since the TA tool does not simulate the behavior of the circuit, it cannot automatically eliminate all false paths.

© 2003 by CRC Press LLC

Through knowledge of the signal polarity, TA can eliminate false paths caused by the fan-out and reconvergence of certain signals. However, other forms of false-paths are only identifiable by the designer.

Formal Verification

Development of a formal method to verify the equivalence of two different representations of a design began during the 1970s. Boolean verification analyzes a circuit against a known good reference and provides a mathematical proof of equivalence. An RTL model, for example, of the reference circuit is verified using standard simulation techniques. The Boolean verification program then compiles the known-good reference design into a canonical NAND-NOR equivalent circuit. This equivalent circuit is compared with the gate-level hardware design using sophisticated theorem provers to determine equivalence. User controls map the logically corresponding design signals in the RTL to their equivalent node in the gate-level model. To reduce processing times, formal verification pre-processes the two circuits to create an overlapping set of smaller logic *cones* to be analyzed. These *cones* are simply the set of logic traversed by backtracing across the circuit from an output node (latch positions or primary outputs) to the controlling input nodes (latch positions or primary inputs). User controls specify the nodes that are supposed to be logically equivalent between the two circuits.

Early work in this field explored the use of test generation algorithms to prove equivalence. Two *cones* to be compared can be represented as $F_{cone1} = f(a,b,c,X,Y,Z,\ldots)$ and $F_{cone2} = f(d,e,f,\ldots,X',Y',Z',\ldots)$. F_{cone1} and F_{cone2} are user defined output nodes to be compared for equivalence. The terms a,b,c and d,e,f represent the set of input nodes for the function and X,Y,Z are the computational sub-functions. User input defines the equivalence between a,b,c and d,e,f. If F_{cone1} and F_{cone2} are functionally equivalent, then the value of G must be 0 for all possible input states. If the two cones are equivalent, then use of D-ALG test generation techniques for $G = F_{cone1}$ XOR F_{cone2} will be unable to derive a test for the stuck-at-zero fault on the output of G. Similarly, the use of random pattern generation and simulation can be applied to prove equivalence between *cones* by observing the value on G for all input states.

Research throughout the 1980s provided improvements in Boolean equivalence checking techniques and models (such as Binary Decision Diagrams), and modern Boolean equivalence checking programs may employ a number of mathematical and simulation algorithms to optimize the overall processing. However, Boolean equivalence checking methods require the existence of a reference design against which equivalence is proved. This implies there must be a complete validation of the reference design against the design specification. Validating the reference design has typically been a job for simulation. However, this leads to the problems of assuring coverage and completeness of the simulation experiment. Consequently, formal methods to validate the correctness of functional-level models have become an important topic in EDA. Modern design validation tools use a combination of techniques to validate the correctness of a design model. These typically include techniques used in software development to measure completeness of simulation test cases, such as:

- checking for coverage of all instructions [in the model]
- checking to assure all possible branch conditions [in the model] were exercized

They may also provide more formal approaches to validation, such as:

- checking [the model] against designer asserted conditions (or constraints) that must be met
- techniques that construct a proof that the intended functions are realized by the design

These concepts and techniques continue to be the subject of research and will gain more importance as the size of IC designs stretch the limits of simulation-based techniques.

Verification Methodologies

With the use of structured design techniques, the design to be verified can be treated as a set of combinational designs. With the arsenal of verification concepts that began to emerge during this period, the user had many verification advantages not previously available. Without structured design, delay simulation of the entire design was required. Use of functional models intermixed with gate-level descriptions of subsections

© 2003 by CRC Press LLC

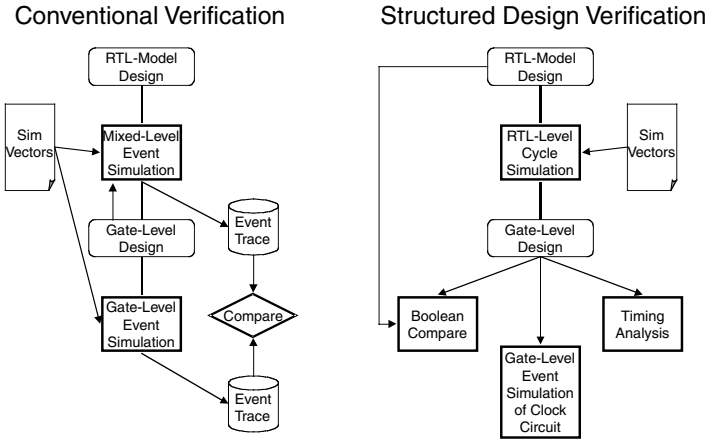

FIGURE 67.8 Verification methodology.

of the design provided major improvements, but was still very costly and time consuming. Further, to be safe, the practical designer would always attempt to delay simulate the entire design at the gate-level.

With structured design techniques, the designer could do the massive simulations at the RTL level focusing on the logic function only, without regard for timing. Cycle-simulation improved the simulation performance by 1 to 2 orders of magnitude by eliminating repetitive simulations of the clock circuitry and use of compiled (or table look-up) simulation. For some, the use of massively parallel hardware simulators offered even greater simulation speeds — the equivalent of hundreds of millions of events per second. Verification of the logic function of the gate-level design could be accomplished by formally proofing its equivalence with the simulated RTL-level model instead of additional simulation. TA provided the basis to verify the timing of all data paths in a rigorous and methodical manner. Functional and timing verification of the clock circuitry could be accomplished with the standard delay-simulation techniques using the event simulator. Collectively, these tools and techniques provided major design productivity improvements. However, the IC area and performance overhead required for these structured design approaches limited the number of designs taking advantage of them. Throughout the 1980s as the commercial EDA business developed, these new verification tools and techniques remained as in-house tools in a few companies. Commercial availability did not emerge until the 1990s when the densities and complexities of ICs began to demand the change.

The 1980s — Birth of the Industry

Until the 1980s, design automation was, for the most part, developed in-house by a small number of large companies for their own proprietary use. Almost all EDA tools operated against large mainframe computers using company-specific interfaces. High-level modeling languages were unique and most often proprietary, technology rules formats were proprietary, and user interfaces were unique. As semiconductor foundries made their manufacturing lines available for customer-specific chip designs, however, the need for access to EDA tools grew. With the expansion of the application-specific integrated circuit (ASIC), the need for commercially available EDA tools increased. Suddenly, a number of commercial EDA companies began to emerge and electronic design companies had the choice of developing tools in-house or purchasing them from a variety of vendors. The EDA challenge then became one of integrating tools from multiple suppliers into a homogeneous system. Therefore, one major paradigm shift of the 1980s was the beginnings of EDA standards to provide the means to transfer designs from one EDA design system to another or from a design system to manufacturing. VHDL and Verilog matured and became industry-standard hardware description languages (HDL). EDIF[12] (electronic data interchange format) was developed as an industry standard for the exchange of netlist and GDSII became a standard interface for the transfer of shapes data to manufacturing. This was only the start of a necessary

© 2003 by CRC Press LLC

change, however. As time progressed, the need for standard interfaces between EDA tools became evident in order to provide efficient design flows containing EDA tools from a number of different vendors.

A second paradigm shift of the 1980s was the introduction of the interactive workstation as the platform for EDA tools and systems. Although some may view it as a step backward, the "arcade" graphics capabilities of this new hardware caught the attention of enough designers to make it a clear choice over the mainframe wherever possible. For a time, it appeared that many of the advances made in alphanumeric HDLs were about to yield to the pizzazz of graphical schematic editors. Nevertheless, although the graphics may have dictated the purchase of one solution over another, the dedicated processing and the ability to incrementally add compute power made the move from the mainframe to the workstation inevitable. Early commercial EDA entries such as from Daisy (Logician) and Valid (SCALD) were developed on custom hardware using commercial microprocessors from Intel and Motorola. This soon gave way, however, to commercially available workstations using RISC-based microprocessors, and UNIX became the de facto operating system standard. During this period, there was a rush of redevelopment of many of the fundamental algorithms for EDA to the workstation. However, as with commercial products and with the new power of high-function graphics, these applications were vastly improved along the way. Experience and new learning streamlined many of the fundamental algorithms. The high-function graphic display provided the basis for enhanced user interfaces to the applications. The commercial ASIC business provided focus on the need for technology libraries from multiple manufacturers. Finally, there was significant exploration into custom EDA hardware such as hardware simulators and accelerators, and parallel processing techniques.

From an IC design perspective, however, the major paradigm shift of the 1980s was synthesis. With the introduction of synthesis, automation could be used to reduce an HDL description of the design to the final hardware representation. This provided major productivity improvements for ASIC design, as chip designers could work at the HDL level and use automation to create the details. Also, there was a much higher probability that the synthesis-generated design would be more accurate than manually created schematics. The transgression from the early days of integrated circuit design to the 1980s is similar to what occurred earlier in software. Early computer programming was done at the machine language level. This provided optimum program performance and efficiency but at the maximum labor cost. Programming in machine instructions proved too inefficient for the vast majority of software programs; thus the advent of assembly languages. Assembly language programming offered a productivity advantage over machine instructions because the assembler abstracted up several of the complexities of machine language. Thus, the software designer worked with less complexity, using the assembler to add the necessary details and build the final machine instructions. However, assembly language programming is still at a low level of abstraction. Introduction of functional level program languages and compilers provided even more productivity improvements by providing a set of programming statements that each provided function that would otherwise require many machine instructions to implement. Thus, the level at which the programmer could now work was even higher, allowing construction of programs with far fewer statements. The analog in IC design is the progression of transistor level design (machine level), to gate level design (assembler level), to HDL-based design. Synthesis provided the basis for HDL-based design, its inherent productivity improvements, and major changes to the IC design methodology.

Synthesis

Fundamentally, synthesis is a three-step process:

1. Compile an HDL description of a design into an equivalent NAND-NOR description.
2. Optimize the NAND-NOR description based on design targets.
3. Map the resulting NAND-NOR description to the building blocks supported for the final package.

Although work on synthesis techniques has occurred on and off since the beginnings of design automation and back to TTL-based designs, it was not until gate array style ICs reached a significant density threshold that it found production use. In the late 1970s and early 1980s, considerable research and development in industry and universities took place on high-speed algorithms and heuristics for

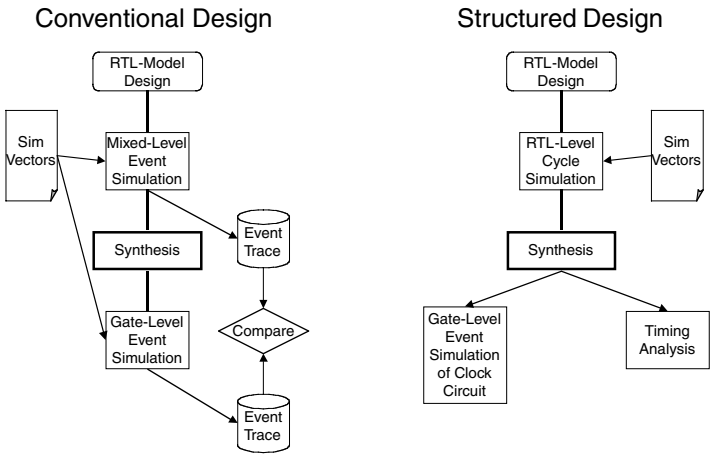

FIGURE 67.9 Synthesis methodology.

synthesis. In the early 1980s, IBM exploited the use of synthesis on ICs used in the 3090 and AS400 computers. These computers used chips that were designed from qualified sets of pre-designed functions interconnected by personalized wiring. These functions (now called cells) represented the basic building blocks for each specific IC family. The computers used a high number of uniquely personalized chip designs so it was advantageous to design at the HDL level and use automation to compile to the equivalent cell-level detail. The result was significant improvements to overall design productivity.

Today, synthesis is a fundamental cornerstone of the design methodology for ASICs (both gate-array and standard-cell) supporting both VHDL and Verilog as the standard input.

As the complexities of IC design have increased, so have the challenges for synthesis. Early synthesis had relatively few constraints to be observed in its optimization phase. Based on user controls, the design was optimized for minimum area, minimum fanout (minimum power), or maximum fanout (maximum performance), etc. This was accomplished by applying a series of logic reduction algorithms (transforms) that provide different types of reduction and refinement.[13] Cell behavior could also be represented in primitive-logic equivalent form and a topological analysis could find matches between the design gates and equivalent cell patterns. The mapping phase would then select the appropriate cells based on function and simple electrical and physical parameters for each cell in the library, such as drive strength, area, etc. Early synthesis was not overly concerned with signal delays in the generated design, or other electrical constraints that the design may have been required to meet. As IC feature sizes decrease, however, these constraints are becoming more demanding and automation is required to achieve them. Thus, synthesis is now required to make intelligent choices not only based on the HDL function and simple controls, but also on a number of constraints that must be met by its result.

The design input to modern synthesis tools is not the functional HDL design alone, but now includes constraints such as the maximum allowed delay along a path between two points in the design. This complicates the synthesis decision process as it must now generate a solution that meets the required function with a set of cells and interconnections that will fall within the required timing constraints. Therefore, additional trade-offs must be made between the optimization and mapping phases, and the effects of interconnection penalty need to be considered. Additionally, synthesis must now have additional technology characteristics available to it such as delay for cells and wiring. To determine this delay it is necessary to understand the total load seen by a driver cell as a result of the input capacitance of the cells it drives and the RC parasitics on the interconnect wiring. However, the actual wiring of the completed IC is not yet available (since routing has not yet taken place) and estimates for interconnect parasitics must be made. These are often based on wire load models that are created from empirical analysis of other chip designs in the technology. These wire load models are tables that provide an estimate of interconnect length and parasitic values based on the fanout and net density.

© 2003 by CRC Press LLC

As interconnect delay became a more dominant portion of path delay, it became necessary to refine the wire load estimations based on more than total net count for the chip. More and more passes through the synthesis-layout design loop became necessary to find a final solution that achieved the required path delays. The need for a new design tool in the flow became apparent as this estimation of interconnect delay was too coarse. This was due to different regions on a typical chip having different levels of real estate (net) congestion. In other words, wire load estimates differ across different regions on the chip because the average amount of wiring length for a net with a given pin count is different by region. Conversely, the actual placement of cells on the chip affect the congestion and, therefore, the resulting wire load models. Consequently, a new tool, called floor planning, was inserted in the flow between synthesis and layout.

Floorplanning

The purpose of floorplanning is to provide a high-level plan for the placement of functions on the chip, which is used to both refine the synthesis delay estimations and direct the final layout. In effect, it inserts the designer into the synthesis-layout loop by providing a number of automation and analysis functions used to effectively partition and place functional elements on the chip. As time progressed, the number of functions integrated into the floorplanner grew to a point where today it is more generally thought of as design planning.[14] The initial purpose of the floorplanner was to provide the ability to partition the chip design functions and develop a placement of these partitions that optimized the wiring between them. Optimization of the partitioning and placement can be based on factors such as minimum wiring or minimum timing across a signal path. A typical scenario for the use of a design planner is as follows:

- Run synthesis on the RTL description and map to the cell level.
- Run the design planner against the cell-level design with constraints such as path delays and net priorities.
  - Partition and floorplan the design, either automatically or manually, with the design planner.
  - Create wire load models based on the congestion within the physical partitions and empirical data.
- Rerun synthesis to optimize the design at the cell level using the partitioning, global route, and wire load model data.

User-directed graphics and auto placement-wiring software algorithms are used to place the partitions and route the inter-partition (global) nets. One key to the planner is the tight coupling of partitioning and routing capability with electrical analysis tools, such as power analysis, delay calculation, and timing analysis. Checking of the validity of a design change (such as placement) can be made immediately on that portion of the design that changed. Another is that it needs to be reasonably tightly connected to synthesis, as it is typical to pass through the synthesis-planner-synthesis loop a number of times before reaching a successful plan for the final layout tools.

After a pass in the floorplanner, more knowledge is available to synthesis. With this new knowledge, the optimization and mapping phases can be rerun against the previous results to produce a refined solution. The important piece of knowledge now available is the gate density within different functions in the design (or regions on the chip). With this, the synthesis tool can be selective about which wire load table to use and develop a more accurate estimate of the delay resulting from a specific solution choice.

Floorplanning has been a significant enhancement to the design process and is widely used today. In addition to floorplanning, modern design planners include support for clock tree, power bus design, I/O assignment, and a wealth of electrical analysis tools. As will be discussed later, semiconductor technology trends will place even more importance on the design planner and dictate an ever-tightening integration between it with both synthesis and layout. Today, synthesis, design planning, and layout are three discrete steps in the typical design flow. Communication between these steps is accomplished by file-based interchange of the design data and constraints. As designs become more dense and with the growing

© 2003 by CRC Press LLC

complexities of electrical analysis required, it will become necessary to integrate these three steps into one tight process as are the functions within the modern design planners.

The 1990s — The Age of Integration

Before EDA tools were commercially available, software architecture standards could be established to assure smooth integration of the tools into complex EDA systems supporting the entire design flow. Choice of languages, database and file exchange formats, host hardware and operating systems, and user interface conventions could be made solely by the developing company. Moreover, the need for comprehensive EDA systems supporting the entire flow through design and manufacturing release in a managed process is paramount. Design of ICs with hundreds of thousands of gates (growing to the millions) across a design team requires gigabytes of data contained within thousands of files. All of this data must be managed and controlled to assure its correctness and consistency with other design components. Design steps must be carried out and completed in a methodical manner to assure correctness of the design before release to manufacturing. The EDA system that encompasses all of this must be efficient, effective, and manageable. This was always a challenge for EDA system integrators, but the use of EDA tools from external vendors compounded the problem. EDA vendors may develop their tools to different user interfaces, database and file formats, computer hardware, and operating systems. In turn, it is the EDA system integrator who must find a way to connect them in a homogeneous flow that is manageable, yet provides the necessary design efficiency across the tools. By the late 1980s, it was said that the cost to integrate an EDA tool into the in-house environment was often over twice that of the tool itself. Consequently, the CAD Framework Initiative (CFI) was formed, with a charter to establish software standards for critical interfaces necessary for EDA tool integration. Thus began the era of the EDA Framework.

The EDA Framework[15] is a layer of software function between the EDA tool and the operating system, database, or user. CFI defined a set of functional elements for this software layer, each of which had a standard interface and provided a unique function in support of communication between different tools. The goal was to provide EDA system integrators the ability to choose EDA tools from different vendors and be able to plug them into a homogeneous system to provide an effective system operation across the entire design flow. The framework components included:

- Design Information Access — a formal description of design elements and a standard set of software functions to access each, called an API (Application Program Interface).
- Design Data Management — a model and API to provide applications the means to manage concurrent access and configuration of design data.
- Inter-Tool Communication — an API to communicate control information between applications and a standard set of controls (called messages).
- Tool Encapsulation — a standard for specifying the necessary information elements required to integrate a tool into a system such as input files, output files, etc.
- Extension Language — specification of a high-level language that can be used external to the EDA tools to access information about the design and perform operations on it.
- Session Management — a standard interface used by EDA tools to initiate and terminate their operation and report errata, etc.
- Methodology Management — APIs used by tools so that they could be integrated into software systems to aid the design methodology management.
- User Interface — a set of APIs to provide consistency in the graphical user interface (GUI) across tools.

Each of these functional areas needs to be considered for integration of EDA tools and to provide interoperability. In its first release, CFI published specifications for design representation and access (DR), intertool communication (ITC), tool encapsulation (TES), and extension language (EL). Additionally,

© 2003 by CRC Press LLC

the use of MOTIF and X-Windows were specified as the GUI toolkit. However, for many practical, business, and human nature reasons, these standards did not achieve widespread adoption across the commercial EDA industry beyond the use of MOTIF and X-Windows. Offerings for DR, ITC, and EL became available in products such as CDB (Mentor Graphics' DR-based product), ToolTalk (SUN Microsystems ITC product), and SCHEME (the CFI EL standard). However, because use of these required EDA tools to modify their internal structures to interact directly with the committee-derived APIs, their use across the industry was less than desired and the "Plug-and-Play" motto of CFI was not realized. However, the work at CFI did serve to formalize the science of integration and communication, and a number of the information models developed for the necessary components are used today but often they have been slightly modified and are used within a proprietary interface.

As it was learned, not only was it costly to change EDA tools to use a different internal interface (API), neither was it considered good business to allow tools to be integrated into commercial system offerings from competitors. For a period, several framework offerings became available, but these quickly became the end product rather than a means to an end. These products were marketed as a means to bring outside EDA tools into the environment, but few vendors modified their tools to support this by adopting the CFI APIs. Instead, to meet the need for tool integration, the commercial industry focused on data flow only and chose an approach that provided communication between tools by file generation and translation. Consequently, today's EDA systems are typically a disparate set of heterogeneous tools stitched together by the creation of data files. These files are created from one tool and translated by another tool (within the design flow) to its internal data structures. Many of these formats evolved from proprietary formats developed within commercial companies that were later transferred or licensed for use across the industry. Common EDA file formats in use today are:

- Electronic Data Interchange Format (EDIF) — netlist exchange (EIA → IEC)
- Physical Data Exchange Format (PDEF) — floorplan exchange (Synopsys → IEEE)
- Standard Delay File (SDF) — delay data exchange (Cadence Design Systems → IEEE)
- Standard Parasitic Exchange File (SPEF) — parasitic data exchange (Cadence Design Systems → IEEE)
- Library Exchange File (LEF) — physical characteristics information for a circuit family (Cadence → OpenEDA)
- Data Exchange Format (DEF) — physical data exchange (Cadence → OpenEDA)
- Library Data Format (.LIB) — ASIC cell characterization (Synopsys)
- ASIC Library Format (ALF) — ASIC cell characterization (Open Verilog International)
- VISIC High Level Design Language (VHDL) — behavorial design description language (IEEE)
- Verilog — RTL-level design description language (Cadence Design Systems → IEEE)

These "standard" formats have provided the desired engineering and business autonomy necessary for adoption and their use across the industry has drastically improved the ability to integrate tools into systems compared with the 1980s. It has proved to be an effective method for the design of today's commodity ICs above .18 micron. However, the inherent ambiguities, translation requirements, rapidly increasing file sizes (due to increasing IC density), and the fundamental non-incremental sequential nature of design flows based on them will soon give way to IC technology advances.

67.3 The Future

It may be said that the semiconductor industry is the most predictable industry on earth. Whether it was an astute prediction or the cause, the prediction of Gordon Moore (now known as Moore's law) has held steadily across the past two decades. Every 18 months, the number of transistors or bits on an IC doubles. To accomplish this, feature sizes are shrinking, spacing between features is shrinking, and chip die sizes are increasing. In addition, the fundamental physics that govern the electrical properties of these

© 2003 by CRC Press LLC

devices has been documented in electrical engineering textbooks for some time. However, there are points within this progression where paradigm shifts occur in the elemental assumptions and models required to characterize these circuits, and where fundamental EDA design and analysis must change. Earlier we discussed paradigm shifts in design verification because of inability to repair. We also discussed shifts resulting from the number of elements in a design vs. the necessary tool performance and designer productivity. Over the past three decades, we have seen shifts in test, verification, design abstraction, and design methodologies. Now, as semiconductor technology crosses the .25 micron barrier another paradigm shift is required. Feature packing, decreased rise times, increased clock frequencies, increased die sizes, and the explosion of the number of switching transistors are all interacting to place new demands of models, tools, and EDA systems. Thus, the next decade will require new work in design tools, rules, systems, and schools for problematic areas of delay, signal integrity, power, test, and mixed technology.

International Technology Roadmap for Semiconductors

The Semiconductor Industry Association and SEMATECH periodically publish a report called the "International Technology Roadmap for Semiconductors"[16] (ITRS). This report characterizes planned semiconductor directions and advances across the next decade and the necessary technology advancements in all support areas including:

- Design and test
- Process integration devices and structures
- Front end [manufacturing] processes
- Lithography
- Interconnect
- Factory integration
- Assembly and packaging
- Environment, safety, and health
- Defect reduction
- Metrology
- Modeling and simulation

ITRS provides a wealth of information on the semiconductor future, as well as the problematic areas that will arise and the inventions that will be required. Some relevant ITRS projected semiconductor advancements for high-function microprocessors are shown in Table 67.1. The roadmap for ASICs is also within the ITRS and though not shown here, ASIC advancement does not lag far behind that of the high-volume microprocessors. The reader is encouraged to study the technology characteristics in the ITRS as it details the roadmap for microprocessors, ASICs, and memory.

To understand the implications of the ITRS data, it is convenient to review the effects of scaling on a number of electrical parameters.[17]

TABLE 67.1 ITRS Microprocessor Roadmap

Characteristic	2001	2004	2007	2010	2013	2016
Transistor gate length (nm)	90	53	35	25	18	13
Feature size scale factor ($S_{feature}$)	1	0.59	0.39	0.28	0.20	0.14

Delay is typically specified as the time from when the switching input to a driver gate reaches 50% of its voltage to the time the input to a receiver gate reaches its 50% value. It may be viewed as the driver gate delay plus the interconnect delay. The intrinsic **gate delay** is a function of the gate capacitance and transistor resistance. The gate capacitance is a function of the gate width and length and the gate-oxide thickness (T_{gox}). Assuming a normal scaling, decreasing the size of transistors by a factor of $S_{feature}$ decreases the gate capacitance by the same scale because:

$$C_{gate} = \varepsilon_{ox}\left(W_{gate}L_{gate}\right)/T_{gox}\ \alpha\left(S_{feature}S_{feature}\right)/S_{feature} = S_{feature}$$

The transistor on-resistance (R_{tr}) is proportional to supply voltage and current, which both scale down proportionally, so the resistance is constant. Therefore, the gate delay decreases by a factor of $S_{feature}$ since:

$$T_{gate}\ \alpha\ R_{tr}C_{gate}\ =\ S_{feature}$$

Thus, intrinsic gate delay decreases in direct proportion to transistor size ($S_{feature}$).

Loading imposed on a driving gate affects this delay and for cases where the interconnect resistance $R_{int} < R_{tr}$, this load is the sum of the capacitances of the receiver gates. As R_{int} becomes larger, however, the actual delay of a driving gate must also take into account the parasitics of the interconnects.

Interconnect delay is a function of the RC-time constant, which is a result of resistance and distributed capacitance of the interconnect. Assuming normal scaling, as feature sizes decrease by a factor of $S_{feature}$, the local interconnects are likewise scaled down in their cross-sectional area and length. Additionally, the interconnection insulator layer (t_{ox}) would scale with feature size.

Interconnect resistance is proportional to the length and inversely proportional to the cross-sectional area of the interconnect:

$$R_{int}\ \alpha\ L_{int}/\left(W_{int}H_{int}\right)\ \alpha\ L_{int}/S_{feature}S_{feature} = L_{int}/S_{feature}^{2}$$

Here, L_{int}, H_{int}, and W_{int} are the length, width, and height of the interconnect, respectively.

Capacitance is a function of the plate area and the spacing between the plates. The self-capacitance (to ground) of the interconnect is proportional to length and the width of the interconnect and inversely proportional to oxide thickness (t_{ox}, which also scales with $S_{feature}$):

$$C_{self} = \varepsilon_{ox}L_{int}\ W_{int}/t_{ox}\ \alpha\ L_{int}\ S_{feature}/S_{feature} = L_{int}$$

The resulting interconnect RC constant therefore scales by:

$$R_{int}\ C_{int}\ \alpha\ \left(L_{int}/S_{feature}^{2}\right)\left(L_{int}\right) = L_{int}^{2}/S_{feature}^{2}$$

Scaling down of transistor sizes is accompanied by closer spacing. Thus, for **local nets** the interconnect length (L_{int}) is scaled down by a factor of $S_{feature}$ and the RC constant remains relatively constant:

$$\left(R_{int}\ C_{int}\right)_{local}\ \alpha\ L_{int}^{2}/S_{feature}^{2}\ \alpha\ S_{feature}^{2}/S_{feature}^{2} = 1$$

Therefore, the delay along local interconnects is relatively constant. However, because the gate delay is reduced by a factor of $S_{feature}$, the relative impact of local interconnect delay with respect to gate delay on the overall timing across a signal path is increasing. Below the 1 μm technology node this became a significant factor and at around the .35 μm node the delay of local nets approached that of the gate. As feature size scales down further, the local interconnect delays exceed that of the gate delays.

For **global nets**, the interconnect length does not scale down with the feature sizes. For these, the die size is the more predominant determinant and this remains constant in the ITRS roadmap. Therefore, the RC constant scales like:

© 2003 by CRC Press LLC

TABLE 67.2 Interconnect Delay Scaling

Characteristic	2001	2004	2007	2010	2013	2016
Transistor gate length (nm)	90	53	35	25	18	13
Gate delay scale factor	1	0.59	0.39	0.28	0.20	0.14
T_{int}/T_{gate} (local nets)	1	1.70	2.57	3.60	5.00	6.92
T_{int}/T_{gate} (global nets)	1	2.88	6.61	12.96	25.00	47.93

$$\left(R_{int}\ C_{int}\right) = L_{int}^2 / S_{feature}^2 \ \alpha\ S_{die}^2 / S_{feature}^2 = 1 / S_{feature}^2$$

where L_{int}, H_{int}, and W_{int} are the length, width, and height of the interconnect, respectively.

Thus, the interconnect delay for global nets increases in inverse proportion to the square of the feature size decrease.

Applying this simple RC approximation for delay against the ITRS data indicates that interconnect analysis is increasing in importance to the overall timing of digital circuits (see Table 67.2). However, another critical effect of closely spaced features on the chip is now affecting the necessary analysis of interconnects.

Capacitance results whenever two conducting bodies are charged to different electric potentials and may be viewed as the reluctance of voltage to build or decay quickly in response to injected power. The self-capacitance between the interconnect surfaces and ground is only a part of the overall capacitance to be considered. Another important consideration is the **mutual capacitance** between interconnects in close proximity. To obtain an accurate measure of the total capacitance along any interconnect, it is necessary to consider all conducting bodies within a sufficiently close proximity. This includes not only the ground plane, but also adjacent interconnect signals, as there is a mutual capacitance between these. This mutual capacitance is a function of the interconnect's side-wall area, the distance between it and adjacent interconnects, and the dielectric constant. Its impact increases due to decreasing interconnect pitch and increasing side-wall aspect ratios (used to reduce interconnect resistance by increasing the cross-sectional area). (See Table 67.3.)

Figure 67.10 depicts three interconnect wires on a signal plane. An approximate formula for the capacitance[18] of the center wire is:

$$C = \text{Self Capacitance} + \text{Mutual Capacitance} = C_{int\text{-}ground} + 2\ C_m.$$

The mutual capacitance is a function of the plate area along the sides of the interconnects and the spacing between them and may be simply approximated as:

$$C_m = \varepsilon_{ox} L_{int}\ H_{int} / S_{int}.$$

Here, S_{int} is the distance between the interconnects.

TABLE 67.3 Interconnect Aspect Ratio and Pitch

Characteristic	2001	2004	2007	2010	2013	2016
Transistor gate length (nm)	90	53	35	25	18	13
Aspect ratio (local wire)	1.6	1.70	1.70	1.80	1.90	2.00
Aspect ratio (global wire)	2	2.10	2.20	2.30	2.40	2.50
Wire pitch (local wires) (nm)	350	210	150	105	75	50
Wire pitch global wires) (nm)	670	460	290	205	140	100

© 2003 by CRC Press LLC

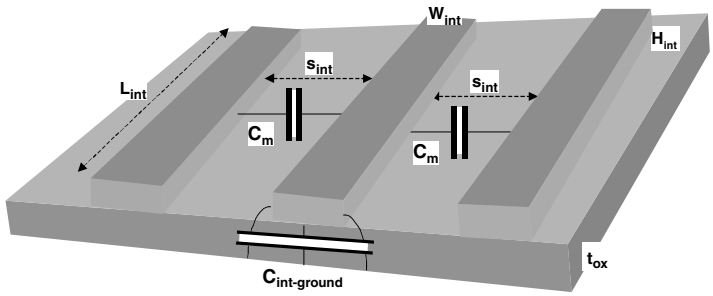

FIGURE 67.10 Mutual capacitance.

More accurate approximations for capacitance must take into account fringing effects, and the referenced literature gives the more accurate expression for capacitance as:

$$C_{\text{int-ground}} = \left[\varepsilon_{ox}\left(1.15\left(W_{int}/t_{ox}\right) + 2.8\left(H_{int}/t_{ox}\right)^{0.222}\right)\right]L_{int}$$

$$C_m = \left[\varepsilon_{ox}\left(0.03\left(W_{int}/t_{ox}\right) + 0.83\left(H_{int}/t_{ox}\right) - 0.07\left(H_{int}/t_{ox}\right)^{0.222}\right)\left(t_{ox}/s_{int}\right)^{1.34}\right]L_{int}$$

Further examination of the effects with adjacent interconnects may not be complete enough. Full analysis may require consideration of all interconnects within a sphere around the one being analyzed.

The full effect of mutual capacitance is also a function of the voltage potential between the conductors (Miller Effect) and, therefore, analysis of the simultaneous signal transitions on each. **Noise** is the introduction of unwanted voltage onto a signal line, and is proportional to mutual capacitance and mutual inductance, and inversely proportional to signal rise times. Mutual capacitance injects current into adjacent (victim) signal lines proportional to the rate of change in voltage along the exciting (aggressor) signal line. The amount of induced current can be approximated by the following equation:[19]

$$I_{mC} = C_m\left(dV_{aggressor}/dt\right)$$

The amount of cross talk noise induced onto the victim net is proportional to the resistance on the victim net and the mutual capacitance, and inversely proportional to the rise time (τ_r) of the aggressor waveform:

$$V_{mC} = I_m Z_{victim} = C_m\left(\Delta V_{aggressor}/\tau_t\right)R_{victim}$$

Noise can increase or even decrease[20] the signal delay on the victim net. Voltage glitches induced can also give rise to faulty operation in the design (e.g., if the glitch is of sufficient amplitude and duration to cause a latch to go to an unwanted logic state). Accurate yet high-speed models and algorithms for analyzing noise in IC designs is a current and important topic in EDA R&D.

Inductance can also cause noise according to the following relationship:

$$V_L = L\left(dI/dt\right)$$

Sudden changes in large amounts of current can be seen on the power grid resulting from a large number of circuits switching at the same time. The inductance in the power grid and this large current draw over short periods of time (di/dt) result in a self-induced electromagnetic force whose voltage is Ldi/dt. This induced voltage causes the power supply level to drop, resulting in a voltage glitch that is proportional to the switching speed, the number of switching circuits, and the effective inductance in the power grid.

EDA Impact

The references point to a number of texts that discuss the complexities of interacting electrical effects resulting from decreasing IC feature sizes and increased die sizes. These give rise to new design rules with which design and analysis applications must deal. The importance of cross talk effects gives rise to the need for accurate parasitic extractors that can work in 2D and 3D space. Mutual capacitance gives rise to the need for more exacting delay calculators, and noise gives rise to new analysis tools that need to be aware of the switching activity of the IC in order to perform complete analysis. Switching activity is particularly important to power and clock bus design analysis and may be required on critical signal paths. Noise, crosstalk, Delta-I, reflection, and electromigration are well-defined properties, but their introduction into the CMOS IC design space is just beginning. Further, while the design complexities due to electrical effects are increasing, the number of circuits on the IC continues to increase. More required analysis on many more circuit elements is the fundamental challenge for EDA to meet.

EDA System Integration

With the design size increases that are projected, it will be necessary for the next generation EDA systems to formalize the use all of the techniques that have been learned over the past three decades. It is not conceivable that current loosely coupled EDA system flows that support only sequential design and analysis steps on a full design will yield the required cycle times. Thus, it will be necessary to integrate EDA systems in a way that provides major decreases in cycle times and provides the increased accuracy and scope of electrical analysis to assure designs that meet specifications. Beyond the extensions to the application algorithms and development of new algorithms, the exploitation of hierarchy, abstraction, shared access, incremental analysis, and concurrent processing across design flows will become essential.

Hierarchy is the term used to describe the logical top-down organization of the design as a set of elements that can be designed and verified with minimum regards to other elements. Different levels within the hierarchy represent different levels of abstraction for the design, where each successively lower level in the hierarchy provides additional design detail. This hierarchy allows decomposition of the design into individual elements, sets of elements at different levels of abstraction, or sets of elements at the same level of abstraction. This allows for large teams of designers to work on different elements in parallel and reduces the overall processing times required of individual EDA tools ($2^n > n2^m$ as discussed earlier). However, hierarchy preserves the integrity of the overall design and provides a system-level view when necessary.

Many steps in the design process can operate on an individual element without the specifics of other elements. Still others may require an abstract representation or model of other elements within the hierarchy but not the complete design detail. Others, however, will depend on the details of the portion of the design they are analyzing as well as other hierarchical nodes and require an expanded occurrence-level description of the design. For example, functional level design of a hierarchical element can be performed in large part without the details of other elements. On the other hand, early delay calculation needs a representation of the actual loading imposed by elements connected to outputs of the element being analyzed. Yet, detailed parasitic extraction requires the detailed wiring on all elements in the design hierarchy. Design systems will need to recognize and support each of these levels of representation for the applications they serve.

Abstraction is used to describe the representation of a design at a less detailed (higher) level. Through abstraction, analysis tools deal with fewer elements thus improving performance and memory requirements. The support for abstraction also provides the basis for a continuum of design analysis across the entire design-cycle. This top-down approach to design is common within simulation, but it will need to be expanded up and out in future EDA systems. Expanding formal design support up will provide the designer formal support in the very early stages of systems design where design algorithms, instruction set analysis, global timing, hardware-software trade-offs, design reuse, and functional partitioning are evaluated. Thus, there will be necessary movement to higher-level (with respect to Verilog and VHDL) system design languages and analysis tools. Today, the use of simulation and synthesis at the RTL

© 2003 by CRC Press LLC

abstracted level is considered commonplace. Support at an even more abstract behavorial level will provide an additional level of efficiency. Expansion out provides for more design and analysis tools operating off abstractions of the physical IC. Accurate abstract models for physical design elements may be key to providing necessary efficiencies in physical design and analysis.

Shared access relates to the architectural principle that the design tools operate off a common representation and a single shared instance of the design. That is to say, there is one common definition of the design elements, and physical store of design data is non-redundant. Today's EDA system architectures communicate data between different design tools via file transfers. These files typically represent design information already existing in the permanent storage of other files or databases in the system. Because there is no common information model for these design elements, there are many different definitions used across these different files. With the increasing number of design elements on an IC, an explosion in the number of bytes of permanent storage and run times required by applications to read and translate the data will occur. Use of standard file formats (such as EDIF, SDF, SPEF, LEF, DEF, etc.) to transfer different types of design information is becoming stressed to the limit even today. Many large designs require gigabytes of storage for these individual files and often hours of processing time to translate them into the form required by individual design applications. Across the next decade, the number of transistors will scale up by two orders of magnitude and these interchange files can be expected to expand at the same rate. Further, more and more design tools will need to access additional types of design data to analyze increasing important electrical effects of delay and noise, making it more difficult to compartmentalize data elements into independent files. Thus, the need for a more data-centric view in design systems will need to replace today's tool-centric architectures.

Incremental analysis means simply that only the affected portion of the design needs to be processed to analyze a change. The goal of this is to make the analysis time required for a design change proportional to the size of that change and not the size of the entire circuit. With the increase in design elements, it will be too time consuming to re-analyze the entire IC, or even a hierarchical node within it, for every design change. Analysis applications will require enhanced algorithms to support analysis of changed portions of the design, and EDA systems will need methods to keep efficient records of design changes. This implies the tagging of records within the design database that have changed since some reference point in time. Using this information, applications can then determine what portions of the design to process (or reprocess). Strictly speaking, however, it is not necessary to keep these change tags directly with the data records. Change history can be kept and managed external to the design data either as change flags or design change orders to be processed on demand.

Structuring design algorithms to perform incrementally is no longer a simple goal. Historically, for example, a wire router could re-route a net by knowing only the open channels. It would not require detailed information about logical nets and physical wires occupying blocked channels — only that they were blocked. Because of the interaction of electrical effects between features on the IC, routers now need details about wire in neighboring channels to correctly predict delay and noise. Further, just re-routing the changed net may not be sufficient. It is possible that the re-routed net produces a mutual capacitance with a previously correctly routed net that results in signal timing of the path that net is within beyond the critical threshold. Similar effects occur in other long running applications, such as parasitic extraction. Here not only does the changed net need to be re-extracted, but so may the nets within its sphere of influence. For applications such as this, a conceptual region of influence around the change needs to be defined and other elements within that region need to be considered. Of course, in the case of the router, this region of influence could grow as additional rework is performed to correctly route the original changed net.

Concurrent processing is the term used to describe a closer coupling (tighter integration) between design and analysis. Typical EDA system flows of today are highly sequential in nature. That is, a set of design changes is made and this is followed by a set of analysis applications to verify their validity within the design environment. Typically, in today's systems individual tools are integrated by file-based data exchange, and each analysis tool needs to be started, parse the design changes, perform the analysis, and terminate before another type of analysis is performed. As design size scales up, cycle times across design

© 2003 by CRC Press LLC

and analysis will scale accordingly. Further, as the complexities of achieving an accurate design increase, the number of design-analyze cycles may increase, thus compounding the overall design time increase. Future EDA design systems will need to provide analysis engines that can be called dynamically, on demand, by design programs to provide incremental analysis of changes [conceptually] concurrent with the change. Development and use of a common set of these sub-routines (engines) working off the same design model will not only streamline the design cycle time, but will also provide better convergence in the cycle. Using common analysis engines throughout the flow will assure that different applications will predict the same results for complex computations that are key to accurate prediction of the hardware. Common engines for delay calculation, noise prediction, extraction, design rule checking, etc. will greatly improve the design cycle by yielding the same answer independent of the design application calling them.

To summarize, future EDA systems will be required to take a data-centric view of the design process as opposed to the tool-centric view common today. There will necessarily be a tighter linkage between design planning and synthesis, and design planning and layout. Links will not be to entire tools as we think of them today, but rather to functional modules within those tools. For example, a design planner may realize that a floorplan cannot be derived to meet the required design points, or constraints, given the current netlist. Therefore, it may call up a synthesis transform to re-optimize the troublesome subsection of the design. Global routing of nets between partitions may require the design planner to call on extraction and delay calculation engines, and local simulation to predict noise spikes in adjacent routes in order to find a correct result. Final layout will require tight concurrent integration with all forms of analysis engines as the end design becomes more dependent on complex inter-relationships between netlist, interconnect properties, feature spacing, frequency, and signal transition. A tightly integrated model that uses a common view of the design data and common engines will be more than just a productivity enhancement, it may be essential to converge all the constraints, rules, and physics to a valid result.

This is recognized today, and the movement toward data-centric EDA system architectures has begun in several major EDA system companies. Additionally, an effort has begun to promote an industry-wide model and access API (called OpenAccess) enabling all of the above architectural features across design-analysis functions. With this, design flows can be developed using tools and engines from different suppliers and integrated into a homogeneous system. This is in contrast to the proprietary architectural solutions now being developed by the commercial EDA system companies that hinder the necessary level of integration with competing tools.

Delay

Simplifying assumptions and models for delay have provided the foundation for high-speed event-driven delay simulation since its initial use in the 1970s. More accurate waveform simulation such as that provided by SPICE implementations has played a crucial role in the characterization of IC devices across over three decades and continues to do so. SPICE level simulations are important for characterization and qualification of ASIC cells and custom macros of all levels of complexity. However, the run times required for this level of device modeling are too large to support its use across entire ICs. SPICE is often used to analyze the most critical signal paths, but SPICE level simulation on circuits with millions of transistors is not practical. Consequently, event-based simulation at the abstracted gate-level or higher is essential for IC verification. However, simplifying models used to characterize delay for discrete-event simulation and other timing analysis algorithms have had to improve and become more complex as feature sizes on ICs have shrunk, and the importance of interconnect resistance and crosstalk increased. In the future, these models will need to improve even more.

When ICs were well above 1 μm, gate delay was the predominant factor in determination of timing. Very early simulation of TTL logic used a simple model which assigned a fixed unit of delay to each gate and assumed no delay across the interconnects. Timing was based on only the number of gates through which a signal traversed along its path. As LSI advanced delay was based on a foundry specified intrinsic gate delay value (actually a rise delay and a fall delay), that was adjusted based on the capacitive load of the gates it fanned out to (receiver gates). At integration levels above 1 μm, the load seen by a gate was

© 2003 by CRC Press LLC

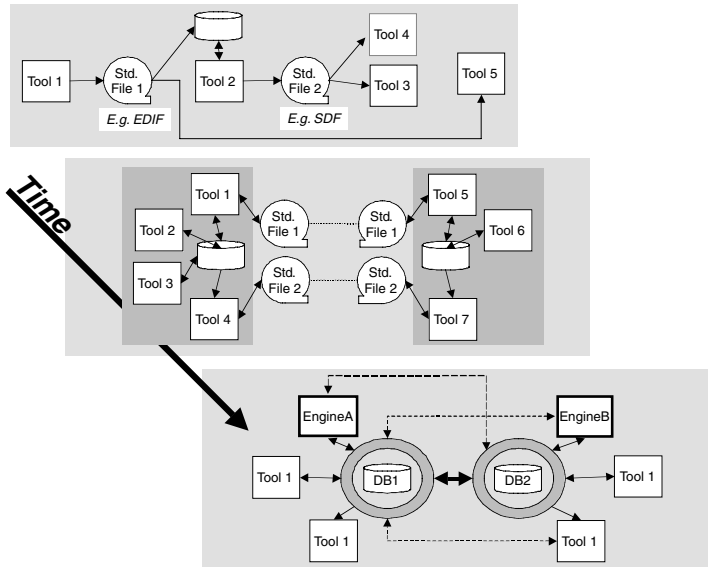

FIGURE 67.11 EDA system architecture progression.

dominated by the capacitance of its receivers, so this delay model was sufficiently accurate. As feature sizes crossed below 1 μm, however, the parasitic wire resistance and capacitance became a significant factor. More precise modelling of the total load effect on gate delay and interconnect delay had to be taken into account. By 0.5 μm the delay attributed to global nets about equalled that of gates, and by 0.35 μm the delay attributed to short nets equalled the gate delay.

Today, a number of models are used to represent the distributed parasitics along interconnects using lumped-form equations. The well-known π-model, for example, is a popular method to model these distributed RCs. Different degrees of accuracy can be obtained by adding more sections to the equivalent lumped RC model for interconnect.

Delay calculators are developed to analyze the circuit topology, in particular the length of interconnect wires and gate loads, and compute delay across circuit elements based on the characterization model

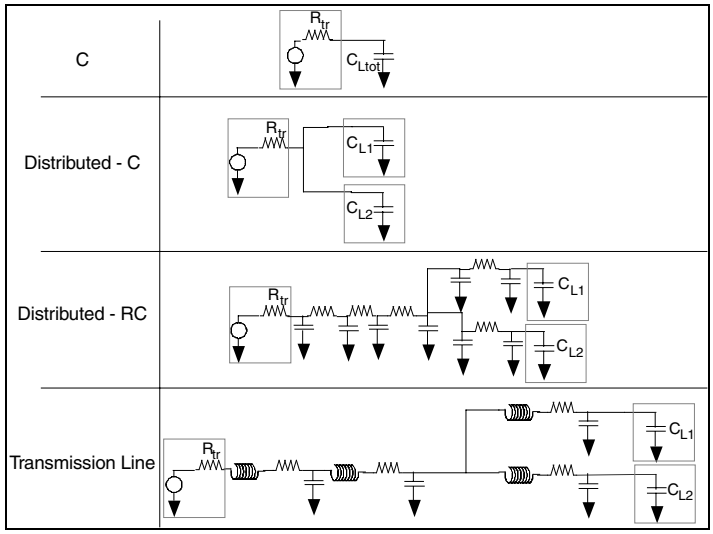

FIGURE 67.12 Delay models.

© 2003 by CRC Press LLC

used. Calculated delay for gates and interconnects is used by design tools such as synthesis, floorplanning, and routing to constrain design choices, and analysis tools such as simulators and STV for circuit verification.

As the importance of timing-based design tools grows, integration of multiply sourced design tools into an EDA flow becomes problematic. As more EDA vendors use built-in models for gate and interconnect delays, these different delay models often result in different calculated delays for the same circuit. This results in difficult and time consuming analysis on the designers' part to correlate the different results. In mid-1994, an industry-wide effort to develop a common delay-calculation engine began.[21] The goal of this effort was to provide a standard language usable by ASIC suppliers to specify the delay calculation models and equations (or table look-ups) for their technology families. In this way, the complexities of deciding appropriate models to be used to characterize circuit delay and the resulting calculation expressions could be placed in the hands of the technology supplier rather than across the EDA vendors. These calculation models and expressions were to be rendered into a form that could be used directly by any EDA application requiring delay calculation and in a way that would protect the intellectual property these specifications represented. By providing a single source for the calculation of delay, all applications in the design flow could provide consistency in the computed results. The Delay Calculation Language (DCL) technology developed by IBM was contributed to the industry as the basis for this. Today, DCL has been extended to cover power calculation in addition to delay and it has been ratified by the IEEE as an open industry standard (Delay and Power Calculation System — DPCS, IEEE 1481-1999).

DPCS is an example of an industry-wide available computational engine as described in the previous section. DCL language statements that specify the characterizing models for delay and power are compiled into an executable program that can be used by any EDA tool. The power of the DCL language allows the technologist the means to characterize the delay model and calculation algorithms. Once compiled, the DCL program becomes a calculation engine for a particular technology family that can be called on demand by any EDA application adhering to the DPCS API. Compilation protects the intellectual property of the semiconductor company while providing a common executable subroutine. With DPCS, the EDA application provides the design details, and the calculation engine returns the calculated delays. The DPCS-API specifies the interface between the compiled engine and the EDA application. EDA applications may call the DPCS engine to compute delay for cells and interconnects individually, or traverse across the entire design. Use of the DPCS engine across a broad scope of EDA tools provides the necessary accuracy and consistency in the computed delays resulting in shorter design times.

By 0.25 μm, mutual capacitance between signal lines begins to have a significant effect on interconnect delay. In this technology generation, it is necessary to consider wire size, length, and the proximity of adjacent wires. When features are significantly close so that mutual capacitance between them becomes sufficient, determination of the RC parasitics along an interconnect is no longer a simple multiplication of RC parasitics per unit length times interconnect length. Now, sophisticated tools must additionally analyze the proximity of features (including wires, vias, pads, etc.) and electrical characteristics of dielectrics between them in order to extract the parasitics from the design. Parasitic extraction tools derive the total circuit parasitics including the mutual capacitance in a two-dimensional space, and as ICs shrink further a three-dimensional space.

Extraction tools are now in the commercial EDA market. They are available as stand-alone products and as part of complete system offerings. Unfortunately, similar to what occurred with delay calculation, different extractors from different suppliers may yield different results because of different simplifying models used. In addition, because of the large amount of processing time required to perform full extraction, it is becoming desirous to have the capability to mix and match extractors within a design flow. On nets where timing is critical, exacting parasitic models are needed, while for less critical nets, less accuracy is acceptable in favor of shorter run-times. Further, there is a growing need to call up extraction within a design tool to test the validity of a design choice. For these reasons, it is apparent that the industry need for incremental extraction engines will become as important as did the delay calculation engine.

© 2003 by CRC Press LLC

Distributed RC models used to characterize delay are very accurate approximations so long as the rise-time (t_r) of the signals is much larger than the time-of-flight (t_{of}) across the wire. As transistor size scales down, so do the signal rise times. As t_r approaches t_{of}, transmission line analysis may be necessary to accurately model timing. Between these points is a grey area where transmission line analysis may be necessary depending on the criticality of the timing across a particular path. Published papers[22,23] address the question of where this level of analysis is important and design rules to be considered for time-critical global lines. For future EDA systems, however, it means more complexities in the design and analysis of circuits. Extraction tools will now need to derive inductance for interconnects so that the effects of the magnetic fields surrounding these lines can be factored into the delay calculations. Effects of mutual inductance also become important, particularly along the power lines that will drive large amounts of current in very short times ($e = L di/dt$). Design planners and routers will need to be aware of these effects when designing global nets and power bus structures. Design rules will need to be developed and checked by EDA tools to assure final designs that meet the expected timing. This again gives rise to the need for the use of calculation and checking engines within design tools, which are developed with appropriate models and rules for these calculations by those best understanding the particular IC technology.

Although the use of standard files such as SDF and the SPEF to communicate delays and parasitics between tools provides a great advantage to multi-vendor tool flows, it is problematic in the long-term. As ICs shrink below 0.25 μm, the amount of data generated for millions of gates and their interconnects is huge thus causing large performance overhead due to the read and translation times. Files exceeding 2 GB are common for circuits of less than 1 million gates, and will scale up with technology. Additionally, the practice of regenerating the entire set of delays or parasitics each time a design change is made becomes impractical, as the required processing times are too large. Therefore, future IC tools will need the ability to incrementally extract parasitics, calculate delay, and analyze the effects of electrical interactions between features on the IC. However, different models and methods for these complex calculations can yield different conclusions across the design flow and result in design inefficiency. Thus, there will be a growing need for industry-standard calculation engines that are characterized by technologists best understanding their device technology and made available for EDA tools independent of their source.

Signal Integrity

Beyond delay, the IC roadmap indicates the growing importance of a number of electrical analysis checks. Many of these checks have been necessary for high-performance MCMs and PCBs, but their importance for CMOS ICs has now begun. The combined effect of decreased feature spacing, signal rise times, and voltage levels will soon reach a point where these new checks are of critical importance to all IC design. Of most importance is the effect of signal noise, which can result from mutual capacitance and mutual inductance between signal lines and signal reflections. Noise can affect the integrity of signals and result in unacceptable delay or logic failures, and is a function of the design's topology and functional operation. Analysis of noise is a complex and time-consuming process and new analysis techniques, models, and design rules will become critical in next generation design systems. Further, its effects are increasing the need for enhanced support for design and analysis of power and clock distribution networks.

New design constraints, such as the maximum noise tolerated on a signal line, will become design rules that must be adhered to. However, this means that design tools, such as routers, may need to call upon noise calculation engines to determine if a decision falls within the tolerable limits. Unfortunately, for critical nets these [relatively] quick approximations and checks may be overly pessimistic and for these interconnects, it will be necessary to perform more exhaustive analysis of the effects of noise. To determine whether or not a signal has integrity requires knowledge of the functional operation in addition to the topological and electrical characteristics of the design and the properties of the materials. Therefore, a new type of EDA analysis is becoming more necessary in the design flows. This is signal integrity verification.

Precise signal integrity verification requires functional patterns to exercize signal paths, in addition to the electrical characteristics of those paths for accurate analysis. Induced noise on a signal may or may not represent a problem depending on whether that condition can exist in the real machine operation

© 2003 by CRC Press LLC

(if a tree falls in the woods and no one is there to hear it, does it make noise?), and whether the path is sensitive to the state of the noisy net. Therefore, simulation of functional patterns is necessary to completely determine if a noise spike causes a fault. This, however, takes on the same problems as functional design verification — pattern generation and completeness analysis. Current and future research in this field must develop formal solutions and more algorithmic solutions to pattern generation — similar to those employed by test generation.

Test

Manufacturing tests of ICs today is becoming a heuristic process involving a number of different strategies in combination to assure coverage and maximize generation costs and throughput at the tester. Today, IC test employs the use of one or more of the following approaches:

- Static stuck-fault test using stored program testers — The test patterns may be derived algorithmically or from random patterns and the test is based on final steady state conditions independent of arrival times. The goal of stuck-fault test is to achieve 100% detection of all stuck-at faults (except for redundancies and certain untestable design situations that can result from the design). Algorithmic test generation for all faults in general sequential circuits is often not possible, but test generation for combinational circuits is. Therefore the use of design-for-test strategies (such as scan-design) is becoming more accepted.
- Delay test using stored program testers — Delay test patterns may be algorithmically generated or functional patterns derived from design verification. The tester measures output pins for the logic state at the specified time after the test pattern is applied.
- Built-in self test (BIST) — BIST tests are generated at the tester by the device under test and output values are captured in scan latches for comparison with simulated good-machine responses. BIST tests may be exhaustive or random patterns and the expected responses are determined by simulation. BIST requires special circuitry on the device-under-test (linear feedback shift registers and scan-latches) for pattern generation and results capture. To improve tester times, output responses are typically compressed into a signature and comparison of captured results and simulated results is made only at the end of sequences of tests.
- Quiescent current test (I_{DDQ}) — I_{DDQ} measures quiescent current draw (current required to keep transistors at their present state) on the power bus. This form of testing can detect faults not observable by stuck-fault tests (such as bridging faults), which may cause incorrect system operation.

Complicating semiconductor trends that will affect manufacturing tests in the future are the speed at which these future chips operate and the quiescent current required for the large density of transistors on the IC. In order to perform delay test, for example, the tester must operate at speeds of the device-under-test. That is, if a signal is to be measured at a time *n* after the application of the test pattern, then the tester must be able to cycle in *n* units of time. It is possible that the hardware costs required to build testers that operate at frequencies above future IC trends will be prohibitive. I_{DDQ} tests are a very effective means to quickly identify faulty chips because only a small number of patterns are required. Further, these tests find faults not otherwise detected by stuck-fault test. Electric current measurement techniques are far more precise than voltage measurements. However, the amount of quiescent current draw required for the millions of transistors on future ICs may make it impossible to detect the small amount of excess current resulting from small numbers of faulty transistors. New inventions and techniques may be introduced into the test menu. However, at present, it appears that future manufacturing tests must rely on static stuck-fault tests and BIST. Therefore, it is expected that more and more application of scan-design will be prevalent in future ICs. This will be a second order benefit for many EDA tools, as the design and analysis of combinational circuits and divide and conquer approaches can be utilized.

Design Productivity

The ITRS points out that future ICs will contain hundreds of millions of transistors. Even with the application of the aforementioned architectural features, faster tools, and support for architectural design,

© 2003 by CRC Press LLC

it is unclear if design productivity (number of good-circuits designed per person-year) will achieve the necessary level. Designing and managing anything containing over 100,000,000 sub-elements is almost unthinkable. Doing it right and within the typical 18-month product cycles of today seems impossible. Yet, if this is not accomplished, semiconductor fabs may run at less than full production, and the ability to see returns on the exorbitant capital expenditures required for new fabs will be at risk. Ultimately, this could negate the predictions in the ITRS.

Over the history of IC design, a number of paradigm shifts enhanced designer productivity, the most notable being high-level design languages and synthesis. Use of design rules, such as LSSD, to constrain the problem has also represented productivity advances. Algorithm advances and faster processing computers will necessarily play a crucial role, as the design cycle-time is a function of computer resources required. Many of the EDA application algorithms, however, are not linear with respect to design size, and processing times can increase as an exponential function of transistors. Therefore, exploitation of hierarchy, abstraction, shared, incremental, and concurrent EDA system architectures will play an important role in overall productivity. Even with all of this, there is a major concern that industry will not be able to design enough good circuits fast enough. Consequently, there is a major push in the semiconductor industry toward design reuse. There is a major activity in the EDA industry (Virtual Sockets Interface Alliance — VSIA) to define the necessary standards, formats, and test rules to make design reuse real on ICs.

Design reuse is not new to electronic design or EDA. Early TTL modules were an example of reuse, standard cell ASICs and PCB-level MSI modules. With each, the design of the component is done once, then qualified, then reused repeatedly in application-specific designs. Reuse is also common within design teams. A logical function may be designed, verified, then reused in many other sections of the system's design. However, the ability to embed semiconductor designs from one process into chips manufactured on another process, or from one company to another is just in its beginnings.

The VSIA has defined three different types of reusable property for ICs:

1. Hard macros — These functions have been designed and verified, and have completed layout. They are characterized by being a technology fixed design and a mapping of manufacturing processes is required to re-target them to another fabrication line. The most likely business model for hard macros is that they will be available from the semiconductor vendor for use in application-specific designs being committed to that supplier's fabrication line. In other words, hard macros will most likely not be generally portable across fabs except in cases where special business partnerships are established. The complexities of plugging a mask-level design for one process into another process line are a gating factor for further exploitation at present.
2. Firm macros — These can be characterized as reusable parts that have designed down to the cell level and through partitioning and floorplanning. These are more flexible than hard macros since they are not process-dependent and can be re-targeted to other technology families for manufacture.
3. Soft macros — These are truly portable design descriptions but are only completed down through the logical design level. No technology mapping or physical design is available.

In order to achieve reuse at the IC level, it will be necessary to define or otherwise establish a number of standard interfaces for design data. The reason for this is that it will be necessary to fit design data from other sources into the design system being used to develop the IC. Therefore, VSIA was established to determine where standard interfaces or data formats are necessary, and elect what the standard is to be. For soft macros, these interfaces will need to include behavorial descriptions, simulation models, timing models, etc. For firm macros, the scope will additionally include cell libraries, floorplan information, and global wiring information. For hard macros, GDSII may be supplied.

In order to reuse designs that were developed elsewhere (hereafter called intellectual property blocks, or IP blocks), the first essential requirement is that the functional and electrical characteristics of the available IP blocks be available. Since internal construction of firm and hard IP may be highly sensitive and proprietary, it will become more important to describe the functional and timing characteristics at the I/Os. This will drive the need for high-level description methods such as the use of VHDL behavorial

© 2003 by CRC Press LLC

models, DCL, IBIS models, and dynamic timing-diagrams. Further, the need to test these embedded IP blocks will mandate more use of scan-based test techniques such as JTAG boundary scan. Use of standard methods such as these to encapsulate IP blocks will be paramount for broad use across many designs and design systems.

There are risks, however, and reuse of IP will not cover all design needs. Grand schemes for reusable software yielded less than desired results. Extra effort to generalize the IP block design points for broad use and describe its characteristics in standard formats is compounded with the ability to identify an IP block that fits a particular design need. Design and characterization of reusable IP will need to be robust in timing, power, reliability, and noise in addition to function and cost. Further, the broad distribution of IP information may conflict with business objectives. Moreover, even if broadly successful, use of reusable IP will not negate the fundamental need for major EDA advances in the areas described. First, tools are needed to design the IP. Second, tools are needed to design the millions of circuits that will interconnect IP. Finally, tools and systems will require major advances to accurately design and analyze the electrical interactions between, over, and under IP and application-specific design elements on the IC. Standards are essential, but they are not sufficient for success. Tools, rules, and systems will be the foundation for future IC design as they have been over the past. Nevertheless, the potential rewards are substantial and there is an absence of any other clear EDA paradigm shift. Consequently, new standards will emerge for design and design systems, and new methods for characterization, distribution, and look-up of IP will become necessary.

Mask Generation

As the size of printed features on the IC shrinks below the wavelength on the light used to expose the photoresist, a whole new set of complexities results in the area of mask making. At the 0.25-μm technology node, the 248 nm wavelength of the light used to expose the photoresist equalled the size of the features to be etched. This gap is widening (despite planned light sources with a smaller wavelength) and will continue to do so for the foreseeable future. The consequence of this is optical distortions that cause printed line edges to vary from the intended design, depending upon the density, size, and location of nearby features. These are called "proximity effects" and they manifest themselves in the form of undesired patterns and line geometries that translate to line-width variations and other distortions that can decrease performance, or even worse, cause missing, incomplete, or shorted structures that result in failures. Below the 0.25 μm node, IC designers can no longer expect that the manufactured IC will reflect their design intent without correcting for this phenomenon. Thus, a rather new design task has become necessary which is optical proximity correction (OPC) which serves to add additional shapes to the design that will correct the distortions. Examples are shape biasing, corner serifs, line-end extensions, and line-end anchors.[24] Unfortunately, correction by the addition of geometric shapes causes the already large mask data files (these files can exceed 50 GB in 2001) to increase at a rate beyond that of Moore's law. This, in turn, causes undue time (and resulting costs) in the capital-intensive mask development phase. This is acceptable for high-volume ICs (memory and microprocessors), but is rapidly becoming a problem for low-volume ASICs. New correction techniques and ways to optimize the mask data file sizes will be required to keep the mask prep costs at an acceptable level.

67.4 Summary

Over the past three decades, EDA has become a critical science of many disciplines. Where it may have begun as a productivity enhancement, it is now a fundamental requirement for all electronic design. The criticality of EDA for IC design is the focus of much attention because of the expanding semiconductor advancements. Fundamental approaches in test, simulation, and physical design are constantly being tested by these semiconductor advancements. New EDA disciplines are opening up. Fundamental electrical models are becoming more important and at the same time, more complex. New problems in design and IC failure modes will surely surface. The next decade of EDA should prove to be as exciting as the past three!

68.1 Introduction

It has been noted by the digital design community that the greatest potential for additional cost and iteration cycle time savings is through improvements in tools and techniques that support the early stages of the design process.[1] As shown in Fig. 68.1, decisions made during the initial phases of a product's development cycle determine up to 80% of its total cost. The result is that accurate, fast analysis tools must be available to the designer at the early stages of the design process to help make these decisions. Design alternatives must be effectively evaluated at this level with respect to multiple metrics, such as performance, dependability, and testability. This analysis capability will allow a larger portion of the design space to be explored yielding higher quality as well as lower cost designs.

There are a number of current tools and techniques that support analysis of these metrics at the system level to varying degrees. A major problem with these tools is that they are not integrated into the engineering design environment in which the system will ultimately be implemented. This problem leads to a major disconnection in the design process. Once the system-level model is developed and analyzed, the resulting high-level design is specified on paper and thrown "over the wall" for implementation by the engineering design team, as illustrated in Fig. 68.2. As a result, the engineering design team has to often interpret this specification in order to implement the system, which often leads to design errors. It also has to develop their own initial "high-level" model from which to begin the design process in a top-down manner. Additionally, there is no automated mechanism by which feedback on design assumptions and estimations can be provided to the system design team by the engineering design team.

For systems that contain significant portions of both application-specific hardware and software executing on embedded processors, design alternatives for competing system architectures and hardware/software (HW/SW) partitioning strategies must be effectively and efficiently evaluated using high-level performance models. Additionally, the selected hardware and software system architecture must be

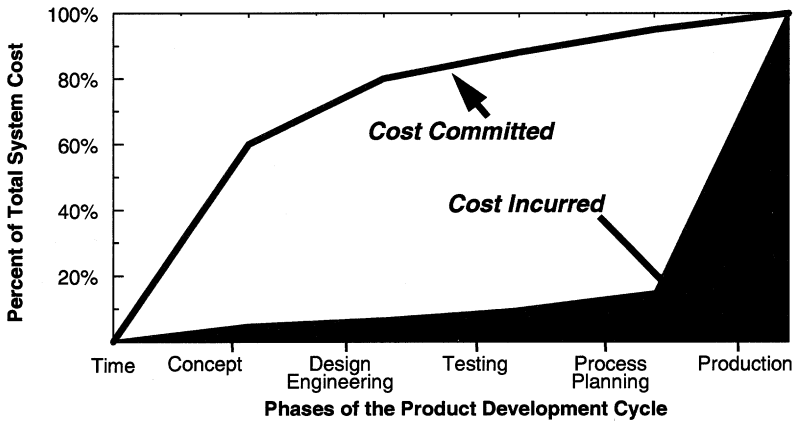

FIGURE 68.1 Product costs over the development cycle.

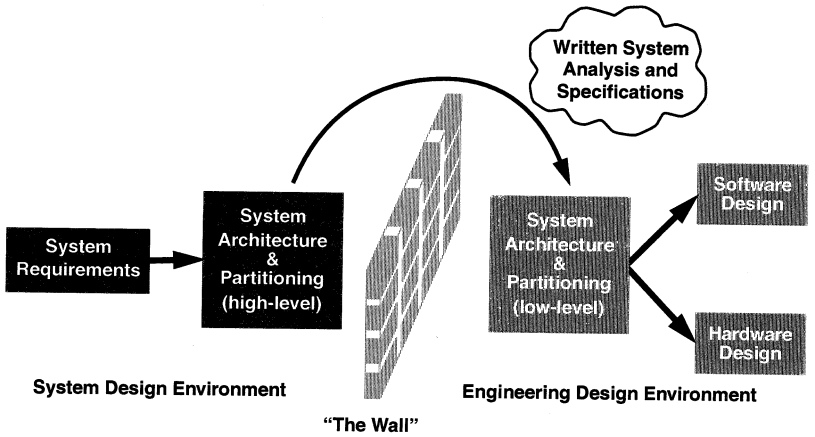

FIGURE 68.2 The disconnection between system-level design environments and engineering design environments.

refined in an integrated manner from the high-level models to an actual implementation in order to avoid implementation mistakes and the associated high redesign costs. Unfortunately, most existing design environments lack the ability to model and design a system's hardware and software in the same environment. A similar wall to that between the system design environment and the engineering design environment exists between the hardware design environment and the software design environment. This results in a design path as shown Fig. 68.3, where the hardware and software design process begins

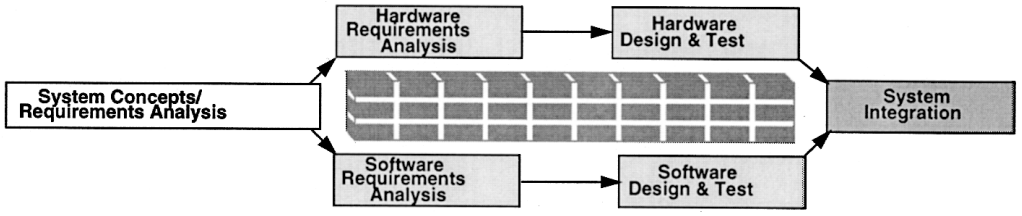

FIGURE 68.3 Current hardware/software system development methodology.

© 2003 by CRC Press LLC

with a common system requirement and specification but proceeds through a separate and isolated design process until final system integration. At this point, assumptions on both sides may prove to be drastically wrong, resulting in incorrect system function and poor system performance.

A unified, cooperative approach in which the hardware and software options can be considered together is required to increase the quality and decrease the design time for complex hardware/software (HW/SW) systems. This approach is called hardware/software codesign, or simply codesign.[2-4] Codesign leads to more efficient implementations and improves overall system performance, reliability, and cost-effectiveness.[4] Also, because decisions regarding the implementation of functionality in software can impact hardware design (and vice versa), problems can be detected and changes made earlier in the development process.[5]

Codesign can especially benefit the design of embedded systems,[6] systems which contain hardware and software tailored for a particular application. As the complexity of these systems increases, the issue of providing design approaches that scale up to more complicated systems becomes of greater concern. A detailed description of a system can approach the complexity of the system itself,[7] and the amount of detail present can make analysis intractable. Therefore, decomposition techniques and abstractions are necessary to manage this complexity.

What is needed is a design environment in which the capability for performance modeling of HW/SW systems at a high-level of abstraction is fully integrated into the engineering design environment. In order to completely eliminate the "over the wall" problem and the resulting model discontinuity, this environment must support the incremental refinement of the abstract system level performance model into an implementation level model. Using this environment, a design methodology based on incremental refinement can be developed.

The design methodology illustrated in Fig. 68.4 was proposed by Lockheed Martin Advanced Technology Laboratory as a new way to design systems.[8] This methodology uses the level of the risk of not meeting the design specifications as the metric for driving the design process. In this spiral-based design methodology, there are two iteration cycles. The major cycles (or spirals), denoted as CYCLE 1, CYCLE 2, …, CYCLE N, on the figure correspond to the design iterations where major architectural changes are made in response to some specification metric(s) and/or the system as a whole is refined and more design detail is added to the model. Consistent with the new paradigm of system design, these iterations will actually produce virtual or simulation-based prototypes. A virtual prototype is simply a simulatable model of the system with stimuli described at a given level of design detail or design abstraction that describes the system's operation. Novel to this approach are the mini spirals. The mini spiral cycles, denoted by the levels on the figure labled SYSTEMS, ARCHITECTURE, and DETAILED DESIGN, correspond to the refinement of only those portion(s) of the design that are deemed to be "high risk." High risk is obviously defined by the designer but is most often the situation where if one or more of

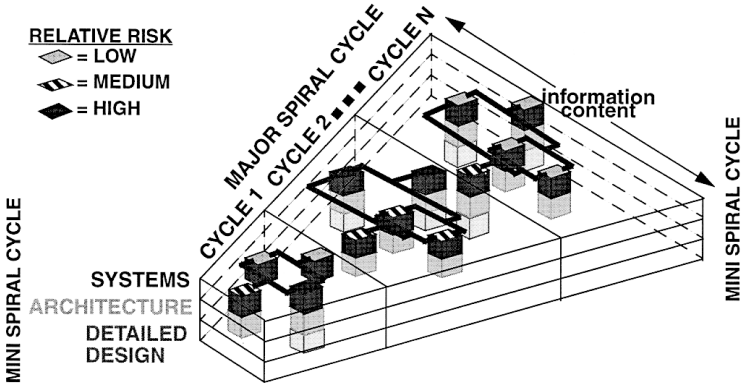

FIGURE 68.4 Risk-driven expanding information model (RDEIM).

© 2003 by CRC Press LLC

these components fail to meet their individual specifications, the system will fail to meet its specifications. The way to minimize the risk is to refine these components to possibly an implementation so that the actual performance is known. Unlike the major cycles where the entire design is refined, the key to the mini spirals is the fact that only the critical portions of design are refined. For obvious reasons, the resulting models have been denoted as risk-driven expanding information models (RDEIMs).

The key to being able to implement this design approach is to be able to evaluate the overall design with portions of the system having been refined to a detailed level while the rest of the system model remains at the abstract level. For example, in the first major cycle of Fig. 68.4, the element with the highest relative risk is fully implemented (detailed design level) while the other elements are described at more abstract levels (system level or architectural level). If the simulation of the model shown in the first major cycle detects that the overall system will not meet its performance requirements, then the "high risk" processing element could be replaced by two similar elements operating in parallel. This result is shown in the second major cycle, and at this point another element of the system may become the new "bottleneck", i.e., the highest relative risk, and it will be refined in a similar manner.

Implied in the RDEIM approach is a solution to the "over the wall" problem, including HW/SW codesign. The proposed solution is to fully integrate performance modeling into the design process.

Obviously, one of the major capabilities necessary to implement a top-down design methodology like the RDEIM is the ability to co-simulate system models which contain some components that are modeled at an abstract performance level (uninterpreted models) and some that are modeled at a detailed behavioral level (interpreted models). This ability to model and co-simulate uninterpreted models and interpreted models is called mixed-level modeling (sometimes referred to as hybrid modeling). Mixed-level modeling requires the development of interfaces that can resolve the differences between uninterpreted models that, by design, do not contain a representation of all of the data or timing information of the final implementation, and interpreted models which require most, or possibly all, data values and timing relationships to be specified. Techniques for systematic development of these mixed-level modeling interfaces and resolution of these differences in abstraction is the focus of the latest work in mixed-level modeling.

A unified end-to-end design environment has been developed at the University of Virginia that attempts to achieve this goal. This environment supports the development of system-level models of digital systems that can be analyzed for multiple metrics, like performance and dependability, and can then be used as a starting point for the actual implementation. A tool called ADEPT (Advanced Design Environment Prototype Tool) has been developed to implement this environment. ADEPT actually supports both system-level performance and dependability analysis in a common design environment using a collection of predefined library elements. ADEPT also includes the ability to simulate both system level and implementation-level (behavioral) models in a common simulation environment. This capability allows the stepwise refinement of system-level models into implementation-level models.

Multi-Level Modeling

The need for multi-level modeling was recognized almost three decades ago. Multi-level modeling implies that representations at different levels of detail coexist within a model.[7,9,10] Until the early 1990s, the term multi-level modeling was used for integrating behavioral or functional models with lower level models. The objective was to provide a continuous design path from functional models down to implementation. This objective was achieved, and the VLSI industry utilizes it today. An example is the tool called Droid, developed by Texas Instruments.[11]

The mixed-level modeling approach, as described in this chapter, is a specific type of multi-level modeling which integrates performance and behavioral models. Thus, only related research on multi-level modeling systems that spans both the performance and the functional/behavioral domains will be described.

Although behavioral or functional modeling is typically well-understood by the design community, performance modeling is a foreign topic to most designers. Performance modeling, also called uninterpreted modeling, is utilized in the very early stages of the design process in evaluating such metrics as

© 2003 by CRC Press LLC

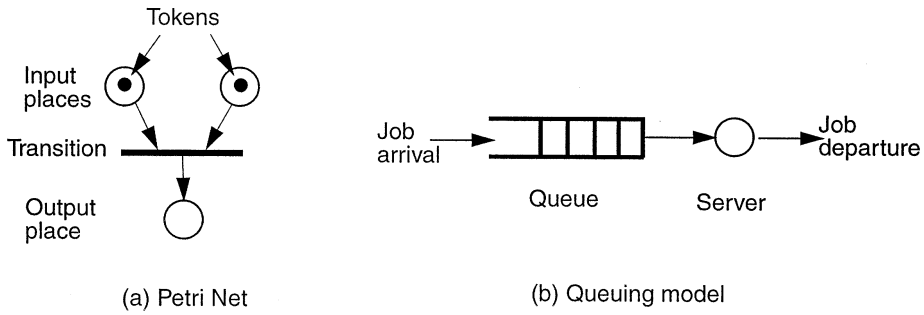

FIGURE 68.5 Petri Net and queuing model.

throughput and utilization. Performance models are also used to identify bottlenecks within a system and are often associated with the job of a system engineer. The term "uninterpreted modeling" reflects the view that performance models lack value-oriented data and functional (input/output) transformations. However, in some instances, this information is necessary to allow adequate analysis to be performed.

A variety of techniques have been employed for performance modeling. The most common techniques are Petri Nets[12-14] and queuing models.[15,16] A combination of these techniques, such as a mixture of Petri Nets and queuing models,[17] has been utilized to provide more powerful modeling capabilities. All of these models have mathematical foundations. However, models of complex systems constructed using these approaches can quickly become unwieldy and difficult to analyze.

Examples of a Petri Net and a queuing model are shown in Fig. 68.5. A queuing model consists of queues and servers. Jobs (or customers) arrive at a specific arrival rate and are placed in a queue for service. These jobs are removed from the queue to be processed by a server at a particular service rate. Typically, the arrival and service rates are expressed using probability distributions. There is a queuing discipline, such as first-come-first-serve, which determines the order in which jobs are to be serviced. Once they are serviced, the jobs depart and arrive at another queue or simply leave the system. The number of jobs in the queues represents the model's state. Queueing models have been used successfully for modeling many complex systems. However, one of the major disadvantages of queuing models is their inability to model synchronization between processes.

As a system modeling paradigm, Petri Nets overcome this disadvantage of queuing models. Petri Nets consist of places, transitions, arcs, and a marking. The places are equivalent to conditions and hold tokens which represent information. Thus, the presence of a token in the place of a Petri Net corresponds to a particular condition being true. Transitions are associated with events, and the "firing" of a transition indicates that some event has occurred. A marking consists of a particular placement of tokens within the places of a Petri Net and represents the state of the net. When a transition fires, tokens are removed from the input places and are added to the output places, changing the marking (the state) of the net and allowing the dynamic behavior of a Petri Net to be modeled.

Petri Nets can be used for performance analysis by associating a time with the transitions. Timed and stochastic Petri Nets contain deterministic and probabilistic delays, respectively. Normally, these Petri Nets are uninterpreted, since no interpretation (values or value transformations) are associated with the tokens or transitions. However, values or value tranformations can be associated with the various elements of Petri Net models as described below.

Petri Nets that have values associated with tokens are known as colored Petri Nets (CPNs). In the colored Petri Nets, each token has an attached color, indicating the identity of the token. The net is similar to the basic definition of the Petri Net except that a functional dependency is specified between the color of the token and the transition firing action. In addition, the color of the token produced by a transition may be different from the color of the token(s) on the input place(s). CPNs have an increased

© 2003 by CRC Press LLC

ability to efficiently model real systems with small nets which are equivalent to much larger plain Petri Nets due to their increased descriptive powers.

Numerous multi-level modeling systems exist based on these two performance modeling techniques. ADAS (Architecture Design and Assessment System) is a set of tools specifically targeted for high-level design.[18] ADAS models both hardware and software using directed graphs based on timed Petri Nets. The flow of information is quantified by identifying discrete units of information called tokens. ADAS supports two levels of modeling. The more abstract level is a dataflow description and is used for performance estimation. The less abstract level is defined as a behavioral level but still uses tokens which carry data structures with them. The functionality is embedded into the models using C or Ada programs. The capability of generating high-level VHDL models from the C or Ada models is provided. These high-level VHDL models can be further refined and developed in a VHDL environment, but the refined models cannot be integrated back into the ADAS performance model. The flow of information in these high-level VHDL models is still represented by tokens. Therefore, implementation-level components cannot be integrated into an ADAS performance model. Another limitation is that all input values to the behavioral node must be contained within the token data structure.

SES/Workbench (Scientific and Engineering Software) is a design specification, modeling and simulation tool.[19] It is used to construct and evaluate proposed system designs and to analyze their performance. A graphical interface is used to create a structural model which is then converted into a specific simulatable description (SES/sim). SES/Workbench enables the transition across domains of interpretation by using a user node, in which C-language and SES/sim statements can be executed. Therefore, SES/Workbench has similar limitations to ADAS; the inability to simulate a multi-level model when input values of behavioral nodes are not fully specified and the inadequacy of simulating components described as implementation-level HDLs (the capability of integrating VHDL models will be introduced later in the next paragraph). In addition, multiple simulation languages (both SES/sim and C) are required for multi-level models.

The Reveal Interactor is a tool developed by Redwood Design Automation.[20] A model constructed in Reveal is aimed at the functional verification of RTL-level VHDL and Verilog descriptions and, therefore, does not include a separate transaction-based performance modeling capability. However, Reveal can work in conjunction with SES/Workbench. By mixing models created in Reveal and SES/Workbench, a multi-level modeling capability exists. Again, these multi-level models are very limited due to the fact that all the required information at the lower level part of the model must be available within the higher level model.

IDAS (Integrated Design Automation System) is a multi-level design environment which allows for rapid prototyping of systems.[21] Although the behavioral specifications need to be expressed as Ada, C, or Fortran programs, IDAS provides the capability of automatically translating VHDL description to Ada. However, the user cannot create abstract models in which certain behavior is unspecified. Also, it does not support classical performance models (such as queuing models and Petri Nets) and forces the user to specify a behavioral description very early in the design process.

Transcend claims to integrate multi-level descriptions into a single environment.[22,23] In the more abstract level, T-flow models are used, in which tokens are used to represent flow of data. The capability of integrating VHDL sub-models into a T-flow model is provided. However, interfacing between the two models requires a "C++ like" language, which maps variables to/from VHDL signals, resulting in a heterogeneous simulation environment. Although its approach is geared toward the same objective as mixed-level modeling, the T-flow model must also include all the necessary data to activate the VHDL sub-models. Therefore, the upper level model cannot be "too abstract" and must include lower level details.

MIDAS (Methodology for Integrated Design and Simulation) supports the design of distributed systems via iterative refinement of PIPS (Partially Implemented Performance Specification) models.[24] A PIPS model is a partially implemented design where some components exist as simulation models and others as operational subsystems (i.e., implemented components). Although the term "hybrid model" is used in this context, it refers to a different type of modeling. MIDAS is an "integrated approach to

© 2003 by CRC Press LLC

software design."[24] It supports the performance evaluation of software being executed on a given machine. It does not allow the integration of components expressed in an HDL into the model.

The Ptolemy project is an academic research effort being conducted at the University of California at Berkeley.[25,26] Ptolemy, a comprehensive system prototyping tool, is actually constructed of multiple domains. Most domains are geared toward functional verification and have no notion of time. Each domain is used for modeling a different type of system. The domains also vary in the modeling level (level of abstraction). Ptolemy provides limited capability of mixing domains within one design. The execution of a transition across domains is accomplished with a "wormhole." A wormhole is the mechanism for supporting the simulation of heterogeneous models. Thus, a multi-level modeling and analysis capability is provided. There are two major limitations to this approach compared with the mixed-level modeling approach being described. The first one is the heterogeneity — several description languages. Therefore, translation between simulators is required. The second limitation is that the interface between domains only translates data. Therefore, all the information required by the receiving domain must be generated by the transmitting domain.

Honeywell Technology Center (HTC) currently has a research effort that is specifically addressing the mixed-level modeling problem.[27] This research has its basis in the UVa mixed-level modeling effort. The investigators at HTC have developed a Performance Modeling Library (PML)[28,29] and are currently working on adding a mixed-level modeling capability to this environment. The PML is used for performance models at a relatively low level of abstraction. Therefore, it assumes that all the information required by the interpreted element is provided by the performance model. In addition, their interface between uninterpreted and interpreted domains allows for bidirectional data flow.

To summarize, numerous multi-level modeling efforts exist. However, they are being developed not addressing the issue of lack of information at the transition between levels of abstraction. A solution to this problem is essential for true stepwise refinement of the performance models to behavioral models. In addition, integration of performance modeling level and behavioral modeling level was mostly performed by mixing different simulation environments, which results in heterogeneous modeling approach.

68.2 The ADEPT Design Environment

Two approaches to creating a unified design environment are possible. An evolutionary solution is to provide an environment that translates data from different models at various points in the design process and creates interfaces for the noncommunicating software tools used to develop these models. With this approach, users must be familiar with several modeling languages and tools. Also, analysis of design alternatives is difficult and is likely to be limited by design time constraints.

A revolutionary approach, the one being developed in ADEPT, is to use a single modeling language and mathematical foundation. This approach uses a common modeling language and simulation environment, which decreases the need for translators and multiple models, reducing inconsistencies and the probability of errors in translation. Finally, the existence of a mathematical foundation provides an environment for complex system analysis using analytical approaches.

Simulators for hardware description languages accurately and conveniently represent the physical implementation of digital systems at the circuit, logic, register-transfer, and algorithmic levels. By adding a system-level modeling capability based on extended Petri Nets and queuing models to the hardware description language, a single design environment can be used from concept to implementation. The environment would also allow for the mixed simulation of both uninterpreted (performance) models and interpreted (behavioral) models due to the use of a common modeling language. Although it would be possible to develop the high-level performance model and the detailed behavioral model in two different modeling languages and then develop some sort of translator or foreign language interface to hook them together, a better approach is to use a single modeling language for both models. A single modeling language that spans numerous design phases is much easier to use, encouraging more design analysis and consequently better designs.

© 2003 by CRC Press LLC

ADEPT implements an end-to-end unified design environment based on the use of the VHSIC Hardware Description Language (VHDL).[30] VHDL is a natural choice for this single modeling language in that it has high-level language constructs, but unlike other programming languages, it has a built-in timing and concurrency model. VHDL does have some disadvantages in terms of simulation execution time, but techniques have been developed to help address this problem.[31]

ADEPT supports the integrated performance and dependability analysis of system-level models and includes the ability to simulate both uninterpreted and interpreted models through mixed-level modeling. ADEPT also has a mathematical basis in Petri Nets, thus providing the capability for analysis through simulation or analytical approaches.[32]

In the ADEPT environment, a system model is constructed by interconnecting a collection of predefined elements called ADEPT modules. The modules model the information flow, both data and control, through a system. Each ADEPT module has a VHDL behavioral description and a corresponding mathematical description in the form of a CPN based on Jensen's CPN model.[33] The modules communicate by exchanging tokens, which represent the presence of information, using a fully interlocked, four-state handshaking protocol.[34] The basic ADEPT modules are intended to be building blocks from which useful modeling functionality can be constructed. In addition, custom modules can be developed by the user if required and incorporated into a system model as long as the handshaking protocol is adhered to. Finally, some libraries of application-specific, high-level modeling modules such a Multiprocessor Communications Network Modeling Library[35] have been developed and included in ADEPT.

The following sections discuss the VHDL implementation of the token data type and transfer mechanism used in ADEPT and the modules provided in the standard ADEPT modeling library.

Token Implementation

The modules defined in this chapter have been implemented in VHDL and use a modified version of the token passing mechanism defined by Hady.[34] Signals used to transport tokens must be of the type token, which has been defined as a record with two fields. The first field, labeled STATUS, is used to implement the token passing mechanism. The second field, labeled COLOR, is an array or integers that is used to hold user-defined color information in the model. The ADEPT tools allow the user to select from a predefined number of color field options. The tools then automatically link in the proper VHDL design library so that the VHDL descriptions of the primitive modules operate on the defined color field. The default structure of the data-type token used in the examples discussed in this document is shown in Fig. 68.6.

There are two types of outputs and two types of inputs in the basic ADEPT modules. Independent outputs are connected to control inputs, and the resulting connection is referred to as a control-type signal. Dependent outputs are connected to data inputs, and the resulting connection is referred to as a data-type signal. To make the descriptions more intuitive, outputs are often referred to as the "source side" of a signal, and inputs are referred to as the "sink side" of a signal.

Tokens on independent outputs may be written over by the next token, so the "writing" process is independent of the previous value on the signal. On the other hand, new tokens may not be placed on dependent outputs until the previous token has been removed, so the "writing" process is dependent on the previous value on the signal. Data-type signals use the four-step handshaking process to ensure that tokens do not get overwritten, but no handshaking occurs on control-type signals.

The STATUS field of a token signal can take on four values. Signals connecting independent outputs to control inputs (control-type signals) make use of only two of the four values. Independent outputs place a value PRESENT on the status field to indicate that a token is present. Since control inputs only copy the token but do not remove it, the independent output only needs to change the value of the status field to RELEASED to indicate that the token is no longer present on the signal, and the control input can no longer consider the signal to contain valid information. The signals connecting dependent outputs to data inputs (data-type signals) need all four values (representing a fully interlocked handshaking scheme) to ensure that a dependent output does not overwrite a token before the data input to which it

function protocol (input : token_vector) return token;
subtype token_res is protocol token;
```

FIGURE 68.6 Token type definition.

is connected has read and removed it. This distinction is important, since a token on control-type signals represents the presence or absence of a condition in the network while tokens on data-type signals, on the other hand, represent information or data that cannot be lost or overwritten. In addition, fan-out is not permitted on dependent outputs and is permitted on independent outputs.

The signals used in the implementation are of type token. The token passing mechanism for data-type signals is implemented by defining a VHDL bus resolution function. This function is called each time a signal associated with a dependent output and a data input changes value. The function essentially looks at the value of the STATUS field at the ports associated with the signal and decides the final value of the signal. At the beginning of simulation, the STATUS field is initialized to REMOVED. This value on a signal corresponds to an idle link in the nets defined by Dennis.[36] This state of a signal indicates that a signal is free and a request token may be placed on it. Upon seeing the REMOVED value, the requesting module may set the value of the signal to PRESENT. This operation corresponds to the ready signal in Dennis's definition. The requested module acknowledges a ready signal (PRESENT) by setting the signal value to ACKED, after the requested operation has been completed. Upon sensing the value of ACKED on the signal, the requesting module sets the value of the signal to RELEASED, which in turn causes the requested module to place the value of REMOVED on the signal. This action concludes one request/acknowledge cycle, and the next request/acknowledge cycle may begin.

In terms of Petri Nets, the models described here can be described as one-safe Petri Nets, since at any given time, no place in the net can contain more than one token. The correspondence between the signal values and transitions in a Petri Net may be defined in general in the following manner:

1. PRESENT: A token arrives at the input place of a transition.
2. ACKED: The output place of a transition is empty.
3. RELEASED: The transition has fired.
4. REMOVED: The token has been transferred from the input place to the output place.

```

FIGURE 68.7 Wye module ADEPT symbol, its behavioral VHDL description, and its CPN representation.

The modules to be described in this chapter may be defined in terms of Petri Nets. As an example, a Petri Net description of the Wye module is shown in Fig. 68.7.

The function of the Wye module is to copy the input token to both outputs. The input token is not acknowledged until both output tokens have been acknowledged. In the Petri Net of Fig. 68.7, the "R" and "A" labels correspond to "ready" and "acknowledge", respectively. When a token arrives at the place labeled "0r", the top transition is enabled and a token is placed in the "1r", "2r", and center places. The first two places correspond to a token being placed on the module outputs. Once the output tokens are acknowledged (corresponding to tokens arriving at the "1a" and "2a" places, the lower transition is enabled and a token is placed in "0a", corresponding to the input token being acknowledged. The module is then ready for the next input token. Note that since this module does not manipulate the color fields, no color notation appears on the net.

The specific CPN description used is based on the work of Jensen.[33] The complete CPN descriptions of each of the ADEPT building blocks can be found in the work of Swaminathan et al.[37]

ADEPT Handshaking and Token Passing Mechanism

Recall that the ADEPT standard token has a status field which can take on four values: PRESENT, ACKED, RELEASED, and REMOVED. These values reflect which stage of the token passing protocol is currently in progress. Several examples will now be presented to show how the handshaking and token passing

3	0 ns	3	Source module releases token on A	released
4	0 ns	4	Sink module removes token on A	removed
1	5 ns	1	Source module places token on A	present

FIGURE 68.8 Two-module handshaking example.

occurs between ADEPT modules. Figure 68.8 illustrates the handshaking process between a source module connected to a Sink module.

Figure 68.8A describes the simplified event sequence. Here, we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. Thinking of the handshaking in this simplified manner, Table A in Fig. 68.8 shows the simplified event sequence and times. At time 0 ns, the source module places a token on A, corresponding to Event 1. The token is immediately acknowledged by the sink module, corresponding to Event 2. Since the source module has a step generic of 5 ns and there is no other delay along the path to the sink, the next token will be output by the source module at time 5 ns.

© 2003 by CRC Press LLC

Figure 68.8B details the entire handshaking process. Table B in Fig. 68.8 lists the detailed event sequence for this example. Since handshaking occurs in zero simulation time, the events are listed by delta cycles within each simulation time. The function of delta cycles in VHDL is to provide a means for ordering and synchronizing events (such as handshaking) which occur in zero time. The actual event sequence for this example consists of four steps, as shown in Fig. 68.8B. Event 1 is repeated at time 5 ns, which starts the handshaking process over again.

A Three-Module Example

To illustrate how tokens are passed through intermediate modules, a three-module example will now be examined. Consider the case where a fixed delay module is placed between a source and sink. This situation is illustrated in Fig. 68.9.

Figure 68.9A shows the simplified event sequence, where we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. Table A in Fig. 68.9A lists this simplified event sequence. Notice that since now there is a path delay from the source to the sink, the time between new tokens from the source is *step* + *path_delay* = 5 ns + 5 ns = 10 ns. At time 0 ns, the source module places the first token on Signal A (Event 1). This token is read by the delay module and placed on signal B after a delay of 5 ns (Event 2). The sink module then immediately acknowledges the token on signal B (Event 3). The delay module then passes this acknowledgment back through to signal A (Event 4). At time 10 ns, the source module places the next token on Signal A, starting the process over again.

Figure 68.9B shows the detailed event sequence for this example. Since there are two signals, there are a total of eight detailed events. Table B in Fig. 68.9 lists the detailed event sequence for this example. Again, since the handshaking occurs in zero simulation time, the events are listed by delta cycles within each simulation time. Table B lists the resolved values on both signal A and signal B, where a value of "----" indicates no change in value. Notice that the sequence of events on each signal proceeds in this order: place the token (present) by the source side, acknowledge the token (acked) by the sink side, release the token (released) by the source side, and finally remove the token (removed) by the sink side. The important concept to note in this example is the ordering of events. Notice that the delay module releases the token on its output (Event 4) before it acknowledges the token on its input (Event 5), even though the two events occur in the same simulation time. These actions trigger the sink module to then remove the token on signal B (Event 6) and the source module to release the token on signal A (Event 7), both in the next delta cycle. Thus signal B is ready for another token (removed) a full delta cycle before signal A is ready.

Token Passing Example

To illustrate how tokens propagate in a larger system, consider the model shown in Fig. 68.10. This figure shows the simplified event sequence, where again we can think of the four-step handshaking as consisting of simply a forward propagation of the token and a backward propagation of the token acknowledgment. In this system, the source module provides tokens to the sequence A (SA) module (Event 1), who first passes them to the sequence B (SB) module (Event 2). The SB module first passes the token to the fixed delay A (FDA) module (Event 3), which passes it to the sink A (SIA) module after a delay of 5 ns (Event 4). The SIA module then immediately acknowledges the token (Event 5), which causes the FDA module to pass the acknowledgment back to the SB module (Event 6). At this point, the SB module places a copy of the token on its second output (Event 7), where it is passed through the Union A and onto its output (Event 8). The read color A module then places the token on its out_1 output (Event 9) and simultaneously places the token on its independent output. The sink B module then acknowledges the token on signal H (Event 10). Upon seeing this acknowledgment, the read color A module releases the token on its independent output, since the read color module has no "memory" (the *release?* generic equals true). The acknowledgment is then propagated back to the SB module (Events 11 and 12). At this point, the SB module acknowledges its input token (Event 13), freeing the SA module to place a token on its second output (Event 14). This token is then passed through the union A, read color A, and sink module (Events

Table A: Simplified Event Sequence

Event	Time	Description
1	0 ns	Source module places token on signal A.
2	5 ns	Delay module places token on signal B.
3	5 ns	Sink module acknowledges token on signal B.
4	5 ns	Delay module acknowledges token on signal A.
1	10 ns	Source module places next token on signal A.

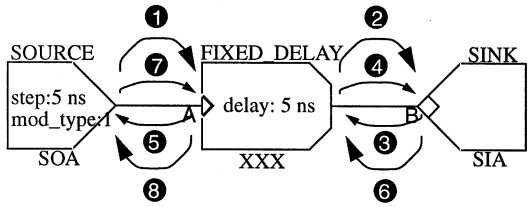

Table B: Detailed Event Sequence

Event	Time	Delta	Description	Resolved Signal A	Resolved Signal B
1	0 ns	1	Source module places token on A	present	removed
2	5 ns	1	Delay module places token on B	--	present
3	5 ns	2	Sink module acknowledges token on B	--	acked
4	5 ns	3	Delay module releases token on B	--	released
5			Delay module acknowledges token on A	acked	--
6	5 ns	4	Sink module removes token on B	--	removed
7			Source module releases token on A	released	--
8	5 ns	5	Delay module removes token on A	removed	--
1	10 ns	1	Source module places token on A	present	--

FIGURE 68.9 Three-module handshaking example.

15, 16) and the acknowledgment is returned (Events 17, 18, and 19). The SA module can then acknowledge the token on its input (Event 20), allowing the source module to generate the next token 5 ns (step) later.

If we examine the activity on Signal I (the independent output of the read color A module), we see that it goes present after Event 8, released after Event 10, present after Event 15, and released again after Event 17. Consider the operation of the terminator module attached to this signal. Since the Terminator module halts simulation after the number of active events specified by the *stop_after* generic, if we were to simulate this example, the simulation would halt after Event 15 (the second active event).

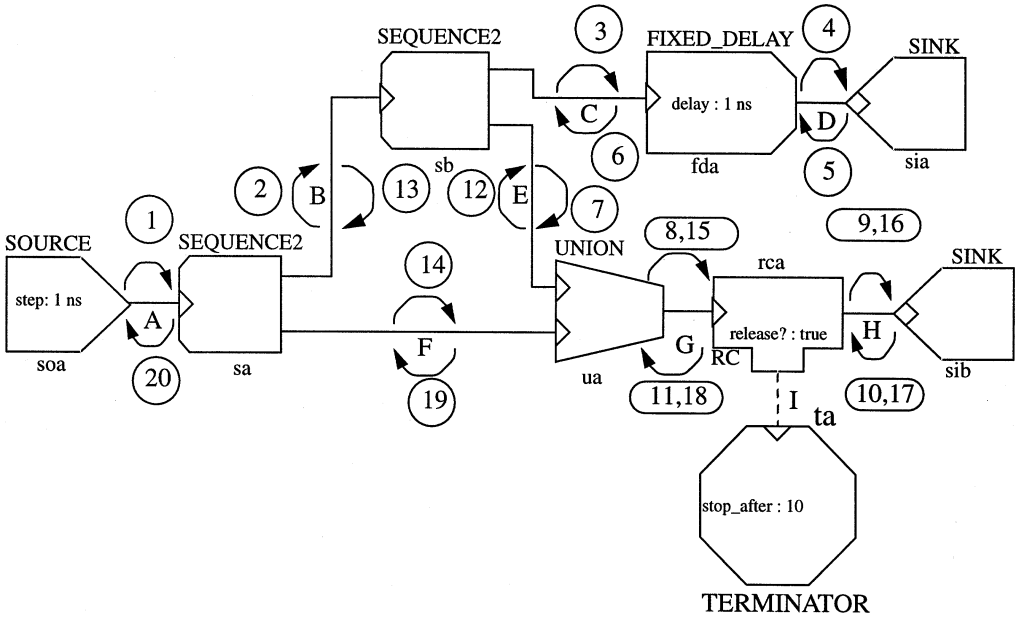

FIGURE 68.10 Token passing example showing simplified event sequence.

Module Categories

The ADEPT primitive modules may be divided into six categories: control modules, color modules, delay modules, fault modules, miscellaneous parts modules, and mixed-level modules. The control modules, except the Switch, Queue and logical modules, have been adapted from Dennis.[36] The color and delay categories of primitive modules have been defined to enable the manipulation of the coloring of tokens and to introduce the element of time into model descriptions, respectively. The fault modules are used to model the presence of faults and errors in a system model. The miscellaneous parts category contains some modules that are used for statistical data-collection with the ADEPT system. The mixed-level modules were created to aid in mixed-level modeling. The functionality of each primitive module is defined and the generics associated with each of the modules is described in the *ADEPT Library Reference Manual*.[38] The standard ADEPT module symbol convention is also explained in more detail in the *ADEPT Library Reference Manual*.

In addition to the primitive modules, there are libraries of more complex modules included in ADEPT. In general, these libraries contain modules for modeling systems in a specific applications area. These libraries are also discussed in more detail in the *ADEPT Library Reference Manual*.

Control Modules

The ADEPT representations of the 20 control modules are shown in Fig. 68.11. For each module in the figure, the XXX label represents a user-defined unique name that is assigned to each module in the system model. Further, some of the modules have generic parameters that need to be set when the module is instantiated.

The control modules operate only on the STATUS field of a signal and do not alter the color of a token on a signal. Further, no elapsed simulation time results from the activation of the control modules, since they do not have any delay associated with them.

The modules whose names end in a numeral, such as "union2", are part of a family of modules that have the same function, but differ in the number of inputs or outputs that they possess. For example, there are eight "union" modules, "union2," "union3," "union4,"… "union8."

© 2003 by CRC Press LLC

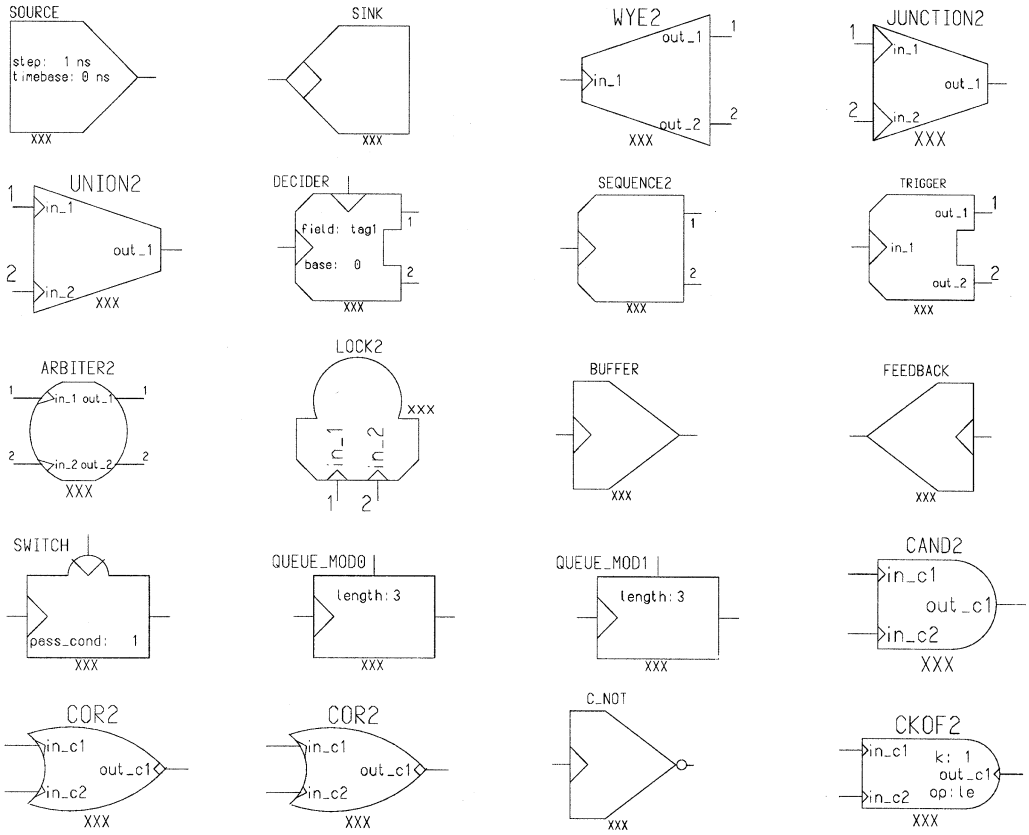

FIGURE 68.11 ADEPT control modules.

Color Modules

As noted when describing Petri Nets, using tokens that can be distinguished significantly increases the modeling capability and understanding of a given net. Therefore, ADEPT supports the ability to encapsulate pertinent system state (values) in a portion of the token called the color field. Such state information might include a memory address or an instruction opcode for a performance model of a computer system. The Control modules described in the previous section process colored tokens but do not alter the color fields of the tokens passing through them. Manipulation of the color field of a token is reserved to color modules. These color modules permit various operations on the color fields such as allowing the user to read and write the color fields of the tokens. The color modules also permit the user to compare the color information carried by the tokens and to control the flow of the tokens based on the result of the comparisons.

The ADEPT representations of the ten color modules are shown in Fig. 68.12. The use of these modules enables high-level modeling of systems at different levels of detail. These modules permit the designer to add more detail or information to the model by placing and manipulating information placed on the color fields of tokens flowing through the model. The color fields of these tokens can be set and read by these modules to represent such things as destination or source node addresses, data length, data type ("digital" or "analog," for example), or any type of such information that the designer feels is important to the design.

Delay Modules

The delay modules facilitate the description of data path delays at the conceptual or block level of a design. The ADEPT representation of the six delay modules is shown in Fig. 68.13. The fixed delay (FD) module, may be used in conjunction with the control modules to model the delay in the control structure

© 2003 by CRC Press LLC

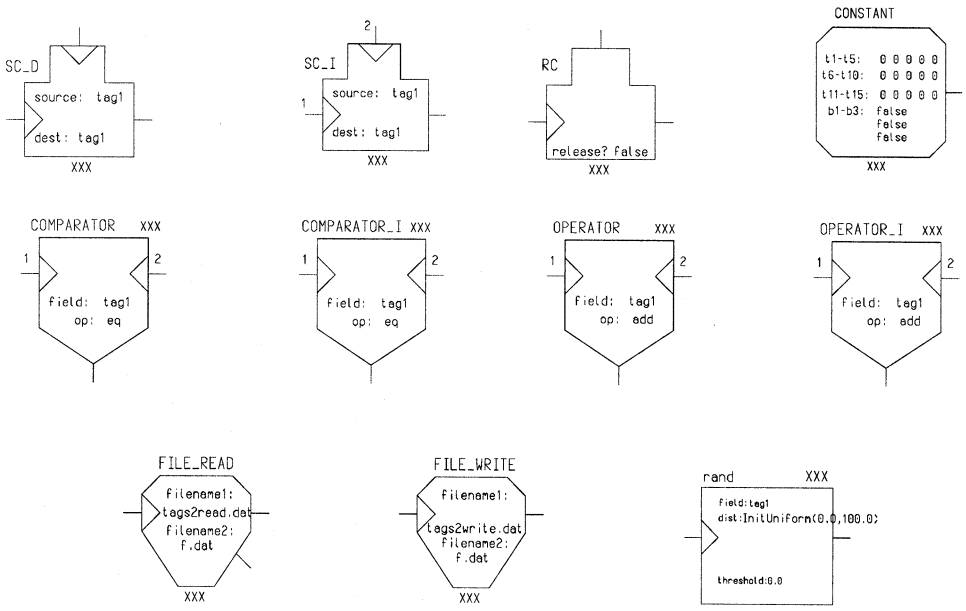

FIGURE 68.12 ADEPT color modules.

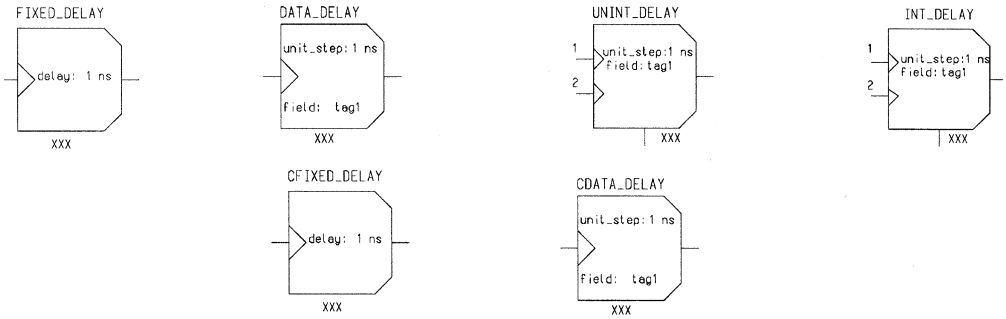

FIGURE 68.13 ADEPT delay modules.

of a design. The data-dependent delay module may be used to model processes in which the time to complete a particular operation is dependent on the data being processed. The uninterruptible data-dependent delay (UD) module and the interruptible data-dependent delay module (ID) may be used to model both hardware and software processes at the uninterpreted level. The control fixed delay (CFD) and control data-dependent delay (CDD) modules are used to add delay to independent paths in an ADEPT model that models real control processes.

Fault Modules

The fault modules are used to represent the presence of faults and errors in a system model. The modules allow the user to model fault injection, fault/error detection, and error correction processes. The ADEPT representation of the 13 Fault modules is shown in Fig. 68.14.

Miscellaneous Parts Modules

The Miscellaneous Parts category contains six modules that perform convenience functions in ADEPT. The ADEPT representation of three these modules is shown in Fig. 68.15. The collector module is used to write input activation times to a file, and the terminator module is used to halt simulation after a

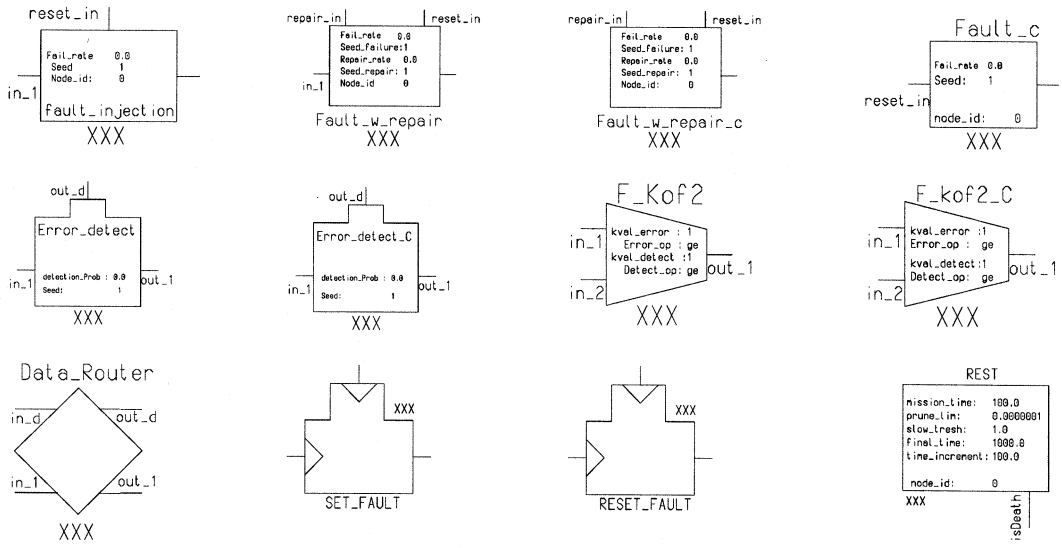

FIGURE 68.14 ADEPT fault modules.

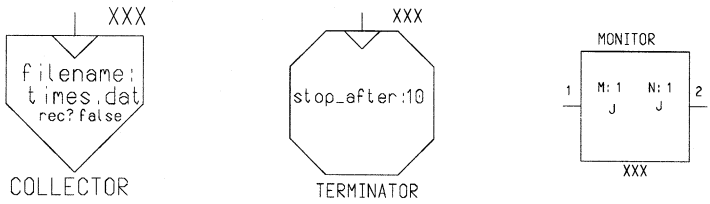

FIGURE 68.15 ADEPT miscellaneous parts modules.

specified number of events has occurred. The monitor module is a data-collection device that can be connected across other modules to gather statistical information during a VHDL simulation. This category also contains three additional modules (not shown in the figure) which are used to collect statistical information during simulation. These modules have no symbolic representation and are inserted automatically into the VHDL representation by the ADEPT tools.

Mixed-Level Modeling Modules

In order to support mixed-level modeling in the ADEPT environment, a category of building blocks called mixed-level modules was created which are used to define the interfaces around the interpreted and uninterpreted components in a system model. The functions of these modules and their use in creating mixed-level models is described in more detail in Section 68.4.

ADEPT Tools

The ADEPT system is currently available on Sun platforms using Mentor Graphics' *Design Architect* as the front-end schematic capture system, or on Windows PCs using OrCAD's *Capture* as the front-end schematic capture system. The overall architecture of the ADEPT system is shown in Fig. 68.16.

The schematic front-end is used to graphically construct the system model from a library of ADEPT module symbols. Once the schematic of the model has been constructed, the schematic capture system's netlist generation capability is used to generate an EDIF (Electronic Design Interchange Format) 2.0.0 netlist of the model. Once the EDIF netlist of the model is generated, the ADEPT software is used to

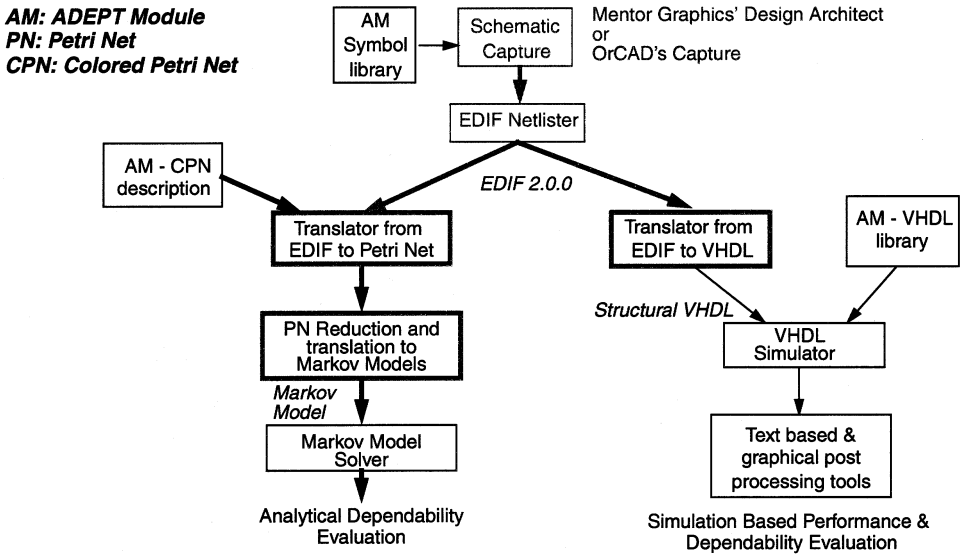

FIGURE 68.16 ADEPT design flow.

translate the model into a structural VHDL description consisting of interconnections of ADEPT modules. The user can then simulate the structural VHDL that is generated using the compiled VHDL behavioral descriptions of the ADEPT modules to obtain performance and dependability measures.

In addition to VHDL simulation, a path exists that allows the CPN description of the system model to be constructed from the CPN descriptions of the ADEPT modules. This CPN description can then be translated into a Markov model using well-known techniques and then solved using commercial tools to obtain reliability, availability, and safety information.

Figure 68.17 is an illustration of the construction of a schematic of an ADEPT model using *Design Architect*. The schematic shown is that of an ADEPT model of a simple three-computer system used in the ADEPT tutorial. Most of the elements in this top-level schematic are hierarchical, with separate schematics describing each component. The most primitive elements of the hierarchy are the ADEPT modules.

68.3 A Simple Example of an ADEPT Performance Model

This section presents a simple example of the usage of the primitive building blocks for performance modeling. The example is a three-computer system wherein the three computers share a common bus. The example also presents simulation results and system performance evaluations.

A Three-Computer System

This section discusses a simple example to illustrate how the modules discussed previously may be interconnected to model and evaluate the performance of a complete system. The system to be modeled consists of three computers communicating over a common bus, as shown in Fig. 68.18. Each block representing a computer can be thought to contain its own processor, memory and peripheral devices. The actual ADEPT schematic for the three-computer system is shown in Fig. 68.19.

Computer C1 contains some sensors and preprocessing capabilities. It collects data from the environment, converts it into a more compact form, and sends it to computer C2 via the bus. The computer C2 further processes the data and passes it to computer C3 where the data is appropriately utilized. It is assumed that data is transferred in packets and each packet of data is of varying length. In the example described here, computers C1 and C2 receive packets whose sizes are uniformly distributed between 0

© 2003 by CRC Press LLC

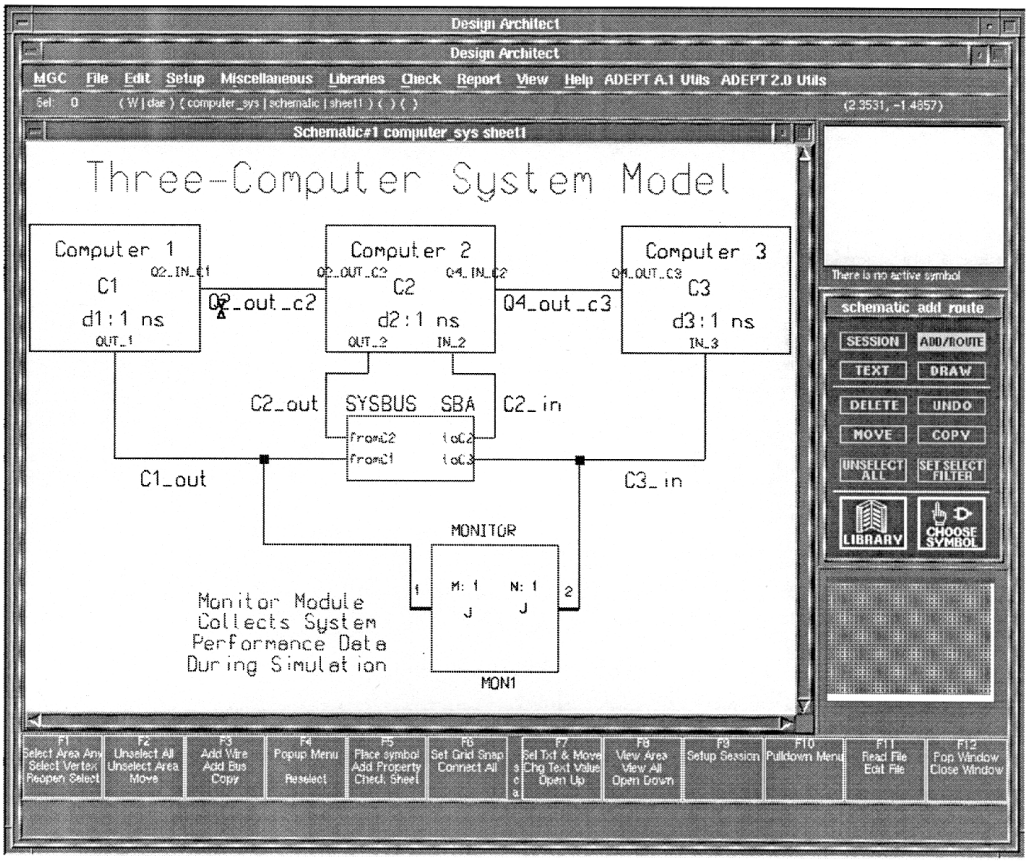

FIGURE 68.17 Sample ADEPT schematic (*Design Architect*).

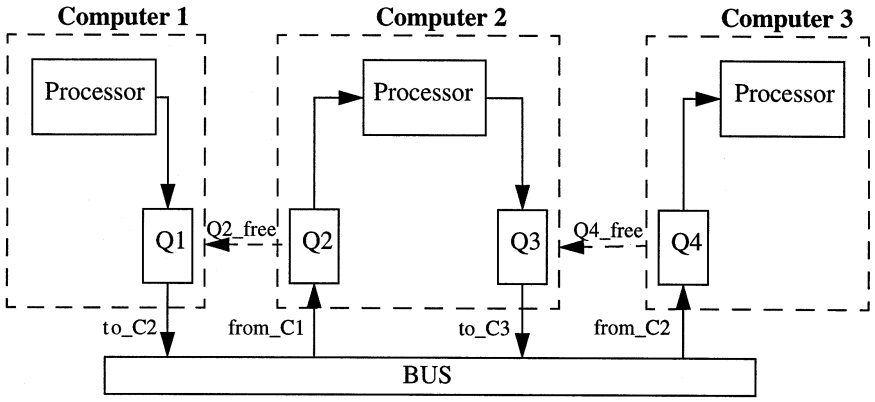

FIGURE 68.18 A three-computer system.

and 100. The packet size of computer C3 is uniformly distributed between 0 and 500. The external environment in this example is modeled by a Source module in C1 and a sink module in C3.

C1 has an output queue, C2 has both an input queue and an output queue, while C3 has one input queue. All queues in this example are assumed to be of length 8. If the input queues of C2 or C3 are full, the corresponding Q_free signal is released (value = RELEASED). This interconnection prevents the

© 2003 by CRC Press LLC

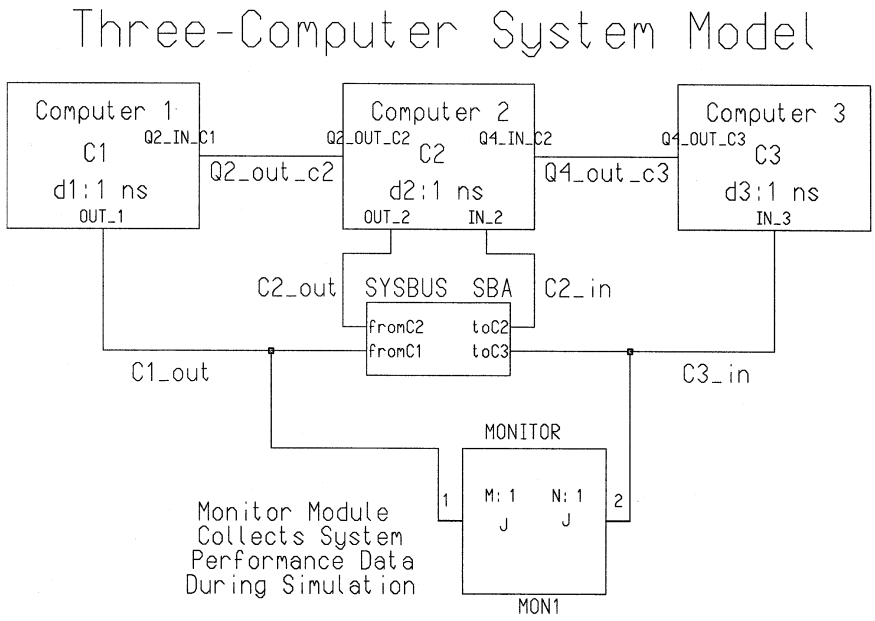

FIGURE 68.19 A three-computer system ADEPT schematic.

computer writing into the corresponding queue from placing data on the bus when the queue is full. This technique not only prevents the bus from being unnecessarily held up but also eliminates the possibility of a deadlock.

The ADEPT model of Computer 1 (C1) is shown in Fig. 68.20. The Source A (SOA) module along with the SA, Set_Color A (SCA), and random A (RA) modules generate tokens whose *tag1* field is set according to a distribution which is representative of the varying data sizes that C1 receives. The data-dependent delay A (DDA) models the processing time of C1, which is directly proportional to the packet size. The *unit_step* delay for the DDA module is passed down as a generic *d1**1ns. As soon as a token, representing one packet of data, appears at the output of the DDA module, the SB, Set_Color B (SCB), and random B (RB) modules together set the *tag1* field of the token to represent the packet size after processing. The constant A (COA) and Set_Color C (SCC) modules set the *tag2* field of the token to 2. This coloring indicates to the bus arbitration unit that the token is to be transferred to C2. The token is then placed in the output queue (Q1) of C1 and the token is acknowledged. This acknowledge signal is passed back to the source A module, which then produces the next token. The fixed delay (FDA & FDB) modules represent the read and write times associated with the queue. The switch A (SWA) element is controlled by the Q_free signal from C2 and prevents a token from the output queue of C1 from being placed on the bus if the incoming Q_Free signal is inactive.

Figure 68.21 shows the ADEPT model of Computer 2 (C2). When a token arrives at the *data* input of C2, the token is placed at the input of the queue (Q2). The *control* output of the queue becomes the Q2_Free output of C2. The remaining modules perform the same function as in C1 except that the tag2 field of the tokens output by C2 is set to 3, which indicates to the bus arbitration unit that the token is to be sent to C3. The DDA module represents the relative processing speed of Computer C2. The *unit_step* delay for the DDA module is passed down as a generic *d2**1ns.

The modules defining Computer 3 (C3) are shown in Fig. 68.22. A token arriving at the input is placed in the queue. The DDA element reads one token at a time and provides the delay associated with the processing time of C3 before the Sink A (SIA) module removes the token. The *unit_step* delay for the DDA module is passed down as a generic *d3**1ns.

The bus is shown in Fig. 68.23. Arbitration is provided to ensure that both C1 and C2 do not write onto the bus at the same time. The arbiter A (AA) element provides the required arbitration. Since the

© 2003 by CRC Press LLC

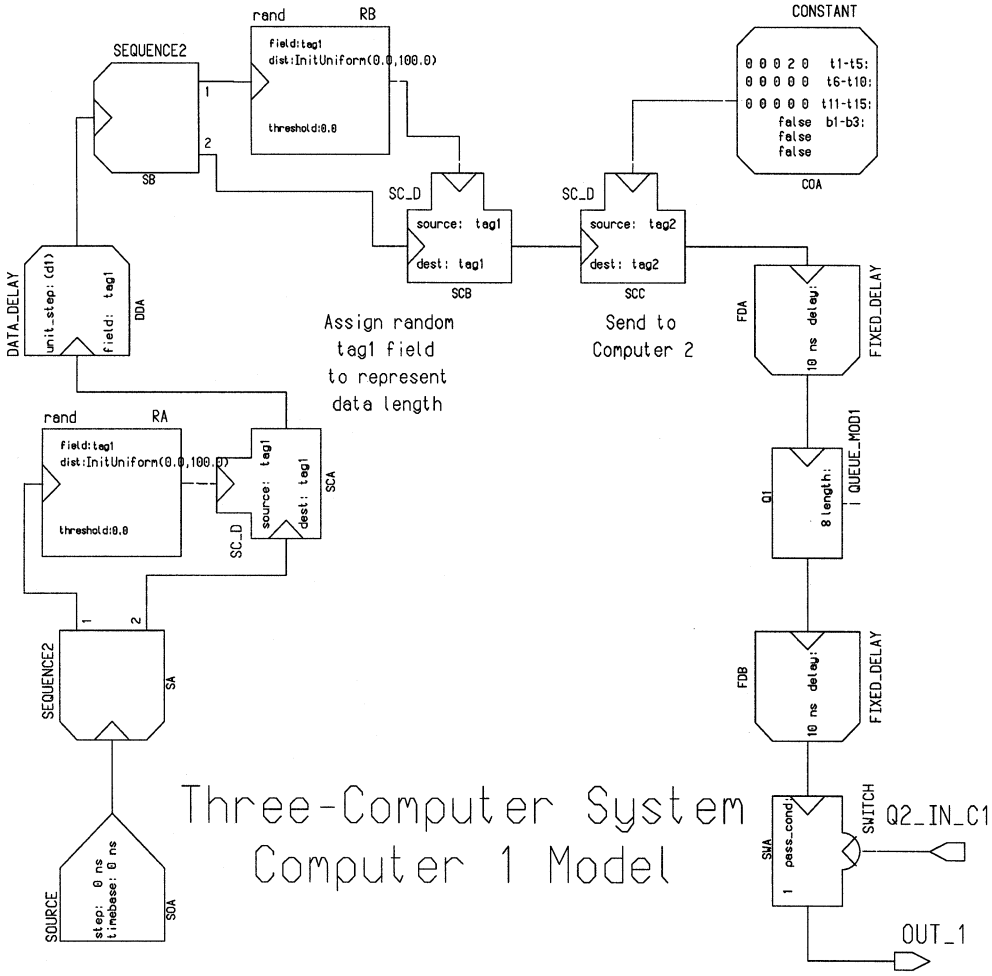

FIGURE 68.20 ADEPT model of computer 1.

output of C2 is connected to the IN_1(1) input of the AA element, it has a higher priority over C1. The union A (UA) element passes a token present at either of its inputs to its output. The output of the UA element is connected to the DDA element, which models the packet transfer delay associated with moving packets over the bus. The delay through the bus is dependent on the size of the packet of information being transferred (size stored on the *tag1* field). Note that in this analysis, the bus delay was set to zero. The independent output of the Read_Color A(RCA) element is connected to the control input of the Decider A (DA) module. The base of the DA element is set to 2. Since the *tag2* field of the token is set to 2 or 3 depending on whether it originated from C1 or C2, the first output of the DA module is connected to C2 and the second output is connected to C3. This technique ensures that the tokens are passed on to the correct destination, C2 or C3.

Simulation Results

This section presents simulation results that illustrate the queuing model capabilities of the ADEPT system. The model enables the study of the overall speed of the system in terms of the number of packets of information transferred in a given time. It also allows the study of the average number of tokens present in each queue during simulation, and the effect of varying system parameters on the number of items in the queues and overall throughput of the system. The generic unit_step delay of the DD elements

© 2003 by CRC Press LLC

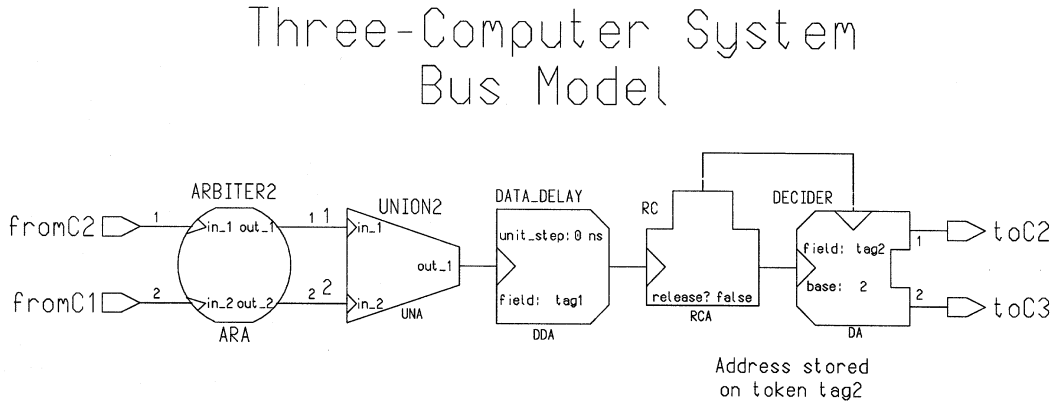

FIGURE 68.23 ADEPT model of system bus.

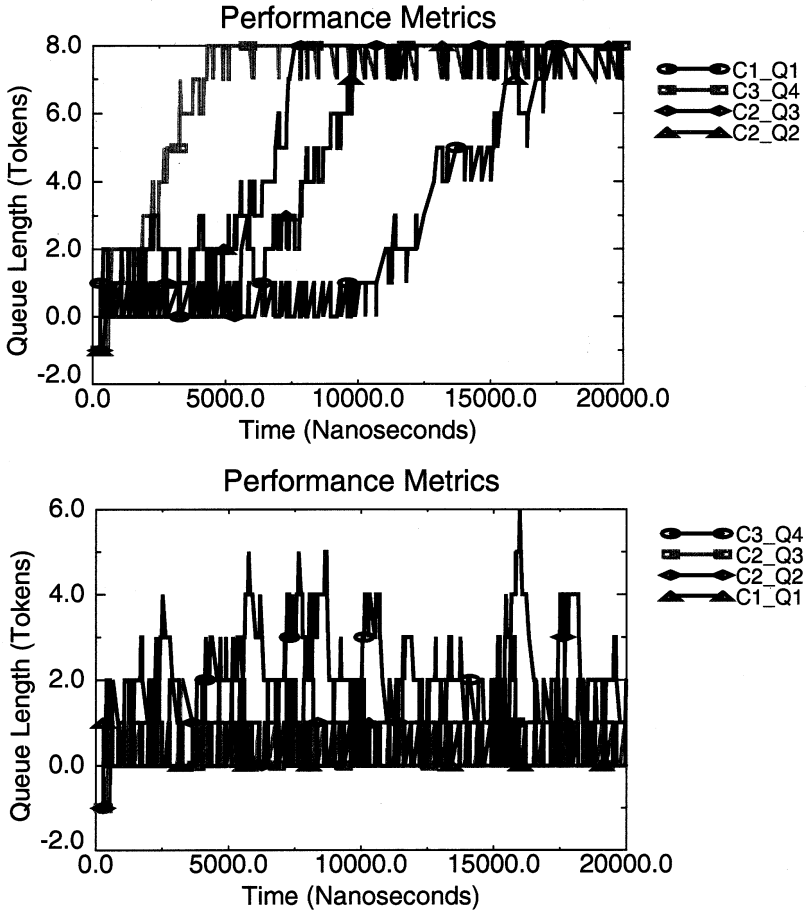

FIGURE 68.24 Queue lengths vs. simulation time for various processing delay times.

(*d1*, *d2*, and *d3*) associated with the three computers is representative of the processing speed of the computers. The optimal relative speeds of the computers may also be deduced by simulation of this model. Figure 68.24 shows graphs of the number of items in each queue versus simulation time. These graphs were generated using the BAARS postsimulation analysis tool. The upper graph shows the queue

© 2003 by CRC Press LLC

lengths when *d1*, *d2*, *d3* was set to 5 ns, 5 ns, and 2 ns. The lower graph shows the queue lengths when *d1*, *d2*, *d3* was set to 5 ns, 4 ns, and 1 ns. In the first case, because the processing time of Computer 3 was so much longer than Computers 1 or 2, the queue in Computer 3 became full at approximately 4000 ns of simulation time. The filling of the queue in Computer 3 delayed items coming out of Computers 1 and 2, thus causing their queues to also become full. In the second case, the processing time ratios were such that Computer 3 could keep up with the incoming tokens and the queues never got completely full.

Table 68.1 summarizes the effect of relative speeds of the computers on the number of packets transferred. Since the size of the packets received by C3 is uniformly distributed between 0 and 500 while the size of the packets received by C1 and C2 is uniformly distributed between 0 and 100, it is intuitively obvious that the overall throughput of the system is largely determined by the speed of computer C3. The results do indicate this behavior. For example, when the relative instruction execution times for C1, C2, and C3 are 5, 5, and 2, respectively, a total of 197 packets are transferred. By increasing the instruction execution time of C2 by one time unit and decreasing the instruction execution time of C3 by one time unit, it is seen that a total of 321 packets are transferred, an increase of slightly over 60%.

TABLE 68.1 System Throughput vs. Computer Delay Times

C1 delay (ns)	C2 delay (ns)	C3 delay (ns)	Packets per 100000 time units (ns)
8	8	3	131
9	10	2	194
5	5	2	197
3	5	2	197
2	2	2	197
5	6	1	321
5	4	1	322
4	3	1	384
3	2	1	385
2	2	1	386

This example has illustrated the use of the various ADEPT modules to model a complete system. Note how the interconnections between modules describing a component of the system are similar to a flow chart describing the behavior of the component. This example also demonstrated that complex systems at varying levels of abstraction and interpretation can easily be modeled using the VHDL-based ADEPT tools.

68.4 Mixed-Level Modeling

As described earlier, performance (uninterpreted) modeling has been previously used primarily by systems engineers when performing design analysis at the early stages of the design process. Although most of the design detail is not included in these models, since this detail does not yet exist, techniques such as token coloring can be used to include that design detail that is necessary for an accurate model. However, most of the detail, especially very low-level information such as word widths and bit encoding, are not present. In fact, many additional design decisions must be made before an actual implementation could ever be constructed. In performance models constructed in ADEPT, abstract tokens are used to represent this information (data and control) and its flow in the system. An illustration of such a performance model with its analysis was given the three-computer system described in Section 68.3. On the other hand, behavioral (interpreted) models can be thought of as including much more design detail often to the point that an implementation could be constructed. Therefore, data values and system timing are available and variables typically take on integer, real, or bit values. For example, a synthesizable model of a carry-lookahead adder would be one extreme of a behavioral model.

© 2003 by CRC Press LLC

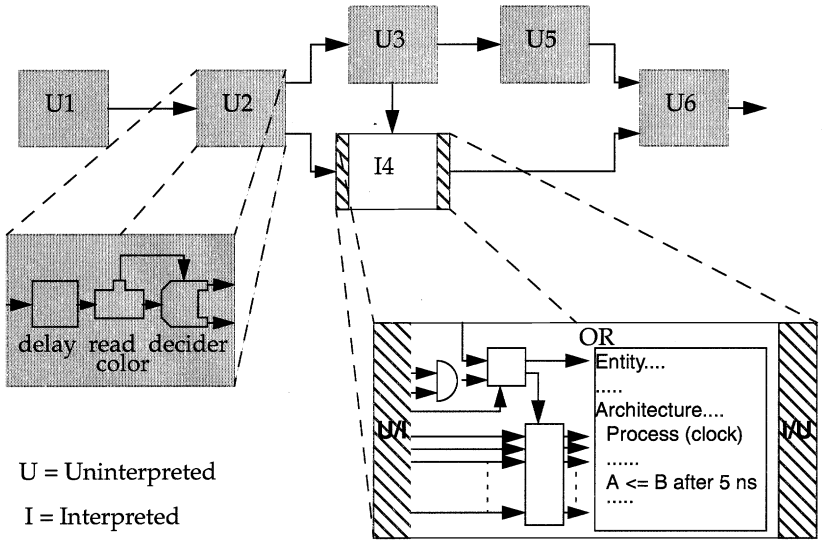

FIGURE 68.25 General structure of a mixed-level model.

It should be obvious that the two examples described above are extremes of the two types of models. Extensive design detail can be housed in the tokens of a performance model and information in a behavioral model can be encapsulated in a very abstract type. However, there is always a difference in the abstraction level of the two modeling types. Therefore, in order to develop a model that can include both performance and behavioral models, interfaces between the different levels of design abstraction, called mixed-level interfaces, must be included in the overall model to resolve differences between these two modeling domains.

The mixed-level interface is divided into two primary parts that function together: the part that handles the transition from the uninterpreted domain to the interpreted domain (U/I) and the part that handles the transition from the interpreted domain to the uninterpreted domain (I/U). The general structure of a mixed-level model is shown in Fig. 68.25.

In addition to the tokens-to-values (U/I) and values-to-tokens (I/U) conversion processes, the mixed-level interface must resolve the differences in design detail that naturally exist at the interface between uninterpreted and interpreted elements. These differences in detail appear as differences in data and timing abstraction across the interface. The differences in timing abstraction across the interface arise because the components at different levels model timing events at different granularities. For example, the passing of a token that represents a packet of data being transferred across a network in a performance model may correspond to hundreds or thousands of bus cycles for a model at the behavioral level.

The differences in data abstraction across the interface are due to the fact that typically performance models do not include full functional details, whereas behavioral models require full functional data (in terms of values on their inputs) to be present before they will execute correctly. For example, a performance level modeling token arriving at the inputs to the mixed-level interface for a behavioral floating point coprocessor model may contain information about the operation the token represents, but it may not contain the data on which the operation is to take place. In this case, the mixed-level interface must generate the data required by the behavioral model and do it in a way that a meaningful performance metric, such as best or worst case delays, is obtained.

Mixed-Level Modeling Taxonomy

The functions that the mixed-level interface must perform and the most efficient structure of the interface is affected by several attributes of the system being modeled and the model itself. In order to partition

© 2003 by CRC Press LLC

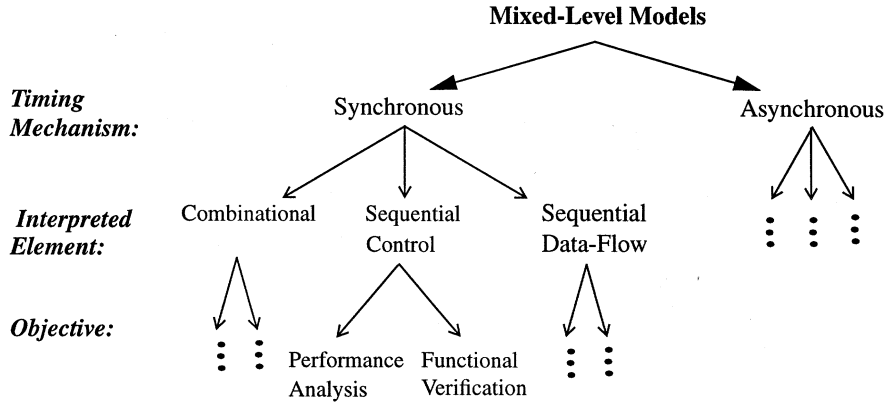

FIGURE 68.26 Mixed-level modeling categories.

the mixed-level modeling space and better define the specific solutions, a taxonomy of mixed-level model classes has been developed.[39] The classes of mixed-level modeling are defined by those model attributes which fundamentally alter the development and the implementation of the mixed-level interface. The mixed-level modeling space is partitioned according to three major characteristics:

1. The evaluation objective of the mixed-level model,
2. The timing mechanism of the uninterpreted model, and
3. The nature of the interpreted element.

For a given mixed-level model, these three characteristics can be viewed as attributes of the mixed-level model and the analysis effort. Figure 68.26 summarizes the taxonomy of mixed-level models.

Mixed-Level Modeling Objectives

The structure and the functionality of the mixed-level interface are strongly influenced by the objective that the analysis of the mixed-level model will be targeted toward. For the purposes of this work, these objectives were broken down into two major categories:

1. *Performance analysis* and *timing verification*: To analyze the performance of the system (as defined previously) and verify that the specific component(s) under consideration meet system timing constraints. Note that other metrics, such as power consumption, could be analyzed using mixed-level models, but these were outside the scope of this classification.
2. *Functional verification*: To verify that the function (input-to-output value transformation) of the interpreted component is correct within the context of the system model.

Timing Mechanisms

Typically, performance (uninterpreted) models are asynchronous in nature, and the flow of tokens depends on the handshaking protocol. However, in modeling a system that is globally synchronous (all elements are synchronized to a global clock) a mechanism to synchronize the flow of tokens across the model can be introduced. This synchronization of the performance model will require different mixed-level modeling approaches. Thus, the two types of system models that affect the mixed-level interface are

1. *Asynchronous models*: Tokens on independent signal paths within the system model move asynchronously with respect to each other and arrive at the interface at different times.
2. *Synchronous models*: The flow of tokens in the system model is synchronized by some global mechanism, and they arrive at the interface at the same time according to that mechanism.

© 2003 by CRC Press LLC

Interpreted Component

The mixed-level modeling technique strongly depends on the type of the interpreted component that is introduced into the performance model. It is natural to partition interpreted models into those that model combinational elements and those that model sequential elements. Techniques for constructing mixed-level interfaces for models of combinational interpreted elements have been developed previously.[40] In the combinational element case, the techniques for resolving the timing across the interface were more straightforward because of the asynchronous nature of the combinational elements, and the data abstraction problem was solved using a methodology similar to the one presented here. However, using sequential interpreted elements in mixed-level models requires more complex interfaces to solve the synchronization problem and different specific techniques for solving the data abstraction problem. Further research into the problem of mixed-level modeling with sequential elements suggested that interpreted components be broken down into three classifications as described below:

1. *Combinational Elements*: Unclocked (with no states) elements.
2. *Sequential Control Elements* (SCE): Clocked elements (with states) that are used for controlling data flow, e.g., a control unit or a controller
3. *Sequential Dataflow Elements* (SDE): Elements that include datapath elements and clocked elements that control the data flow, e.g., control unit and datapath.

The major reason for partitioning the sequential elements into sequential dataflow and sequential control elements is based on the timing attributes of these elements. In a SCE, control input values are read every cycle and control output values (that control a datapath) are generated every cycle. On the other hand, SDEs have data inputs and may have some control inputs, but the output data is usually generated several clock cycles later. This difference in the timing attributes will dictate a different technique for mixed-level modeling. Because the solution for the timing and data abstraction problem for SDE elements is more complex and the solution for SCE elements can be derived from the solution for SDE elements, developing a solution for SDE elements was the focus of this work.

An Interface for Mixed-Level Modeling with FSMD Components

This section describes the interface structure and operation for sequential interpreted elements that can be described as Finite State Machines with a Datapath (FSMDs).[41] They consist of a Finite State Machine (FSM) used as a control unit, and a datapath, as shown in Fig. 68.27. System models are quite often

naturally partitioned to blocks which adhere to the FSMD structure. Each FSMD processes the data and has some processing delays associated with it. These FSMDs indicate the completion of a processing task to the rest of the system either by asserting a set of control outputs or by the appearance of valid data on their outputs. This characteristic of being able to determine when the data processing task of the FSMD is completed is a key property in the methodology of constructing mixed-level models with FSMD interpreted components.

The functions performed by the U/I operator include placing the proper values on the inputs to the FSMD interpreted model and generating a clock signal for the FSMD interpreted model. The required values to be placed on the inputs to the FSMD interpreted model are contained on the incoming token's information, or "color" fields, are supplied by the modeler via some outside source, or are derived using the techniques described in the next section. The clock signal is either generated locally if the system-level model is globally asynchronous or converted from the global clock into the proper format if the system-level model is globally synchronous. The functions performed by the I/U operator include releasing the tokens back into the performance model at the appropriate time and, if required, coloring them with new values according to the output signals of the interpreted element. The structure of these two parts of the mixed-level interface is shown in Fig. 68.28. The U/I operator is composed of the following blocks: a driver, an activator, and a clock_generator. The I/U operator is composed of an Output_Condition_Detector, a Colorer, and a Sequential_Releaser.

In the U/I operator, the activator is used to detect the arrival of a new token (packet of data) to the interpreted element, inform the driver of a new token arrival, and drive control inputs of the interpreted element. The activator's output is also connected to the I/U operator for use in gathering information on the delay through the interpreted element. The driver reads information from the token's color fields and drives the proper input signals to the interpreted element according to predefined assignment properties. The Clock_Generator generates the clock signal according to the overall type of system-level model, either synchronous or asynchronous.

In the I/U operator, the Output_Condition_Detector detects the completion of the interpreted element data processing operation, as discussed earlier, by comparing the element's outputs with predefined properties. The colorer samples the datapath outputs and maps them to color fields according to predefined binding properties. The Sequential_Releaser, which "holds" the original token, releases it back to the uninterpreted model on receiving the signal from the Output_Condition_Detector. The information carried by the token is then updated by the colorer, and the token flows back to the uninterpreted part of the model.

Given this structure, the operation of the mixed-level model can be described using the general example in Fig. 68.28. Upon arrival of a new token to the mixed-level interface (U/I operator), the Read_color module triggers the activator component and passes the token to the Sequential_Releaser where it is stored until the interpreted component is finished with its operation. Once triggered by the Read_Color module, the activator notifies the driver to start the data conversion operation on a new packet of data. In the case of a globally asynchronous system-level model, the activator will notify the Clock_Generator to start generating a clock signal. Since the interpreted element is a sequential machine, the driver may need to drive sequences of values onto the inputs of the interpreted element. This sequence of values is supplied to the interpreted element, while the original token is held by the Sequential_Releaser. This token is released back to the uninterpreted model only when the Output_Condition_Detector indicates the completion of the interpreted element operation. The Output_Condition_Detector is parameterized to recognize the completion of data processing by the particular FSMD interpreted component. Once the Output_Condition_Detector recognizes the completion of data processing, it signals the Sequential_Releaser to release the token into the performance model. Once the token is released, it passes through the colorer, which maps the output data of the interpreted element onto color fields of the token. The new color information on the token may be used by the uninterpreted model for such things as delays through other parts of the model or for routing decisions.

Finding Values for the "Unknown Inputs" in an FSMD-Based Mixed-Level Model

As described previously, because of the abstract nature of a performance model, it may not be possible to derive values for all of the inputs to the interpreted component from the data present in the performance model. Typically, the more abstract the performance model (i.e., the earlier in the design cycle), the higher the percentage of input values that will be unknown. In some cases, particularly during the very early stages of the design process, it is possible that the abstract performance model will not provide any information to the interpreted element, other than the fact that new data has arrived. In this case, the data abstraction gap will be large. This section describes an analytical technique developed to determine values for these "unknown inputs" such that a meaningful performance metric — best or worst case delay — can be derived from the mixed-level model.

If some (or all) inputs are not known from the performance model, some criteria for deriving the values on the unknown inputs must be made. Choosing a criterion is based on the objective of the mixed-level model. For the objective of timing verification, delays (number of clock cycles) through the interpreted element are of interest. The most common criterion in such cases is the worst-case processing delay. In some cases, best-case delay may be desired. If the number of unknown inputs is small, an exhaustive search for worst/best case may be practical. Therefore, it is desirable to minimize the number of unknown inputs that can affect the delay through the interpreted element. The methods for achieving this objective are described conceptually in the next section. By utilizing these methods, the number of unknown inputs is likely to be reduced, but unknown inputs will not be eliminated completely. In this case, the performance metrics of best- and worst-case delay can be provided by a "traversal" of the state graph of the SDE component. The next section describes the traversal method developed for determining the delays through a sequential element.

Note that in the algorithms subsequently described, the function of the SDE component is represented by the State Transition Graph (STG) or State Table. These two representations are essentially equivalent and are easily generated from a behavioral VHDL description of the SDE, either by hand, or using some of the automated techniques that have been developed for formal verification.

Reducing the Number of Unknown Inputs

Although it is not essential, reducing the number of unknown inputs can simplify the simulation of a mixed-level model significantly. Since the FSMD elements being considered have output signals that can be monitored to determine the completion of data processing as discussed previously, other outputs may not be significant for performance analysis. Therefore, the "nonsignificant" (insignificant) outputs can

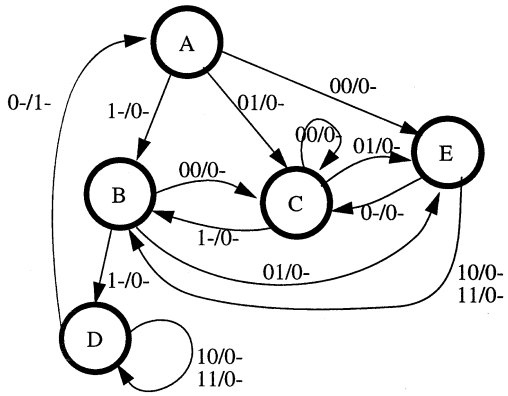

FIGURE 68.30 STG with "significant" output values only.

be considered as "don't-cares." By determining which inputs do not affect the values on the significant outputs, it is possible to minimize the number of unknown delay affecting inputs (DAIs).

The major steps in the DAI detection algorithm are

Step 1: Select the "insignificant" outputs (in terms of temporal performance).
Step 2: In the STG of the machine, replace all values for these outputs with a "don't-care" to generate the modified state machine.
Step 3: Minimize the modified state machine and generate the corresponding state table.
Step 4: Find the inputs which do NOT alter the flow in the modified state machine by detecting identical columns in the State Table and combining them by implicit input enumeration.
